List of Physico-chemical Symbols adopted by the Chemical Society.

[See J.C.S., 1921, **119**, 502—512.]

1. *Mathematical Symbols.*

	Usual symbol.	Alternative symbol.
Base of natural (Napierian) logarithms ...	e	
Diameter	d	
Radius	r	
Ratio of circumference to diameter	π	
Summation.....	Σ	
Variation	δ	
Total differential	d	
Partial differential	∂	

2. *Universal Constants.*

Acceleration due to gravity.....	g	
Mechanical equivalent of heat	J	
Avogadro's constant [number of molecules in 1 gram-molecule (mole)]	N	
Gas constant per mole	R	
Faraday's constant (number of coulombs per gram-equivalent of an ion)	F	
Charge on an electron	e	

3. *General Physics and Chemistry.*

Length	l	
Height.....	h	
Mass	m	
Time	t	
Volume	v, V	
Density (mass per unit volume)	d	D
Pressure	p, P	
Concentration	c, C	
Mole fraction	x	
Critical constants: pressure, volume, temperature (centigrade), temperature (absolute), density	p_c, v_c, t_c, T_c, d_c	
Reduced quantities: pressure, volume, temperature, density	p_r, v_r, t_r, T_r, d	
van der Waals's constants	a, b	
Fluidity	ϕ	
Viscosity	η	
Surface tension	γ	
Diffusion coefficient	Δ	
Atomic weight	A	
Molecular weight	M	
Velocity coefficient of reaction	k	
Equilibrium constant	$K, (K_c, K_p)$	
van't Hoff coefficient		
Degree of dissociation (electrolytic, thermal, etc.)		

4. *Heat and Thermodynamics.*

	Usual symbol.	Alternative symbol.
Temperature (centigrade)	t	
Temperature (absolute)	T	
Critical temperature	t_c, T_c	
Reduced temperature	t_r, T_r	
Critical solution temperature	t_{cs}, T_{cs}	
Quantity of heat	Q	
Entropy	S	
Specific heat	c	
Specific heat at constant pressure	c_p	
Specific heat at constant volume	c_v	
Ratio of specific heats, $c_p : c_v$	γ	
Molecular heat	C	
Molecular heat at constant pressure	C_p	
Molecular heat at constant volume	C_v	
Latent heat per gram	l	
Latent heat per mole	L	
Maximum work (diminution of free energy)	A	

5. *Optics.*

Wave-length of light	λ	
Refractive index	n	n_r
Specific refractive power (Gladstone and Dale)	r_G, $[r_G]_\lambda^{t^\circ}$	
Specific refractive power (Lorentz and Lorenz)	r_L, $[r_L]_\lambda^{t}$	
Molecular refractive power	R_G, R_L $[R_G]_\lambda^{t^\circ}$, $[R_L]_\lambda^{t^\circ}$	
Angle of optical rotation	a	
Specific rotatory power	$[\alpha]$	
Molecular rotatory power	$M[\alpha]$	
Specific magnetic rotation	$[\omega]$	
Molecular magnetic rotation	$M[\omega]$	

6. *Electricity and Magnetism.*

Quantity of electricity	Q	
Current intensity	I	
Resistance	R	W
Electromotive force	E	
Electrode potential, or discharge potential of an ion	E	
Electrode potential referred to the normal hydrogen or normal calomel electrode respectively, the potential of which is taken as zero	E_h, E_c	e_h, e
Normal potential, *i.e.*, the electrode potential referred to the normal hydrogen or normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration	${}_0E_h$, ${}_0E_c$	${}_0e_h$, ${}_0e$
Dielectric constant		
Conductivity (specific conductance)	κ	
Equivalent conductivity	Λ	
Equivalent conductivity at different dilutions—volumes in litres containing 1 gram-equivalent	Λ_{10^p}, Λ_v, Λ_∞	

6. *Electricity and Magnetism*—(continued).

	Usual symbol.	Alternative symbol.
ıt conductivity of kation and ion	Λ_k, Λ_a	
ıt conductivity of specified ions...	Λ_K. Λ_{Cl}	
conductivity	μ	
)f kation and of anion in cm./sec. the potential gradient is 1 volt m.	U_k, U_a	
number of kation and of anion ...	n_k, n_a	
permeability	μ	
susceptibility	κ	

List of Symbols, Arranged Alphabetically.

ol.	Name of quantity.
	Atomic weight; maximum work.
	Van der Waals's constant.
	Van der Waals's constant.
	Concentration; molecular heat.
	Concentration; specific heat.
	Molecular heat at constant pressure, and at constant volume.
	Specific heat at constant pressure, and at constant volume.
	Alternative symbol for density.
	Diameter; total differential; density.
	Critical density.
	Reduced density.
	Electromotive force; electrode potential.
	Base of Napierian logarithms; charge on an electron.
E_a	Electrode potential referred to the normal hydrogen or the normal calomel electrode, respectively, the potential of which is taken as zero.
E_s	Normal potential, that is, the electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration.
	Faraday's constant (number of coulombs per gram-equivalent of an ion).
	Acceleration due to gravity.
	Height.
	Current.
	Van't Hoff's coefficient.
	Mechanical equivalent of heat.
	Equilibrium constant.
	Equilibrium constant, when molar concentrations and partial pressures respectively are employed.
	Velocity coefficient of reaction.
	Latent heat per mole.
	Length; latent heat per gram.
	Molecular weight.
x]	Molecular rotatory power.
v]	Molecular magnetic rotatory power.
	Mass.
	Avogadro's constant (Loschmidt's number) or number of molecules in 1 gram-molecule.
	Refractive index.

List of Symbols, Arranged Alphabetically—(continued).

Symbol.	Name of quantity.
n_k, n_a	Transport number of kation and of anion.
n_r	Refractive index (alternative symbol).
P	Pressure.
p	Pressure.
p_c, p_r	Critical pressure : reduced pressure.
Q	Quantity of heat; quantity of electricity.
R	Gas constant per mole; electrical resistance.
R_G, R_L	Molecular refractive power, according to Gladstone and Dale, and to Lorentz and Lorenz respectively.
r	Radius.
r_G, r_L	Specific refractive power according to Gladstone and Dale, and to Lorentz and Lorenz respectively.
S	Entropy.
T	Absolute temperature.
T_c	Critical temperature (on the absolute scale).
T_r	Reduced temperature (absolute).
T_{cs}	Critical solution temperature (absolute).
t	Time; temperature (centigrade).
t_c	Critical temperature (centigrade).
t_{cs}	Critical solution temperature (centigrade).
t_r	Reduced temperature (centigrade).
U_k, U_a	Velocity of kation and of anion in cm./sec. when the potential gradient is 1 volt per cm.
V	Volume.
v	Volume.
v_c, v_r	Critical volume : reduced volume.
W	Electrical resistance (alternative symbol).
x	Mole fraction.
α	Degree of dissociation (electrolytic, thermal, etc.); angle of optical rotation.
$[\alpha]$	Specific rotatory power.
γ	Surface tension; ratio of specific heats.
Δ	Diffusion coefficient.
δ	Variation.
∂	Partial differential.
ϵ	Electrode potential (alternative symbol); dielectric constant.
ϵ_h, ϵ	Electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, the potential of which is taken as zero (alternative symbols).
${}_0\epsilon_h$, ${}_0\epsilon$	Normal potential, that is, the electrode potential referred to the normal hydrogen or the normal calomel electrode respectively, when the solution is molecular-normal in respect of all participating substances and ions of variable concentration (alternative symbols).
	Viscosity.
	Temperature (centigrade), (alternative symbol).
	Specific conductance (conductivity); magnetic susceptibility.
	Equivalent conductivity.
Λ_{10}, Λ_v, Λ_∞	Equivalent conductivity at different dilutions (volumes in litres containing 1 gram-equivalent).
Λ_k, Λ_a	Equivalent conductivity of kation and of anion.
λ	Wave-length of light.
μ	Molecular conductivity; magnetic permeability.
	Ratio of circumference to diameter.
	Summation.
	Surface tension (alternative symbol).
ϕ	Fluidity.
$[\omega]$	Specific magnetic rotation.

CCXXIV.—*The Preparation and Properties of Selenophen and Certain Halogen Derivatives of Selenophen.*

By HENRY VINCENT AIRD BRISCOE and JOHN BUTTERY PEEL.

ALTHOUGH the analogy between sulphur and selenium is well defined and thiophen is an interesting and important compound, its selenium analogue, *selenophen*, has hitherto been unknown to chemists. Relatively complex derivatives of selenophen, such as dimethylselenophen (Paal, *Ber.*, 1885, **18**, 2255), have been described and one investigator (Foa, *Gazzetta*, 1909, **39**, ii, 527) has stated that selenophen is obtained in small yield by heating together sodium succinate and phosphorus triselenide; but the product of this reaction, described as an unstable yellow liquid, b. p. 147—149°/250 mm., and but slightly soluble in alcohol, differs so seriously from the substance we have prepared (*vide infra*) as to lead us to believe that Foa's observations are untrustworthy.

During attempts to prepare certain simple selenium compounds we found that the action of acetylene upon selenium at moderately high temperatures produced a mixture of substances, liquid at the ordinary temperature, from which selenophen could be isolated. The present communication describes the preparation of selenophen and records data for its b. p., m. p., density, thermal expansion, vapour density, molecular weight, surface tension, and refractive index, its salient chemical properties, and the preparation and properties of tetrabromoselenophen and tetrachloroselenophen.

The Preparation and Identification of Selenophen.—Although the action of acetylene on selenium has not previously been investigated, there are references in the literature to the analogous action of acetylene on sulphur. Meyer and Sandmeyer (*Ber.*, 1883, **16**, 2176) have reported that thiophen is thus produced, and Capelle (*Bull. Soc. chim.*, 1908, **4**, 150) states that the product is thiophten. Work now in progress in these laboratories, however, affords conclusive proof that appreciable quantities of thiophen can be produced from acetylene and sulphur.

The reaction between acetylene and selenium was carried out in a silica tube 22″ long and of 1½″ bore, heated over a length of 9″ by a suitable winding of nichrome wire lagged with alundum cement and asbestos millboard. The tube was slightly inclined and a glass adapter at the lower end led the volatile products into a vertical test-tube immersed in a cooling bath, whence uncondensed gases were led by a tube to the flue. Selenium, in lots of about 10 g., contained in a large porcelain boat, was placed in the heated portion

of the tube, the temperature being held at about 400° by adjustment of a rheostat in series with the furnace winding. Acetylene, taken from a cylinder of dissolved acetylene, was led through concentrated sulphuric acid in a bubbler and a drying-tube charged with phosphoric oxide, into the upper end of the furnace tube. At first no evidence of reaction was perceived, but after several hours hydrogen selenide was evolved and a dark brown oil began to condense in the receiver: in 24 hours about 15 c.c. of the oil were obtained. The tube, when opened, contained a black solid deposit at the lower end and, as in subsequent experiments the production of the brown oil began as soon as the tube attained the proper temperature, it seems probable that its formation is catalytically assisted by the black deposit. This point, however, is obscure.

A quantity of the brown oil, collected in a series of experiments, was fractionally distilled at a pressure of about 30—40 mm. and yielded the following fractions:

(i) A yellow liquid, collected up to 90°.
(ii) A yellow solid, collected at 95—135°.
(iii) A yellow-brown liquid, collected at 135—200°.
(iv) A dark brown residue.

Fraction (ii), after several recrystallisations from hot methyl alcohol, was white and proved to be naphthalene, m. p. 79·5°, mixed m. p. with naphthalene 80°. By a series of fractional distillations and crystallisations other solid products were obtained from the residues of fraction (ii) and fractions (iii) and (iv), among them anthracene, phenanthrene, and a bright yellow crystalline solid, m. p. 124°, which was probably either stilbene or distyrene. None of the higher fractions contained more than traces of selenium.

The low-boiling liquid, fraction (i), burned in an open dish with a bluish-white flame, a considerable amount of selenium being deposited. It was therefore submitted to a systematic fractional distillation at atmospheric pressure. In the first distillation, using an 18″ glass spiral column, the first fraction, collected between 79—90°, contained only a trace of selenium and consisted largely of benzene, but the greater part distilled between 104—110° and was evidently a selenium compound. This was twice fractionated, a well-lagged 48″ column packed with 4 mm. cylindrical glass beads being used, and yielded a final main fraction, b. p. 109·9—110·1°/752·1 mm. The liquid was finally purified by fractional solidification; it was thrice frozen partially in a bath of alcohol cooled with solid carbon dioxide, and the liquid portions were rejected. About 15% of the original oil was thus obtained as a pale lemon-yellow liquid, f. p. −38°, mobile, dense, and highly refractive, and

having a slight odour, not unpleasant, resembling both that of carbon disulphide and that of benzene: it burned in air with a bright blue flame, from which selenium was deposited on a cold surface. Subsequent experiments showed that the yellow colour was due to a minute trace of impurity, and that the liquid was really colourless.

To estimate selenium in the product, it was oxidised with concentrated nitric acid in a sealed tube at 200°, the contents of the tube were evaporated with excess of concentrated hydrochloric acid, the solution was boiled with sulphurous acid, and the precipitated elementary selenium was collected and weighed in the usual way. This method gives poor results but is the only one available. Carbon and hydrogen were determined by combustion in the usual way in a tube packed with copper oxide and lead chromate (Found: Se, 59·4, 58·2; C, 37·1, 37·5; H, 3·3, 3·3. C_4H_4Se requires Se, 60·3; C, 36·6; H, 3·05%).

The vapour density of the substance was determined by the Dumas method with a glass bulb heated in liquid paraffin or glycerol:

Temperature	140°	150°	200°
Barometric pressure (mm. Hg)	737·6	760·0	760·1
Volume of bulb (c.c.)	139·28	174·04	135·84
Weight of selenophen (g.)	0·5341	0·6710	0·4659
Molecular weight	133·9	134·0	133·0

The calculated value for C_4H_4Se is 131·2. The V.D. determinations were confirmed by two cryoscopic determinations of the molecular weight in benzene and bromoform. The former value is a little high, probably because a solid solution of selenophen in benzene crystallises out.

	Benzene as solvent.	Bromoform as solvent.
Weight of selenophen (g.)	0·4948	0·8282
Weight of solvent (g.)	17·91	56·80
Depression of freezing point	0·900°	1·580°
Molecular weight	156·0	132·2

The Physical Properties of Selenophen.—Using the Hofmann apparatus, with water in the jacket, determinations of the vapour pressure of selenophen were made over the range 25—85° and are recorded in Table I.

TABLE I.

Temp.	25°	30°	35°	38°	40°	43°	45°
Vap. press. (mm. Hg. at 0°)	46·5	55	66	74	78·5	87	94
Temp.	48°	50°	55°	58°	60°	65°	68°
Vap. press. (mm. Hg. at 0°)	104	112	131	146	156·5	185·5	206
Temp.	70°	73°	75°	77°	80°	83°	85°
Vap. press. (mm. Hg. at 0°)	221	243	259	277	305·5	335·5	356

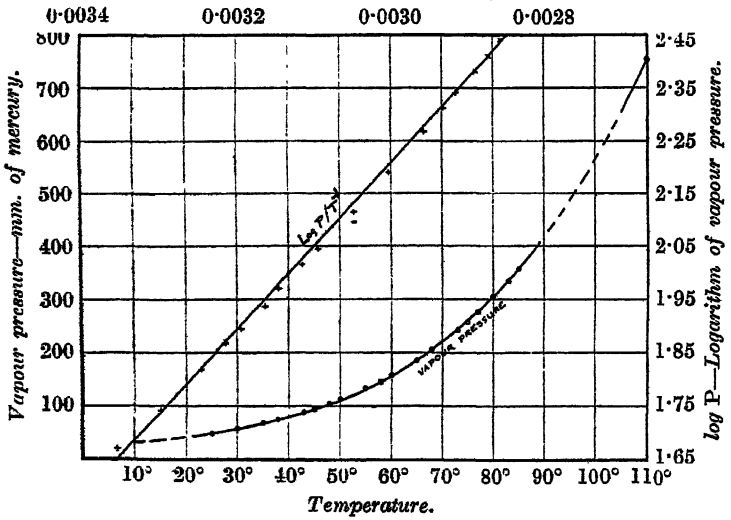

Fig. 1 gives the vapour-pressure curve derived from these data and also the relationship of log P–T^{-1}, which is substantially linear.

The latter curve, extrapolated to 760 mm. pressure, gives a value (108°) for the boiling point in reasonable agreement with that observed in the distillation of selenophen.

Determinations of density were made over the range 15—50° in glass Sprengel pyknometers of 10 c.c. capacity, fitted with ground glass stoppers and weighed against a tare. At each temperature of observation the pyknometer was filled with water and weighed and then filled with selenophen and weighed, the densities of selenophen and water at each of the six selected temperatures thus being directly compared. The data, recorded in Table II, show that the

FIG. 1.

Vapour pressure of selenophen.

coefficient of expansion of the liquid is 3α (15—30°) = 0·001040, 3α (30—50°) = 0·001040, and 3α (15—50°) = 0·001045.

TABLE II.

Temp.	15·00°	20·00°	25·00°	30·00°	40·00°	50·00°
Density (g./c.c.)	1·5307	1·5232	1·5156	1·5078	1·4943	1·4763

The refractive index ($n_D^{15°}$) determined with a Pulfrich refractometer was 1·568.

The surface tension of selenophen was determined by Sugden's method, two especially good capillaries, calibrated by Dr. Robinson and Mr. Mills and kindly lent by them for this purpose, being used.

The radii of the tubes being respectively 0·25287 mm. and 0·49920 mm., the following data were obtained :

Temperature	15°	20°	25°
Difference in capillary rise (mm.) ...	9·56	9·44	9·30
Surface tension (dynes/cm.)	36·49	35·83	35·14
Parachor ($\gamma^{\frac{1}{4}}M/D$)	210·6	210·8	210·5

Dr. Sugden has very kindly made check determinations of the parachor, with the following results :

Temperature	17·5°	28·5°	33·5°	42°
D (g./c.c.)	1·501	1·485	1·476	1·464
γ (dynes/cm.)	35·63	34·28	33·31	32·32
Parachor	213·8	213·9	213·7	213·8

Unfortunately the sample of selenophen available for his measurements was less highly purified than that we had used : nevertheless his data serve to confirm the general nature of our results.

In the Eötvös–Ramsay–Shields' equation $(M/d)^{2/3}\gamma = K(T_c - T_0)$ the value of K is about 2·1, which may be held either to confirm the molecular weight deduced above or to show that selenophen is a " normal " liquid.

Assuming selenophen to have the constitution  , by deducting from its observed parachor (210·5), 4·8 for 4C, 17·1 for 4H, 23·2 for two double bonds, and 8·5 for one five-membered ring (total 142·5), we obtain for selenium the parachor 68·0. This value is in fair agreement with the value 64 obtained by Dr. Sugden (private communication) in a study of several other selenium compounds.

Chemical Properties of Selenophen.—Selenophen is insoluble in water, but is miscible in all proportions with a number of non-aqueous liquids, including acetone, benzene, and carbon disulphide. At its boiling point it dissolves sulphur quite readily. It closely resembles thiophen in its remarkable stability and chemical inactivity. It is unaffected by boiling with water, caustic soda solution or concentrated hydrochloric acid. It does not form a picrate and yields no methiodide even when treated with methyl iodide in a sealed tube at 160° for 24 hours. It has but a very slight reducing action on potassium permanganate in acetone solution and when distilled from the unchanged permanganate and fractionated to remove acetone, practically the whole of the selenophen taken is recovered, but as a *colourless* liquid. Evidently the only effect of the permanganate is to oxidise the small trace of impurity, probably a hydrocarbon, responsible for the slight yellow colour of the distilled and crystallised selenophen.

Selenophen is not reduced by the ordinary agents, such as zinc

and hydrochloric acid, and it is recovered practically unchanged after thrice being passed together with hydrogen at 250° over nickel (on pumice; obtained by heating the sulphate in a current of hydrogen at 400° for 24 hours).

Selenophen reacts with concentrated sulphuric acid with the production of a greenish-black mass; when warmed with concentrated sulphuric acid and isatin, it gives an indophenin reaction characterised by a greenish-blue colour, becoming purple when the product is poured into water. When concentrated sulphuric acid was added cautiously to a solution of selenophen in acetic anhydride well cooled in ice and the product was poured into water, a brown, semi-solid substance was obtained which may possibly have been a sulphonic derivative. It was, however, insoluble in water and the common organic solvents and decomposed on heating. Further attempts are being made to investigate the product.

Difficulties also attended attempts to prepare nitro-derivatives of selenophen. It was vigorously oxidised by concentrated nitric acid, but when solutions of selenophen and of concentrated nitric acid in acetic anhydride were slowly mixed in the cold, and the product was poured into ice-cold water, a dark brown oil separated which slowly set to a brown tar. This tar had the characteristic smell of nitro-compounds and dissolved readily in aqueous caustic soda to give a red solution, but it was insoluble in water, ether, light petroleum, benzene, alcohol, carbon tetrachloride, ethyl acetate, or acetic acid and so its investigation was deferred.

Tetrabromoselenophen.—A vigorous reaction occurred and hydrogen bromide was evolved when a solution of bromine in carbon disulphide, slightly in excess of the calculated amount, was added to a well-cooled solution of selenophen (10 g.) in the same solvent. After 24 hours, the solution was washed with dilute caustic soda solution and with water and evaporated on the water-bath. The brown residue, on recrystallisation from alcohol, gave *tetrabromoselenophen* as a white, finely crystalline substance, m. p. 102° (yield, about 70%). Tetrabromoselenophen is stable at its m. p., and does not reduce permanganate in acetone solution, but on boiling with water it slowly decomposes and deposits selenium.

Bromine and selenium were estimated in the compound by oxidising it with nitric acid and silver nitrate in a sealed tube at 200°, and boiling the silver bromide with dilute nitric acid to dissolve any silver selenite present. The silver bromide was dried, and weighed, and selenium was estimated in the filtrate by precipitation as the element in the usual way after the excess of silver had been removed as silver chloride (Found: C, 11·2, 11·1; Br, 71·5, 71·3; Se, 15·7, 17·7; *M*, cryoscopic in benzene, 565, 541. C_4Br_4Se requires C, 10·7;

Br, 71·4; Se, 17·9%; *M*, 447·2). Hence the compound appears to have the simple molecular formula, but probably forms solid solutions with benzene.

Attempts to isolate a corresponding iodine derivative by similar methods have failed.

Tetrachloroselenophen.—On adding a slight excess of a saturated solution of chlorine in carbon disulphide to a solution of selenophen (10 g.) in the same solvent, reaction occurred and hydrogen chloride was evolved. After 2 days the solution deposited a pale yellow, crystalline solid, which appeared to be insoluble in most solvents and steadily evolved hydrogen chloride on keeping. A similar product, prepared by bubbling gaseous chlorine slowly through a carbon disulphide solution of selenophen (10 g.), when washed well with water and dried on a porous plate, was sufficiently soluble in toluene to be recrystallised from that solvent and the product was a finely crystalline, white solid (Found : C, 16·9; Cl, 53·5; Se, 30·5. C_4Cl_4Se requires C, 17·7; Cl, 52·6; Se, 29·6%).

The yield in this case was only about 25%, and the mother-liquor contained other selenium compounds, which are being investigated. When heated to 87°, the solid decomposes, evolving an acid gas, and fuses to a yellow liquid that does not resolidify. A similar decomposition appears to occur in toluene or alcohol solutions, which, if overheated, become yellow and thereafter do not, on cooling, deposit crystals.

The compound was not soluble in a solvent of convenient freezing point, and so its molecular weight was not determined.

Although the analysis given appears to show that the compound is tetrachloroselenophen, it differs from tetrabromoselenophen to a rather remarkable extent. Unlike the latter, it is easily decomposed, with deposition of selenium, on warming with water or with acids, and slowly decomposes at the ordinary temperature, in air in a closed tube or in a vacuum, evolving acid fumes and turning brown. These differences suggest some difference in chemical character between the two halogen derivatives, and this is the subject of further inquiry.

Acknowledgment is made of a grant from the Research Fund Committee of Armstrong College, which enabled one of us (J. B. P.) to take part in this investigation.

CCXXV.—*Studies of Valency. Part IX. Molecular Structure of Thallium Salts.* (a) *Thallium Tri-iodide;* (b) *Alkyl Derivatives.*

By ARTHUR JOHN BERRY and THOMAS MARTIN LOWRY.

(*a*) *Thallium Tri-iodide* [with MRS. R. R. GOLDSTEIN].

THALLIUM tri-iodide may be formulated either as thallic iodide or as a thallous polyiodide. From analogy with other thallic salts, the first of these formulæ has been generally adopted; but, since the iodide is a black, insoluble compound, whilst thallic chloride and bromide are soluble deliquescent salts, there is ample contrast to justify a different formulation of the iodide. Thus, Wells and Penfield (*Z. anorg. Chem.*, 1894, **6**, 312) concluded that, since thallium tri-iodide is isomorphous with the tri-iodides of rubidium and cæsium, it should be formulated as the polyiodide of a univalent metal. The formation of a polyiodide by thallium would be exceptional, however, since the ease of formation of polyiodides increases with the atomic volume of the kation (Ephraim, "Inorganic Chemistry," 1926, p. 200), reaching a maximum in the case of cæsium, with atomic volume 70, whereas the atomic volume of thallium (17) lies between those of lithium (13) and sodium (23·7). Maitland and Abegg (*Z. anorg. Chem.*, 1906, **49**, 341), on the other hand, suggested that thallium tri-iodide may be tautomeric, exhibiting one or other structure according to the reagent employed. Thus the sparing solubility of the iodide is cited as characteristic of a thallous salt, whilst the capacity of forming complex ions, as in the compound $KTlI_4$, which Johnson prepared in 1878 from potassium tri-iodide and thallous iodide (J., **33**, 183), is characteristic of thallic salts.

This conflict of opinion has been resolved in the present paper with the help of spectroscopic observations, which show that the iodine in alcoholic solutions of thallium tri-iodide is not present in the form of a tri-iodide ion. Spectroscopic observations have also shown that, although thallium tri-iodide does not combine with iodine to form a pentaiodide $[TlI_2]I_3$, the complex salt $KTlI_4$ persists in solution. Several new addition compounds of thallium tri-iodide with pyridine and with the chloropyridines are also described, which retain their individuality in solution. The spectroscopic evidence, which shows that the trihalides are not ionised completely even in dilute solutions, has been corroborated by measurements of conductivities in methyl alcohol and in acetonitrile, which show that the trihalides behave only as weak binary electrolytes. Finally, it has been shown that the chemical properties of

thallium tri-iodide and of its compounds with pyridine are those of a thallic salt, giving only doubtful indications of thallous ions in solution.

Chemical Properties.—Well-formed crystals of thallium tri-iodide were prepared by boiling thallous iodide and iodine in equivalent proportions with methyl alcohol in a reflux apparatus, filtering the liquid, and concentrating it by evaporation in a vacuum desiccator containing calcium chloride. When titrated with potassium iodate in presence of a high concentration of hydrochloric acid (Berry, *Analyst*, 1926, 137), 0·261 g. of the crystals gave a titre corresponding with 0·264 g. of TlI_3. Reduction by heating with excess of sodium arsenite solution gave 56·0% of TlI (TlI_3 requires 56·6%). 0·293 G. of the compound gave 0·353 g. of silver iodide, whence I = 65·1% (Calc., 65·1%).

The brown solutions of thallium tri-iodide in alcohol, acetone, acetonitrile, and nitrobenzene show the reactions of tervalent thallium but only give doubtful indications of the presence of thallous ions. Thus, when excess of alkali is added to solutions of thallium tri-iodide in methyl alcohol or in acetonitrile, a quantitative yield of thallic oxide is produced, *e.g.*, 0·5355 g. of the iodide in acetonitrile gave 0·206 g. of oxide, the calculated yield being 0·209 g. On the other hand, when potassium bromide or iodide in aqueous acetonitrile is added to a solution of thallium tri-iodide in acetonitrile, a slight turbidity is produced, which might be attributed to the separation of thallous bromide or iodide; but this disappears on the addition of an excess of the alkali halide, and no turbidity was observed when methyl alcohol was used as solvent in place of acetonitrile. Again, when potassium chromate in aqueous acetonitrile is added to a solution of thallium tri-iodide in acetonitrile, a little thallous chromate separates; but when methyl alcohol is used as a solvent a precipitate of thallic hydroxide is produced.

When aqueous potassium iodide is added to solutions of thallium tri-iodide, the colour becomes paler, and precipitation of thallic oxide is impeded. Thus, whilst sodium hydroxide gives a precipitate immediately, sodium carbonate does so only after a few moments, unless the liquid is heated. Ammonia precipitates thallic oxide, but precipitation is prevented if ammonium chloride be first added. Since these phenomena appear to be due to the formation of complex ions, experiments were made on the behaviour of aqueous potassium iodide towards thallium tri-iodide dissolved in nitrobenzene. It was found that rather less than one molecular proportion of potassium iodide was taken up by thallium tri-iodide in the nitrobenzene solution.

Reducing agents convert thallium tri-iodide into thallous iodide,

but no conclusions can be drawn regarding the constitution of this compound by considering its response to reagents such as sodium arsenite and thiosulphate, since other thallic salts are reduced by them and both reagents are oxidised by tri-iodide ions.

Preparation of Derivatives of Thallium Tri-iodide with Pyridine and with Chloropyridines.—Meyer (*Z. anorg. Chem.*, 1900, **24**, 321) prepared addition compounds by adding pyridine to aqueous solutions of thallic chloride or bromide; these compounds are white, sparingly soluble substances, which are readily hydrolysed by water with separation of thallic oxide. If, however, pyridine be added to solutions of thallic chloride containing excess of hydrochloric acid, the product contains thallium and chlorine in the ratio of 1 to 4. Addition compounds of thallic iodide with pyridine were prepared by Renz (*Ber.*, 1902, **35**, 1110), who described the compound TlI_3,C_5H_5N as a "dunkel orangerothes krystallinisches Pulver" and the compound $(TlI_3)_2(C_5H_5N,HI)_3$ as a "prächtig zinnoberrothes krystallinisches Pulver." The percentages of thallium in these products were not determined, but those of the other elements were in agreement with the formulæ assigned. Our own observations are set out below.

(*a*) *Pyridinium iodide.* When pyridine is added to solutions of thallium tri-iodide, fine orange-coloured precipitates are formed. Darker-coloured compounds were obtained when the base was added to solutions prepared by dissolving thallic oxide in aqueous hydriodic acid, or to solutions of thallium tri-iodide containing excess of iodine in organic solvents, but since the ratio of thallium to iodine varied from 1/3 to 1/5, it is very doubtful if any of these preparations was pure. One specimen, which separated from acetone in fine, dark red crystals, gave, however, a ratio Tl : I = 1 : 4 exactly, with two molecular proportions of pyridine to each atom of thallium, and therefore appeared to be a definite chemical *compound*.

(i) The compound was reduced with sodium arsenite, the resulting thallous iodide collected and weighed (TlI = 40·2%), and the filtrate analysed by Volhard's method (43·6% of additional iodine), *i.e.*, Tl = 24·8%, I = 59·0%; the pyridine is therefore 16·2% (by difference). (ii) The compound was reduced by sodium arsenite, the resulting thallous iodide being determined by direct titration with potassium iodate (Found: TlI, 39·3%; *i.e.*, Tl = 24·2%). (iii) By gravimetric analysis, I = 58·0% [$(C_5H_5N)_2HTlI_4$ requires Tl, 23·4; I, 58·4; C_5H_5N, 18·2%].

(*b*) *Pyridine.* By grinding pure thallium tri-iodide with a considerable excess of pyridine, a *compound* having the composition $(C_5H_5N)_2TlI_3$ was readily prepared. After filtration from a small insoluble residue, the liquid was largely diluted with water; the

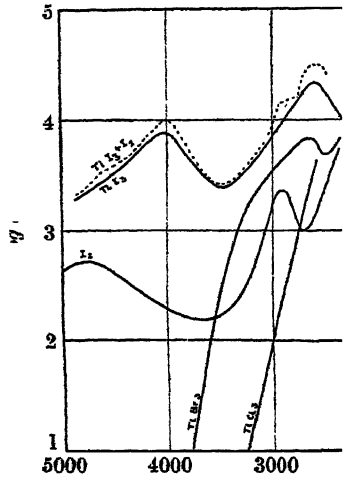
orange-coloured precipitate was collected, and dried over soda–lime in a desiccator. Two such preparations were analysed (i) by titration with potassium iodate directly, and (ii) by titration with potassium iodate of the thallous iodide obtained by reduction with sodium arsenite [Found: TlI, 43·8, 44·1; I (extra), 33·8, 34·5; C_5H_5N (by diff.), 22·4, 21·4; I (total, as AgI), 50·7. $TlI_3(C_5H_5N)_2$ requires TlI, 44·5; I (extra), 34·2; C_5H_5N, 21·3; I (total), 51·3%].

This addition compound dissolves readily in many organic solvents, forming coloured solutions; but whilst iodine is violet in chloroform or benzene, and brown in alcohol or acetone, solutions of the compound of thallium tri-iodide and pyridine have the same golden-yellow colour in methyl and ethyl alcohol, acetone, glacial acetic acid, benzene, nitrobenzene, or nitromethane. Moreover, when pyridine is added to a solution of thallium tri-iodide in aceto-nitrile, the dark brown colour is changed to a pale golden-yellow. The chemical reactions of the tri-iodide do not, however, appear to be modified by the presence of pyridine.

(*c*) *Dichloropyridine.* A *compound* was prepared by boiling thallium tri-iodide (3 g.) and dichloropyridine (4 g.) with methyl alcohol for 2 hours under reflux. The dark brown liquid was decanted from some undissolved thallium tri-iodide, and the compound was precipitated by dilution with water. The golden-yellow, crystalline solid was collected and dried by exposure over soda–lime in a desiccator. Analysis of two samples gave TlI, 25·0, 25·1; I (extra), 19·6, 19·8; $C_5H_3NCl_2$ (by diff.), 55·4, 55·1. $TlI_3(C_5H_3NCl_2)_5$ requires TlI, 25·0; I (extra), 19·2; $C_5H_3NCl_2$, 55·8%.

(*d*) *Trichloropyridine.* When this was boiled with thallium tri-iodide in methyl-alcoholic solution, a *compound* was isolated as before [Found: TlI_3, 37·8. $TlI_3(C_5H_2NCl_3)_5$ requires TlI_3, 39·1%].

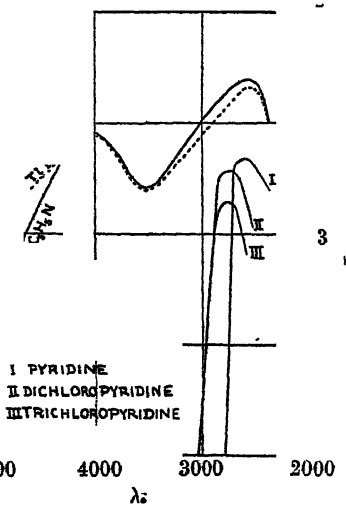
(*e*) *Tetrachloropyridine* combines only slowly with thallium tri-iodide. On addition of excess of water to the alcoholic solution, a yellow precipitate separates, but it soon decomposes with separation of thallous iodide and free iodine. The successive replacement of hydrogen by chlorine in the pyridine nucleus appears to diminish the basic properties to such an extent as to prevent the formation of stable additive compounds.



(*f*) *Pentachloropyridine* did not give an addition compound with thallium tri-iodide.

Absorption Spectra.

The extinction coefficients were determined in absolute methyl alcohol (free from acetone) by methods which have already been described. The iodide was dissolved directly in the solvent by vigorous stirring, but the chloride and bromide, which are very hygroscopic, were extracted with methyl alcohol from the yellow



double salts, $TlCl_3,3TlCl$ and $TlBr_3,TlBr$ (Berry, *Proc. Camb. Phil. Soc.*, 1924, **22**, 363), and the thallium content was determined by analysis. The complex salt, $KTlI_4$, was prepared in blackish-brown crystals by refluxing thallium tri-iodide and potassium iodide with alcohol and allowing the solution to evaporate in a desiccator containing calcium chloride; the alcohol-wet crystals were dissolved in methyl alcohol and the thallium content of the solution was

FIG. 1.

Molecular extinction coefficient of $TlCl_3$, $TlBr_3$, and TlI_3 in methyl alcohol.

FIG. 2.

Molecular extinction coefficients of pyridine compounds in methyl alcohol.

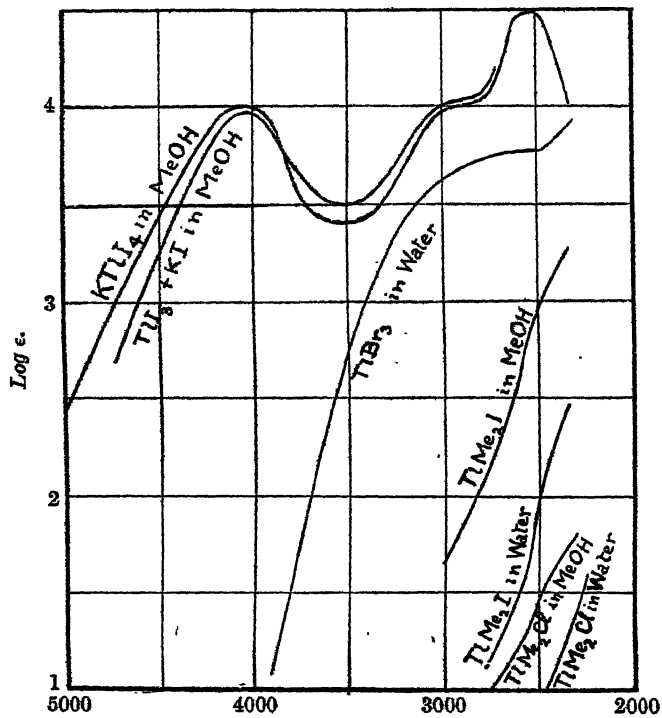
determined by analysis. The extinction coefficients have been plotted in Figs. 1, 2, and 3, and the most important data are summarised in Table I.

TABLE I.

Extinction Coefficients of Tervalent Compounds of Thallium.

Formula.	Logarithm of extinction coefficient.		
$TlCl_3$	1·0 at 3240	3·0 at 2740	
$TlCl_3(C_5H_5N)_2$	1·0 at 3200	3·0 at 2780	
	Maxima.		Step-out.
$TlBr_3$	3·85 at 2670		
TlI_3	3·9 at 4000	4·35 at 2600	
$TlI_3 + I_2$	4·0 at 4000	4·45 at 2550	4·2 at 2900 to 2700
$TlI_3 + KI$	3·9 at 4000	Not observed	4·0 at 2950 to 2750
$KTlI_4$	4·0 at 4020	4·45 at 2550	4·05 at 3000 to 2800
C_5H_5N		3·65 at 2590	
$C_5H_3NCl_2$		3·55 at 2710	
$C_5H_2NCl_3$		3·40 at 2760	
$TlI_3 + (C_5H_5N)_2$.	3·9 at 4010	4·4 at 2600	
$TlI_3,(C_5H_3NCl_2)_5$.	3·9 at 4000	4·4 at 2630	
$TlI_3,(C_5H_2NCl_3)_5$.	3·8 at 4000	4·4 at 2630	
$HTlI_4,(C_5H_5N)_2$.	4·0 at 4030	4·45 at 2580	4·0 at 3000 to 2750

The absorption spectra of $TlCl_3$, $TlBr_3$, and TlI_3 may be compared either with those of $CHCl_3$, $CHBr_3$, and CHI_3 (J., 1926, 622) or with those of KCl, KBr_3, and KI_3 (*loc. cit.*). In each series the chloride shows only a general absorption in the far ultra-violet region, whilst the bromides show at least the close proximity of an absorption band; the iodides, on the other hand, give two absorption bands, one in the more distant part of the ultra-violet spectrum, and the other with its foot extending into the visible spectrum and giving rise to visible colour. This produces a contrast between the black tri-iodide and the colourless trichloride which is sufficient to prove that the thallic salts are not mere aggregates of thallium and halogen ions, as the corresponding thallous salts appear to be. On the other hand, the fact that the two maxima in TlI_3 are separated by 1400 Å.U., whereas the maxima given by $\overset{+}{K}\overset{-}{I_3}$ and by $C_6H_4Br\cdot\overset{+}{N}Me_3\overset{-}{I_3}$ (unpublished measurements) are only separated by 650 and 720 Å.U., respectively, is incompatible with the view that the absorption is caused by a tri-iodide ion. The absorption curves also show that, whereas the tri-iodide ion produces a "general absorption" beyond the twin maxima, the molecular extinction coefficients of thallium tri-iodide decrease progressively at wave-lengths less than those of the two maxima. We therefore conclude that the iodine atoms are not present as a tri-iodide ion, but are joined, at least in part, by covalent bonds directly to the metal. This conclusion is obviously compatible with the view that, since the tri-iodide does not differ from the double salts $Tl_3^{I}(TlCl_6)$, $Tl_3^{I}(TlBr_6)$, and $Tl^{I}(TlBr_4)$ in the same pronounced way as from the simple chloride and bromide, the solid iodide may perhaps be a double salt, $Tl^{III}(TlI_6)$, of the cryolite type; but the data now recorded do not enable us to test the validity of this very plausible view.



A study of the absorption spectra provides a similar solution to the similar problem presented by the tribromide. Since it gives an ultra-violet absorption band ($\log \epsilon = 3{\cdot}85$ at 2670 Å.U.) which is not given either by thallic chloride or by potassium bromide, we can again conclude that the salt is not a mere aggregate of thallium and halogen ions; on the other hand, the bromine cannot be present as a perbromide ion, since the details of the absorption spectra differ very widely, in spite of a superficial resemblance between the maxima set out below:

$\overset{+}{K}\overset{-}{Br_3}$	Maximum at $\log \epsilon = 3{\cdot}5$ at 2700 Å.U. in water.
$C_6H_4Br\cdot\overset{+}{N}Me_3\overset{-}{Br_3}$	,, at $\log \epsilon = 3{\cdot}4$ at 2600 Å.U. in alcohol.
$TlBr_3$	,, at $\log \epsilon = 3{\cdot}85$ at 2670 Å.U. in methyl alcohol.

Thus the two perbromides give a narrow absorption band at 2600—

2700 Å.U., but this is preceded by a well-marked step-out, which only just fails to reach a maximum, $\log \varepsilon = 1{\cdot}8$ at $\lambda = 3800$, just beyond the visible region of the spectrum. Thallium tribromide, on the other hand, gives a broad unsymmetrical maximum at 2670 Å.U., but with no sign of a step-out at 3800 Å.U., since the solutions are highly transparent in the part of the spectrum where the two perbromides only just fail to give an absorption band. The data

FIG. 3.

Molecular extinction coefficients of potassium thallic iodide, etc.

for an *aqueous* solution of thallium tribromide, which are reproduced in Fig. 3, are almost identical with those for the solution in *methyl alcohol* in Fig. 1, but show a step-out in place of the shallow maximum.

In the case of the trichloride no similar question arises, since the trichloride ion appears to be still unknown; and the "general absorption" of the salt is in complete agreement with this conclusion.

In addition to the simple salts, an equimolecular mixture of thallium tri-iodide and iodine was examined, in order to ascertain

whether one of the atoms of iodine could be converted into a tri-iodide ion; but the mixture gave only an additive absorption, including the two maxima of thallium tri-iodide and a step-out at 2900 Å.U. A similar step-out is found in the spectrum of the complex salt $KTlI_4$, solutions of which were prepared both by dissolving the black crystals of the salt and by mixing potassium and thallic iodides. Since potassium tri-iodide gives a band at 2900 Å.U., this step-out might be attributed to a reversible formation of potassium tri-iodide, according to the equation

$$KI + TlI_3 \rightleftharpoons KTlI_4 \rightleftharpoons KI_3 + TlI;$$

but this would not be in harmony with the conclusions of Maitland and Abegg as to the stability of the $[TlI_4]^-$ ion.

The addition compounds of thallium tri-iodide with pyridine and with the chloropyridines have lost the black colour of the tri-iodide, and show instead various shades of orange-red; the pyridinium compound, $(C_5H_5N)_2HTlI_4$, is also bright red. These changes of colour are due to alterations in the foot of an absorption band on the edge of the visible region, the width of which is greatly reduced when the tri-iodide is combined with pyridine, but they are not accompanied by any marked changes in the ultra-violet absorption of the salt.

Molecular Conductivities.

The conductivities of the trihalides were measured by methods that have already been described. Since thallium tri-iodide is insoluble in water, the solvents used were methyl alcohol and acetonitrile. The methyl alcohol was refluxed for 3 hours with sodium hydroxide, fractionated, and then treated with a mercury–aluminium couple until no further action took place. Basic impurities, such as methylamine, were eliminated by distillation from succinic acid, after which the product was dried again with a fresh mercury–aluminium couple; the alcohol was then dry enough to permit of the use of phosphoric oxide for further desiccation. The acetonitrile, from Messrs. British Drug Houses, had an initial conductivity of 35 gemmho. It was allowed to stand over solid potassium hydroxide for several hours to remove acetic acid and moisture, and was then dried with calcium chloride, distilled, shaken with a little phosphoric oxide for several hours, and left in contact with it over-night. After a final distillation the specific conductivity of the liquid had fallen to 1·9 gemmho.

Thallic chloride and bromide were extracted from the double salts, $TlCl_3,3TlCl$ and $TlBr_3,TlBr$ or $TlBr_3,3TlBr$, by prolonged contact with the solvent, and were separated from the thallous

halides by filtration. Since the thallous halides dissolve to an appreciable extent in acetonitrile *in the presence of the thallic halides*, a definite source of error remains, even when the conductivities of the saturated solutions of the two thallous salts (6·037 gemmho for the chloride and 9·781 gemmho for the bromide) are deducted from the values obtained for the corresponding thallic salts. This source of error becomes inappreciable, however, when methyl alcohol is used as the solvent, and is absent in the case of the iodide, which was weighed out and dissolved directly in the solvent.

TABLE II.

The molecular conductivities of the trihalides are shown in Table II, where some other typical data are included for comparison; but the only results from which quantitative conclusions can be drawn are for the trichloride in methyl alcohol and for the tri-iodide in methyl alcohol and in acetonitrile. The conductivities in acetonitrile are several times greater than those of lithium chloride, and rather more than half as great as those of sodium or potassium iodide; but it is clear that the salts are behaving only as binary electrolytes, and that their electrolytic dissociation does not extend

beyond the first halogen $TlX_3 \rightleftharpoons TlX_2^+ + X^-$. A similar statement can be made in reference to the solutions in methyl alcohol, where the conductivities of the two thallium salts at a dilution of $N/2000$ are still only about one-third as great as those of potassium iodide. The conductivity data are therefore in agreement with the absorption spectra in indicating that, even in dilute alcoholic solutions, a part of the halogen is still attached to the metal. Moreover, since the curves obtained by plotting Λ against $\sqrt{c}$, as in Fig. 4, deviate very widely from the linear relation given by potassium iodide in methyl alcohol, and the inflected line for tetraethylammonium iodide in acetonitrile, it is clear that, even when the salts are regarded only as binary

FIG. 4.

Molecular conductivities of thallium salts in acetonitrile and in methyl alcohol.

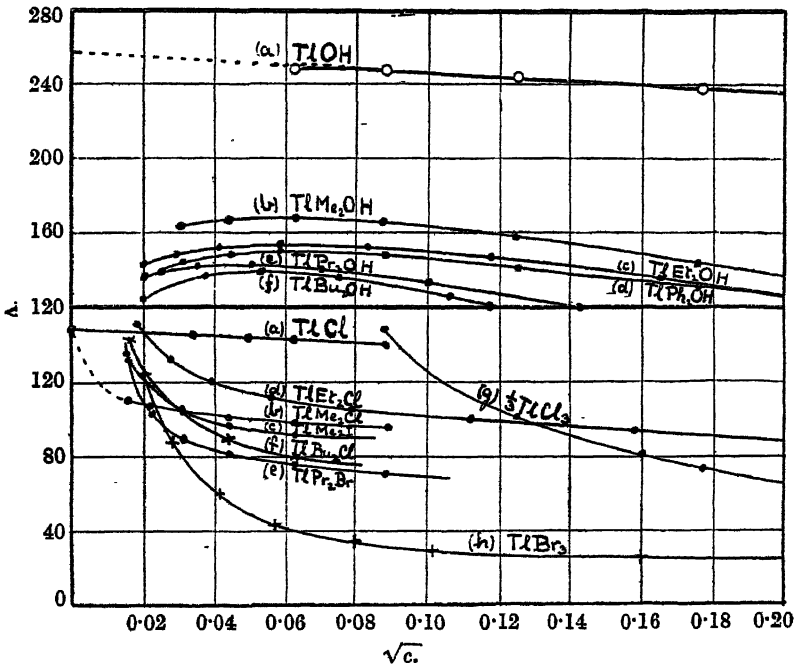
electrolytes, their electrolytic dissociation is very much below that required for complete ionisation according to the formulæ of Debye and Hückel.

(*b*) *Alkyl Derivatives* [with F. L. GILBERT].

Although thallium forms many tervalent salts, the only alkyl derivatives that have been prepared up to the present are of the type $TlMe_2I$; moreover, these dialkyl halides cannot be condensed by the action of metallic sodium to molecules of the type $Me_2Tl{\cdot}TlMe_2$, comparable with the (bimolecular) lead trixylyl, $(C_8H_9)_3Pb{\cdot}Pb(C_8H_9)_3$, prepared by Krause and Smitz (*Ber.*, 1919, **52**, 2165). Since no convincing explanation has yet been given of the non-formation of tri-alkyl compounds of the type $TlMe_3$; it appeared desirable to investigate the dialkyl derivatives, in order to find out whether their ionisation is " complete," as in the case of the quaternary ammonium

bases and salts, or whether it is reversible and incomplete as in the case of ammonium hydroxide and mercuric chloride.

Dimethylthallonium iodide was prepared by the action of the Grignard reagent on the ether-soluble pyridine compound of thallic bromide, and the product was compared with a specimen generously placed at our disposal by Dr. Goddard, which had been prepared by a modification of the method of Meyer and Bertheim (*Ber.*, 1904, **37**, 2051). Our material had a salmon-pink tint, whilst Dr. Goddard's was tinted yellow, but in each case the colour was removed when the solutions were filtered; both specimens decomposed at 275°, although the decomposition point recorded by Goddard (J., 1921, **119**, 674) was 295°. We are also indebted to Dr. Goddard for preparations of the diethyl iodide, the dipropyl bromide and iodide, and the dibutyl bromide. These sparingly soluble salts were washed with water before being converted into the freely soluble bases, and in some cases the salts were recovered in a purified form by neutralising the base with a halogen acid.



The experimental work included measurements of the molecular conductivity of aqueous solutions of several of the dialkyl halides, and of the bases from which they were derived, but comparative observations were also made of the conductivity of thallium tribromide in water. Potentiometric observations were made of the neutralisation of the dimethyl base with *N*-sulphuric acid and of the dipropyl base with *N*-hydrochloric acid; a comparative series of potentiometric measurements was also made of the neutralisation of thallous hydroxide with *N*-sulphuric acid. Finally, the molecular extinction coefficients of dimethylthallonium chloride and iodide were measured in aqueous and methyl-alcoholic solutions, as well as those of aqueous thallic bromide, which had been examined previously in methyl alcohol.

Molecular Conductivities.

(*a*) *Dialkyl Salts.*—The molecular conductivities of aqueous solutions of dimethylthallonium chloride and iodide are set out in Table III (i), with Shukoff's data for the diethyl chloride (*Ber.*, 1905, **38**, 2691), and our own data for the dipropyl bromide (decomposes without fusion at 240°), and for a specimen of the dibutyl chloride (decomposes without fusion at 160°), which we prepared through the free base from Dr. Goddard's specimen of the bromide; the molecular conductivities have also been plotted in Fig. 5 against the square root of the concentration. Ostwald's data for thallous chloride, which give an exactly linear relation between Λ and $\sqrt{c}$, were taken as a criterion of the behaviour of a binary salt which is ionised completely even in the solid state. It is then immediately

obvious that the molecular conductivity of the chloride, $TeMe_2Cl$, falls very far short of the standard for complete ionisation, although there is no clear evidence of hydrolysis, since the curve could be extrapolated quite easily to the value of Λ_∞ given by the data for thallous chloride.* On the other hand, the molecular conductivity of the iodide, $TlMe_2I$, rises so rapidly in dilute solutions that we are obliged to postulate an extensive hydrolysis of the salt, since extrapolation to zero concentration would give a value far in excess of the

FIG. 5.

Molecular conductivities of thallium bases and salts in water.

molecular conductivity of a binary electrolyte. Shukoff's data for diethylthallonium chloride, which were carried to much higher concentrations, show just the same phenomena of incomplete electrolytic dissociation in strong solutions and hydrolysis in weak solutions. The curve for the diethyl chloride is followed fairly closely by our own curve for the dibutyl chloride; the dipropyl bromide, on the other hand, appears to be even less completely dissociated, and more extensively hydrolysed, than the dibutyl

* The curve for the dimethyl chloride intersects the curves for other dialkyl halides, but its accuracy was confirmed by a duplicate series of measurements.

chloride, to which it is related in much the same way as the chloride and iodide of the dimethyl base.

(*b*) *Thallic Chloride and Bromide.*—Evidence of hydrolysis was also obtained on measuring the molecular conductivities of aqueous solutions of thallium tribromide. A solution was prepared by extracting the yellow tetrabromide, $Tl[TlBr_4]$, with water, and its concentration was estimated by gravimetric analysis. Since the thallous salt is insoluble in water, even in the presence of the thallic salt, the correction which was required for solutions in acetonitrile (p. 1756) is no longer needed. The results of the measurements are included in Table III (i), together with Meyer's data for the chloride (*Z. anorg. Chem.*, 1900, **24**, 341). Over the range from 19·4 to 1240 litres, the conductivities are independent of time, but are lower than those of a typical binary salt. At a dilution of 2480 litres, however, the increment of conductivity on doubling the volume, which had been growing progressively throughout, rose to nearly 50% in the freshly diluted solution, and a further increase of nearly 50% occurred when the solution was kept for an hour. This behaviour shows again that a part of the conductivity is due to hydrolysis, exactly as Meyer had postulated in the case of the chloride. The phenomena of incomplete electrolytic dissociation in concentrated solutions and extensive hydrolysis in dilute solutions are, indeed, even more strongly marked in thallic bromide (where the curve plotted in Fig. 5 turns suddenly vertical at $\sqrt{c} = 0{\cdot}02$) than in the alkylated salts. The curve for thallic chloride is of a similar type, but it is difficult to say whether the higher conductivity of the solutions is due to a higher degree of ionisation of the salt or merely to a more extensive hydrolysis.

It is perhaps desirable to add that the evidence cited by Meyer (*Z. anorg. Chem.*, 1900, **24**, 321; 1902, **32**, 72) to show that only two-thirds of the chlorine in thallic chloride is precipitated by silver nitrate has not been confirmed (Cushman, *Amer. Chem. J.*, 1901, **26**, 505) and cannot therefore be used as a proof that only a part of the halogen is ionisable. In our experience, there is a perceptible weakening of the opalescence when a very dilute solution of thallic chloride is mixed with silver nitrate and thallic nitrate is then added; but on keeping for some time the opalescence returns to its original strength. We also find that, just as in the case of ferric oxide, hydrochloric acid is a much better solvent for thallic hydroxide than is nitric acid, which only dissolves the oxide very slowly (Willm, *Ann. Chim. Phys.*, 1865, [4], **149**, 76). For this experiment, equal quantities of thallic hydroxide were precipitated from 1 g. each of the pyridine compound of thallic bromide; the precipitate was only partially dissolved even when heated with 50 c.c. of *N*-nitric acid,

but it was dissolved at once in the cold by only 5 c.c. of *N*-hydrochloric acid; and, when a brown cloud had been produced by diluting to 2000 c.c. and adding 1 c.c. of *N*-sodium carbonate, the liquid was rendered clear again by adding only 2 c.c. of *N*-hydrochloric acid. The incomplete ionisation of thallium tribromide can, however, be demonstrated by a qualitative experiment in the same way as in the case of mercuric chloride. For this purpose, a sample of thallic oxide, which gave no coloration when digested under identical conditions with aqueous phenolphthalein, was heated in a test-tube in a water-bath with aqueous potassium bromide and phenolphthalein, whereupon a very decided alkalinity appeared after a short time. A similar alkalinity was developed in aqueous potassium chloride. This result can be explained by assuming a fixation of bromide ions by the thallium, with a consequent liberation of hydroxyl ions as shown in the reversible equation:

$$Tl(OH)_3 + 3\overset{+}{K}\overset{-}{Br} \rightleftharpoons TlBr_3 + 3\overset{+}{K}\overset{-}{OH}.$$

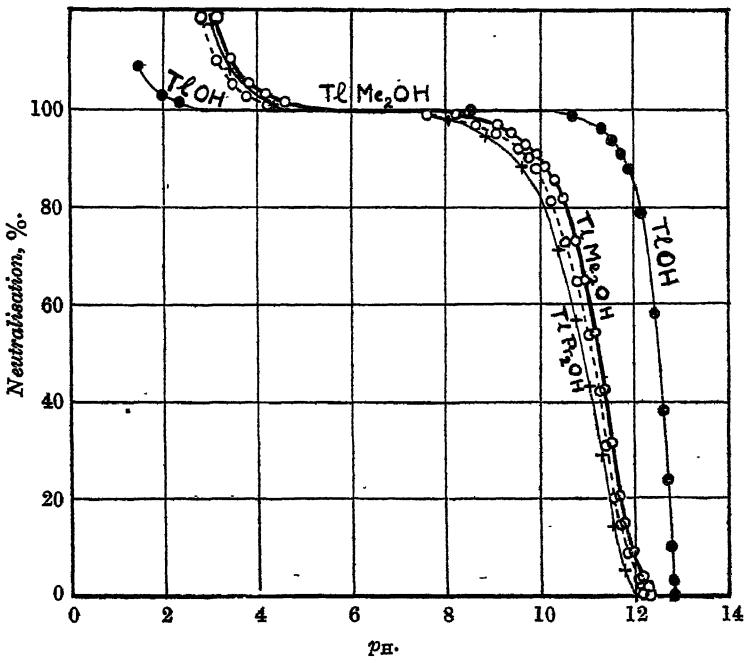
(*c*) *Dialkyl Bases.*—The evidence that the dialkylthallonium halides are extensively hydrolysed in dilute solutions indicates



that these salts are derived from relatively weak bases, which are ionised only incompletely and reversibly in solution. This conclusion was established by observations of the molecular conductivities of the free bases, which are set out in Table III (ii), and are plotted against the square root of the concentration in Fig. 5. Since data were already available for the dimethyl, diethyl, and diphenyl bases (Hein and Meininger, *Z. anorg. Chem.*, 1925, **145**, 95), we have examined only the dipropyl and dibutyl compounds, which we prepared in the usual way by use of silver oxide from Dr. Goddard's specimens of the halides. As a standard of comparison we have taken Ostwald's data for thallous hydroxide (*J. pr. Chem.*, 1886, **33**, 352; 1887, **35**, 112), since this base shows the typical behaviour of a strong electrolyte. Thus, the curve showing the relation between Λ and $\sqrt{c}$ is linear from $N/2$ to $N/128$, and only begins to droop at a dilution of $N/256$, owing probably to the increasing influence of carbon dioxide in the conductivity water. The data of Hein and Meininger, then, show that, whilst the ratio Λ/Λ_∞ is about 85% for thallous hydroxide at $v = 8$, the corresponding percentages for aqueous solutions of the dimethyl, diethyl, and diphenyl bases are 41·8, 42·0, and 42·4 at $v = 8{\cdot}02$, 9·0, and 8·13, respectively. These ratios can no longer be used as a direct measure of the ionisation of the base, but, since the conductivities of the dialkyl bases at $v = 8$ are only about half as great as those of thallous hydroxide, the coefficient of ionisation of these bases cannot be greater than about 50%. This conclusion is confirmed by the data for the dipropyl and dibutyl bases, where the conductivities are even lower in the linear portion of the curves, whilst the drooping of the curves at dilutions beyond $N/128$ corresponds closely with that of the curves plotted from the data of Hein and Meininger.

Electrometric Titrations.

A preliminary titration of a $N/10$-solution of dimethylthallonium hydroxide against N-hydrochloric acid with a hydrogen electrode confirmed the conclusion that the hydroxide could not be classed with the alkalis as a "strong" base; but it did not provide a trustworthy measure of the strength of the base. A direct comparison was therefore made between $N/10$-thallous hydroxide and $N/16$-dimethylthallonium hydroxide with the help of a glass electrode, which had been in constant use for some months, and gave an *E.M.F.* of 54 millivolts per unit of p_H. The bases were titrated with N-sulphuric acid, in order to avoid the precipitation of the sparingly soluble dimethylthallonium chloride, which had been observed in the preliminary experiment; a saturated solution of potassium sulphate was used as a junction liquid to the calomel electrode. The

resulting curves are shown in Fig. 6, together with a curve deduced from the readings of a hydrogen electrode immersed in the same solution. These curves show that, whilst thallous hydroxide behaves as an alkali, the dimethyl base is of a lower order of strength ($-\log K_b = 3$), and is presumably ionised only incompletely and reversibly. The accuracy of the data was confirmed by the fact that a titration with a glass electrode of the dipropyl base at a con-

FIG. 6.

Potentiometric titration of bases.
Full lines = glass electrode.
Broken line = hydrogen electrode.

centration of $N/14{\cdot}3$ gave a curve which followed that for the dimethyl base, with a steady deviation of about 0·2 unit on the side corresponding with the curves for weak bases.

Absorption Spectra.

All the dialkylthallonium halides that we have studied are colourless salts, but the absorption spectra of the dimethyl chloride and iodide were examined in order to ascertain if there was any characteristic absorption in the ultra-violet. The molecular extinction coefficients in water and in methyl alcohol are plotted in Fig. 3. The contrast between the two salts appeared at first to support the view,

which we had deduced from the conductivity data, that the dialkyl halides are ionised only reversibly in solution; but, when the solutions of the iodide were photographed against equivalent solutions of potassium iodide, the extinction coefficients were found to be practically identical with those of the chloride, and are therefore an additive function of the absorption of the two ions. The ratio Λ/Λ_∞ at $N/100$ is about 50% in methyl alcohol and may be estimated at 65% in water (where Λ_∞ cannot be determined directly, on account of hydrolysis); the proportion of undissociated salt in the $N/50$ solutions used for the measurements of absorption was probably at least one-half in methyl alcohol and one-third in water. The additive relation cannot therefore be explained away by the electrolytic dissociation of the salt in the dilute solutions used for the spectroscopic measurements, but must be admitted to hold good also for the undissociated molecules of the salt. On the other hand, in view of the regularity with which covalent iodides, including even methyl iodide itself, give rise to very strong absorption bands in the ultra-violet region, it seems unlikely that the selective absorption of thallium tri-iodide would disappear completely in dimethylthallonium iodide, if the iodine in the latter compound were linked to the halogen by a real bond. We can therefore only conclude that, in this case, the spectroscopic data are in closer accord with Fajans's theory of aggregates of deformable ions as a cause of incomplete electrolytic dissociation, than with the view that a low conductivity always implies the formation of covalent molecules.

General Conclusions.

The chemistry of thallium presents certain peculiarities which await an explanation in terms of the electronic theory of valency. Thus, it is remarkable that *thallium*, although a third-group metal, forms a series of very stable univalent thallous salts, whilst *gold*, which might be expected (like silver) to be most stable in the form of a univalent kation, gives rise generally to tervalent auric salts. Again, the alkyl derivatives, instead of being of the types AuEt and $TlEt_3$, interleaving with $HgEt_2$ and $PbEt_4$, are of the types $AuEtBr_2$, $AuEt_2Br$ (Pope and Gibson, J., 1907, **91**, 2061) and $TlMe_2I$ (Meyer and Bertheim, *loc. cit.*). These apparent anomalies, however, find a simple interpretation in the following observations. (i) The elements Au, Hg, Tl, Pb have escaped from the domination of the *octet* rule, but are still subject to the *duplet* rule (compare *Trans. Faraday Soc.*, 1928, **24**, 31); any even-numbered aggregate of electrons, from 78 up to 86, can therefore form a stable system. As in the case of the acids (*ibid.*, p. 1), this dominance by the duplet rule

is very favourable to reversible ionisation. (ii) As has long been recognised, metallic mercury, with its low boiling point and monatomic vapour, possesses some of the characteristics of an inert gas, although, as Sidgwick has pointed out ("Electronic Theory of Valency," p. 179), it contains two electrons more than are required to complete the outer shell of 18 *O*-electrons; it therefore provides, with niton, an electronic configuration of maximum stability, which the intermediate elements tend to take up in their various compounds. (iii) Mercury and thallium are related to one another in the same way as carbon and nitrogen, so that a molecule in one series becomes an ion in the other, as in the well-established case of CH_4 and $\overset{+}{N}H_4$. The significance of these considerations can be seen from the following table.

Number of electrons.	78	80	82	84	
(*a*) Gold.	Au^+	AuCl	$AuCl_3$	$AuCl_4^-$	
(*b*) Mercury.	Hg^{++}	Hg	$HgPh_2$	$HgCl_3^-$	HgI_4
		Hg_2^{++}	$HgCl_2$		
			Hg_2Cl_2		
(*c*) Thallium.	Tl^{+++}	Tl^+	$TlPh_2^+$	$TlBr_3$	$TlCl_3^{--}$
			$TlMe_2^+$	$TlMe_2^-$	$TlBr_4^-$
			$TlBr_2^+$	$TlMe_2I$	
(*d*) Lead.	Pb^+	Pb^+	$PbEt_2^{++}$	$PbEt_3^+$	$PbEt_4$

(i) 80 *Electrons*. The univalent thallous ion, with 80 electrons round the nucleus, as in the atom of elementary mercury, retains its charge just like the ion of an alkali metal, *e.g.*, in concentrated solutions of thallous salts and of thallous hydroxide, and even in crystals of thallous chloride and bromide, which are built on the same face-centred cubic lattice as cæsium chloride. The hydrolysis of dilute solutions of thallous fluoride (Kohlrausch and Steinwehr, *Sitz. Preuss. Akad. Wiss. Berlin*, 1902, **26**, 581) and of thallous oxalate (Abegg and Spencer, *Z. anorg. Chem.*, 1905, **46**, 406) has been cited as evidence of the weakness of the base, but, since the conductivity of thallous hydroxide is equal to that of the alkalis, and no hydrolysis has been detected in thallous chloride, nitrate, etc., we may suppose that it is the weakness of the acid rather than of the base which is responsible for the hydrolysis. There is therefore no evidence that the 80 electrons of the ion are converted into the system of 82 electrons which would be present in the covalent molecule, TlOH, of a reversibly-ionised base.

(ii) 81 *Electrons*. A more serious reflexion on the stability of the thallous ion is found in Drucker's suggestion (*Z. Elektrochem.*, 1922, **28**, 463) that univalent thallium forms diatomic kations, like mercury, but by a reversible process, $2Tl^+ \rightleftharpoons Tl_2^{++}$. In the case

of mercury, the formation of a diatomic kation makes it possible to formulate the mercurous ion with 80 electrons round each nucleus, just as in the monatomic vapour, and thus to maintain the duplet rule; in the case of thallium, however, this process would increase the number of electrons round each nucleus from 80 to 81, and thus provide an exception to the duplet rule. This hypothesis was introduced as a device to interpret the freezing points, transport numbers, and conductivities of thallous nitrate over the range 0·04—0·14*N* (as well as certain data for thallous sulphate) on the basis of Ostwald's dilution formula, and without using the theory of strong electrolytes. It leads to a ratio $Tl_2^{++}/Tl^+ = 1/7$ at $N/10$, but is not supported by any independent evidence, and can be ruled out on the ground that, whilst the presence of pairs of mercury atoms can be inferred from the *X*-ray analysis of crystalline calomel, the same type of evidence shows equally clearly that the atoms of thallium in the thallous halides are present exclusively as single atoms or univalent ions.

(iii) 82 *and* 84 *Electrons.* The univalent dialkyl ions of the type $TlMe_2^+$ correspond to the covalent molecules, $HgPh_2$ and $HgCl_2$, of the mercury series, with 82 electrons round the nucleus. In marked contrast to the univalent thallous salts, the dialkyl halides do not obey the formulæ for strong electrolytes; the bases from which they are derived are also considerably weaker than thallous hydroxide, and can no longer be classed with the alkalis as examples of "complete ionisation." There can therefore be little doubt that the dialkyl halides, and the bases from which they are derived, as well as the corresponding trihalides and their bases, are capable of yielding non-conducting molecules, such as $TlMe_2I$, $TlMe_2OH$, and $TlBr_3$, which are of the same order of stability as their univalent ions. The spectroscopic evidence, however, indicates that the non-conducting forms of these salts may be ionic doublets, rather than covalent molecules. The existence of systems in which the thallium nucleus is surrounded by 84 electrons in molecules such as $TlMe_2Br$ and $TlBr_3$ is therefore less well-established than in the case of the mercury, where it is unlikely that the three halogens in the ion $HgBr_3^-$ are related unequally to the metal. The doubt which thus arises as to the real existence of the 84-electron system, with only 2 electrons less than the next inert gas, may furnish a clue to the reason why it has not been found possible to prepare the trialkyl derivatives of thallium, since these could not be expected to exist in a form corresponding with the ionised molecules of $\overset{+}{T}l\overset{-}{I}Me_2$, and could therefore only be produced if the 84-electron system were stable.

(iv) 86 *Electrons*. The complex mercury salts of the type $NH_4^+[HgBr_3]^-$ sometimes assume the more stable configuration of niton by combining with a molecule of water; but they do this even more readily by taking up a second molecule of the alkali halide as in K_2HgI_4, etc. In the case of thallium, a similar tendency is seen in the conversion of the deliquescent crystals of thallic chloride and bromide into beautifully crystalline and sparingly soluble salts of the type $Tl^+[TlBr_4]^-$, where the atom of thallium inside the bracket has at last assumed the niton configuration which we find also in $PbCl_4$ and in $PbEt_4$. Another example of the niton configuration is found in the double thallous salt 2AgCl,TlCl, which crystallises from a molten mixture of the silver and thallous chlorides, and to which the structure $Ag_2^{++}[TlCl_3]^{--}$ may be assigned. In complex anions of the type $Tl_3[TlCl_6]$, however, the outer 8-electron shell of the inert gas is replaced by a 12-electron shell, just as in the 6-co-ordination compounds of cobalt and platinum.

(v) 78 *Electrons*. The formation of the 78-electron group in Au^+, Hg^{++}, Tl^{+++}, and Pb^{++++} involves the removal of two electrons from the stable mercury configuration. This becomes progressively more difficult as the charge on the ion increases, so that we cannot be sure whether the relatively high conductivity of aqueous solutions of thallic chloride is due to the ability of the salt to behave as a quaternary electrolyte or merely to hydrolysis; on the other hand, the low conductivity of the salt in non-aqueous solutions shows that, under less favourable conditions, it behaves only as a binary electrolyte, $TlCl_3 \rightleftharpoons \overset{+}{T}lCl_2 + Cl$ (compare $TlMe_2I \rightleftharpoons TeMe_2 + I$). The existence of thallic ions in infinitesimal quantities can, however, be inferred from potentiometric measurements.

Summary and Conclusions.

(*a*) Thallium tri-iodide has been examined in order to determine whether it should be regarded as thallic iodide, or as a thallous polyiodide. Solutions in methyl alcohol and acetonitrile form addition compounds with pyridine and chloropyridines, and complex ions with potassium iodide, and exhibit the general reactions of a thallic salt, but the reactions of thallous ions could not be detected with certainty.

(*b*) The absorption spectrum of the tri-iodide in methyl alcohol shows two maxima, but these are separated by 1400 Å.U., whereas those of potassium tri-iodide are separated only by 650 Å.U. The spectrum is therefore not that of a tri-iodide ion, nor can the compound be a simple aggregate of tervalent thallium and univalent iodide ions, since these ions are colourless and do not give rise to

any absorption bands. The iodide is therefore regarded as a tervalent compound, in which a part at least of the halogen is linked directly to the metal.

(*c*) The molecular conductivities of the thallium trihalides in methyl alcohol and in acetonitrile are less than those of potassium iodide; the salts therefore behave only as binary electrolytes, in which some of the halogen is linked to the metal, even in the most dilute alcoholic solutions.

(*d*) Dimethylthallonium iodide is hydrolysed in dilute aqueous solutions and is derived from a base which is much weaker than thallous hydroxide. The molecular conductivity of thallic bromide is less than that of a binary electrolyte, except in dilute aqueous solutions where it is hydrolysed progressively.

(*e*) The properties of thallium are discussed on the basis of the hypothesis that mercury and thallium are related to one another in the same way as carbon and nitrogen.

The authors desire to express their gratitude to Mr. Heycock for his interest in the work, to Dr. Dootson for presenting them with specimens of chloro-derivatives of pyridine, and to Dr. Goddard for specimens of the dialkylthallonium halides.

DEPARTMENTS OF METALLURGY (GOLDSMITHS') AND PHYSICAL CHEMISTRY, UNIVERSITY OF CAMBRIDGE. [*Received, April 2nd,* 1928.]

CCXXVI.—*The Influence of Constitution on the Stability of Racemates.*

By ALEXANDER FINDLAY and ALAN NEWTON CAMPBELL.

ALTHOUGH a large number of determinations of the freezing-point curves of optically active substances have been carried out, little is known with regard to the range of stability of racemates and the influence of composition or constitution on the transition point. For the purpose of obtaining information on this matter, the solubility relations of a series of related optically active esters have been determined at temperatures between 0° and 40°. The freezing-point curves of the esters were also determined where these were not already known.

For the purpose of our investigation the following substances were employed: tartaric acid, the methyl esters of tartaric acid and of diacetyl-, dipropionyl-, and dibenzoyl-tartaric acids, and the ethyl esters of diacetyl- and dibenzoyl-tartaric acids.

The solvent, where not otherwise stated, was an aqueous alcohol containing 93·8% of alcohol by weight; $d_{15°}^{15°} = 0·8128$. The

solubilities were determined with the active form, with the racemic form, and with a mixture of the active and racemic forms as solid phases. In the case of solutions containing both the active and the inactive forms, the composition was determined polarimetrically, the variation of the specific rotation with concentration and in presence of the inactive form having been previously determined.

(1) *Tartaric Acid.—Freezing-point curve.* The freezing points of mixtures of *d*- and *l*-tartaric acids were determined by Centnerszwer (*Z. physikal. Chem.*, 1899, **29**, 715), and from the resulting curve the conclusion was drawn that *d*- and *l*-tartaric acids form a continuous series of solid solutions. We are unable to confirm this. Owing to the difficulty with which crystallisation takes place, we have determined, not the freezing-point, but the melting-point curve of mixtures, and on plotting the latter a eutectic is found at 161·6° and 94·3% of the *d*-acid. The experimental values are as follows * :

d-Acid, %	100	95	94·3	93	87·6	50
M. p.	168·5°	162·5°	161°	170°	195°	205°

The facts that the melting point of the racemic is much higher than that of the active acid, and that the melting-point curve of the racemic acid extends over such a long range of composition, indicate that the freezing point is far removed from the transition point. The very flat summit of the freezing-point curve indicates that the racemic molecules are largely dissociated in the molten state.

Solubility. The solubilities of the *d*-acid, of anhydrous racemic acid,† and of mixtures of these in 100 g. of alcohol are :

Solid phase.	Solubility (g./100 g. alcohol).			
	0°	15°	25°	40°
d	25·17	30·65	43·04	61·70
r	2·006*	3·153*	5·01*	6·299*
d + *r*	24·92 *d* 1·09 *l*	40·26 *d* 0·2 *l*	51·06 *d* 1·04 *l*	94·04 *d* 1·58 *l*

* Total *d* + *l*.

For the sake of comparison, the solubility in water at 25° was also determined; it is expressed as g. of anhydrous tartaric acid to 100 g. of water, but the hydrated racemic acid was present as solid phase.

$$d\ 147{\cdot}7\ ;\ r\ 21{\cdot}5\ (d+l)\ ;\ d+r\ \begin{cases} 103{\cdot}8\ d \\ 11{\cdot}8\ l \end{cases}$$

* Since the melting-point or freezing-point curve is symmetrical on either side of the line representing the composition of the racemic form, only half the complete curve is given here.

† Perkin (J., 1887, **51**, 367) has shown that racemic acid crystallises from alcohol uncombined with solvent.

When the solubilities in alcohol are plotted with rectangular co-ordinates (Roozeboom, *Z. physikal. Chem.*, 1899, **28**, 494), a curve is obtained of the form which shows that the racemate exists as stable solid phase in contact with the solution. Owing to the fact that the solubility curve for the racemate occupies such a large portion of the diagram, even at 0°, it is clear that the transition point, if one exists, must lie far below zero.

(2) *Methyl Tartrate.*—The active ester melts at 48°, and the racemic at 85°. The melting-point curve for mixtures of the methyl *d*- and *l*-tartrates was determined by Adriani (*Z. physikal. Chem.*, 1900, **33**, 467). The curve for the racemic compound occupies a large part of the diagram, the composition at the eutectic point (42°) being 97% of *d*-ester. The solubility curves also show that the methyl racemate is far removed from its transition point even at 0°. The following are the solubilities in 93·8% alcohol:

Solid phase.	Solubility (g./100 g. solvent).			
	0°	15°	25°	40°
	62·05	199·3	324·5	580
	16·30	20·88	29·2	55·82
	52·05 *d*	88·44 *d*	101·4 *d*	254·5 *d*
	10·25 *l*	10·44 *l*	12·65 *l*	20·5 *l*

(3) *Methyl Diacetyltartrate.*—This ester was prepared by the acetylation of the methyl tartrate. The active ester prepared from methyl *d*-tartrate is lævorotatory.

The fusion or melting-point curve was determined by Adriani (*loc. cit.*). We have determined the following values of the freezing points of mixtures of the active and racemic esters:

d-Ester, %	100	93·05	83·7	79·1	66·9
F. p.	102·5°	98·0°	94·0°	90·1°	86·0°
d-Ester, %	63·1	59·5	54	52·3	50·0
F. p.	85·8°	82·1°	79·8°	79·5°	79·8°

The curve constructed from these data is shown in Fig. 1. It agrees in form with the melting-point curve obtained by Adriani. The temperature of the eutectic point is 79° and the eutectic mixture contains 53·6% of the *d*-ester.

The molecular depression of the freezing point of the racemic ester was found to be 4955, tartaric acid being used as solute. With the help of this value, the degree of dissociation of the racemate was calculated from the slope of the freezing-point curve (Kremann, *Z. Elektrochem.*, 1906, **12**, 259), and found to be about 10%. In the liquid methyl diacetylracemate, therefore, at its freezing point, about 90% of the racemic molecules must exist undissociated.

The following values for the solubility in 93·8% alcohol were obtained:

Solid phase.	Solubility (g./100 g. of solvent).					
	0°	15°	20°	25°	32°	40°
	0·0378	2·14	—	7·025	—	16·65
	3·02	5·20	—	11·59	25·0	37·4
$d + r$	1·51 l	2·60 l	4·11 l	2·72 l		16·9 l
	1·51 d	2·60 d	4·11 d	8·87 d		26·6 d

On plotting the solubility values in rectangular co-ordinates, the curves shown in Fig. 2 are obtained. From the figure, it is seen that up to about 20°, the solubility curve consists of only two branches. Below 20°, therefore, the solid racemic ester is not stable. At 25°

FIG. 1.

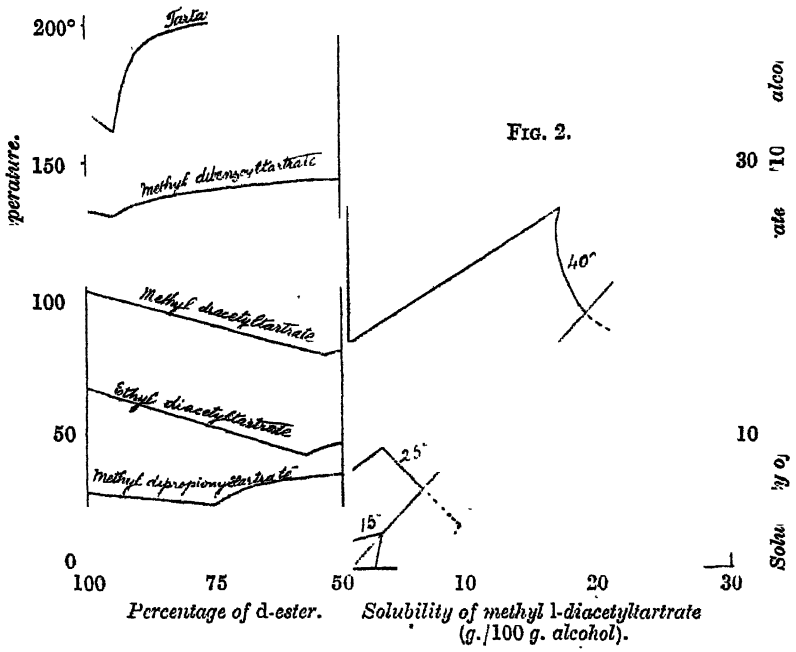


FIG. 2.

and above, the solubility curve consists of three portions, indicating the stable existence of the racemic ester in contact with the solution. The transition point must therefore lie in the neighbourhood of 20°.

The transformation of the racemic into the active esters takes place with great slowness at temperatures below the transition point. It was found, for example, that when the active and the racemic ester were brought in contact with alcohol at a temperature below 20°, a period of a week or more elapsed before equilibrium was attained.

In order to determine the transition point, curves were drawn representing the solubility of the solid phases $d + r$, r, and $d + l$

respectively. The point of intersection of these three curves, which should take place at the transition point, is 23·4°. Great accuracy cannot, however, be claimed for this determination.

The angle of intersection of the solubility curves for $d + l$ mixtures and for the racemic form is small, indicating a small heat of transformation. Accurate determinations of the transition point by means of a dilatometer were not possible owing to the slow rate of transformation of the racemic ester. The value found was between 21·2° and 25·9°.

Determinations of the solubility in carbon tetrachloride were also carried out, and the following values obtained:

Solid phase.	Solubility (g./100 g. of carbon tetrachloride).			
	0·2°	15·0°	25·0°	37·2°
d	1·6	3·73	5·4	9·16
r	2·18	3·66	6·3	16·6
$d + r$	1·03 d	1·72 d	4·1 d	10·32 d
	1·03 l	1·72 l	2·8 l	4·93 l

These data also indicate a transition point between 20° and 25°.

Since the transition point may be taken as 23°, it should be possible to resolve the racemic ester by crystallisation at temperatures below 23°, just as Pasteur obtained a resolution of sodium ammonium racemate. Our attempts to secure such a resolution, however, have had only a very partial success. On one occasion, on allowing a solution to crystallise at the ordinary temperature, one relatively large crystal was picked out which melted at 103°, the m. p. of the active ester. On other occasions, however, bunches of ingrowing crystals were deposited, and it was not possible to distinguish crystals of opposite activity by their outward form. The same difficulty, indeed, was met with in the case of the resolution by crystallisation of rubidium racemate (Traube, *Neues Jahrb. Min., Beil.-Bd.*, 1895—96, **10**, 795).

Very feebly active crystals were obtained by crystallisation from solutions in carbon tetrachloride at −17°.

The conclusion that the racemic ester is unstable below about 23° is in harmony with the results obtained by Anschütz and Pulfrich (*Annalen*, 1888, **247**, 121), who found from cryoscopic measurements in acetic acid solution that the racemate is completely dissociated (compare Bruni and Padoa, *Atti R. Accad. Lincei*, 1902, [v], **11**, i, 212).

(4) *Ethyl Diacetyltartrate.*—The active and racemic esters were prepared by acetylation of the corresponding ethyl tartrates. The *racemic ester* boils at 172°/20 mm., and melts at 48·3° (Found: C, 50·0; H, 6·0. $C_{12}H_{18}O_8$ requires C, 49·7; H, 6·2%). The ester

prepared from ethyl *d*-tartrate is dextrorotatory. The freezing-point curve (Fig. 1) can be constructed from the following data:

d-Ester, %	100	97·17	93·85	88·5	81·2
F. p.	66·6°	65·2°	63·0°	60·3°	56·1°
d-Ester, %	61·6	57·0	53·7	51	50
F. p.	45·8°	42·8°	44·6°	45·9°	46·0°

At the eutectic point, 42·0°, the mixture contains 55·7% of the *d*-ester.

The solubilities in alcohol are as follows:

Solid phase.	Solubility (g./100 g. solvent).			
	0·9°	15·0°	24·2°	38·9°
d	6·03	13·8	38·1	178
r	16·15	53·2	146	—
d + *r*	11·5 *d* 2·5 *l*	40·5 *d* 23·5 *l*	101·75 *d* 49·25 *l*	

The transition point must obviously lie considerably below 0°.

(5) *Methyl Dipropionyltartrate.*—These esters were prepared by Freundler's method (*Ann. Chim. Phys.*, 1894, **3**, 450). The *racemate* melts at 34·2° (Found: C, 49·5; H, 6·1. $C_{12}H_{18}O_8$ requires C, 49·7; H, 6·2%). The ester prepared from methyl *d*-tartrate is lævorotatory.

Owing to the readiness with which supercooling occurs, it was found advisable to determine, not the freezing-point, but the melting-point curve. The following values were obtained:

d-Ester, %	100	95·5	79·3	71	61·5	54·5	50·0
M. p.	27·5°	27·0°	25·7°	28·5°	33·3°	34·0°	34·2°

At the eutectic point, 24°, the mixture contains 75% of *d*-ester.

Owing to the very great solubility of these esters in all common solvents, we have refrained, for the present, from determinations of the solubility curve. With 40% alcohol and with light petroleum, the active ester forms two liquid layers at the ordinary temperature.

(6) *Methyl Dibenzoyltartrate.*—The active ester prepared from methyl *d*-tartrate is lævorotatory, and melts at 132°. The *racemic ester* melts at 144·5° (Found: C, 61·4; H, 4·5. $C_{20}H_{18}O_8$ requires C, 62·2; H, 4·7%); owing to its slight solubility, it is somewhat difficult to purify.

The following freezing points were obtained:

d-Ester, %	100	99·42	98·29	96·17	94·5	92·45
F. p.	132·0°	131·8°	131·3°	130·7°	130·4°	132·5°
d-Ester, %	86·6	66·4	58·2	52·2	50·7	50·0
F. p.	136·2°	141·5°	142·5°	142·8°	143·2°	143·3°

The eutectic point lies at 130·4° and 94·5% of *d*-ester.

The molecular freezing-point depression of the racemic ester, with tartaric acid as solute, was found to be 7055. From this it was calculated that the molten racemate is dissociated to the extent of about 20%.

The following solubilities in alcohol were determined:

Solid phase.	Solubility (g./100 g.).	
	15·6°	25°
d	0·165	0·323
r	0·07	0·236
d + *r*	0·266 *d* 0·047 *l*	0·455 *d* 0·210 *l*

The solubility data show that at the above temperatures the racemic ester is stable in contact with the solution and that it is far removed from its transition point.

(7) *Ethyl Dibenzoyltartrate.*—Since the active ester has a very high solubility and crystallises with very great difficulty (Frankland and Wharton, J., 1896, **69**, 1585), further investigation of it was not undertaken. The *ethyl* r-*dibenzoyltartrate*, however, was purified by repeated recrystallisation (Found: C, 63·4; H, 5·3. $C_{22}H_{22}O_8$ requires C, 63·8; H, 5·3%). Since it melts at 105°, whereas the active ester melts at 62·5°, it is probable, on analogy with other esters which we have investigated, that the racemic ester would be far removed from its transition point even at the ordinary temperature.

When one studies the melting points and melting-point or freezing-point diagrams of the compounds which we have investigated, it is found that the difference between the melting points of an active and a racemic acid (tartaric acid) is but little, if at all, affected by esterification. The difference between the m. p.'s of *d*- and *r*-tartaric acids is about 37°, and the same difference (85°—48°) is found in the case of the *d*- and *r*-methyl esters. The range of composition through which the racemic form is stable is also but little altered. Introduction of an acyl group into the ester, however, lowers the m. p. of the racemic as compared with the active ester, and shortens the range of existence of the freezing-point curve for the racemic form. Specially effective in this respect is the acetyl group; its effectiveness in diminishing the range of stability of the racemic form is shown also by the realisation of a transition point at about 20°. Whether similar relationships are also to be found in the case of other optically active esters is now being investigated.

Summary.

1. The freezing-point and solubility curves of active and racemic forms of tartaric acid, of its methyl ester, of the methyl ester of

diacetyl-, dipropionyl-, and dibenzoyl-tartaric acids, and of the ethyl ester of diacetyl- and dibenzoyl-tartaric acids, have been studied.

2. The introduction of an acyl group into the methyl or ethyl ester of tartaric acid lowers the melting point of the racemic form relatively to that of the active form, and reduces the range of stability of the racemic form. In this respect, the acetyl group is much more effective than the propionyl or the benzoyl group.

3. The transition point of methyl diacetylracemate lies at about 23°.

UNIVERSITY OF ABERDEEN. [*Received, April 28th*, 1928.]

CCXXVII.—*Cryoscopic Irregularities with Phenols.*

By GEORGE MAXWELL RICHARDSON and PHILIP WILFRED ROBERTSON.

IN spite of extensive investigation, the forces causing deviation from Raoult's law are still but poorly understood, especially where solvents and solutes possess such ill-defined electrochemical character as is found with organic compounds. Early attempts to account for such cryoscopic irregularities were based variously on theories of solute ionisation or association, of solvate formation, and of separation of solid solutions, yet their inadequacy has now necessitated the introduction of thermodynamic concepts. The consequent emphasis on intermolecular forces suggests the possibility of correlating cryoscopic irregularities with those physical properties (*e.g.*, molecular volume, viscosity, vapour or osmotic pressure) which are governed by such forces. In this paper, which continues previous investigations of typical organic liquids in phenol solution (Robertson, J., 1903, **83**, 1425; 1904, **85**, 1617; 1905, **87**, 1574; 1906, **89**, 567), cryoscopic measurements have been accompanied in typical cases by simultaneous determination of the alteration in molecular volume of the liquid solutes upon addition to the solvent.

Cryoscopic Deviations.

Calculation of Results.—The molecular depression constant $K = \Delta Mb/100a$ for Raoult's equation was calculated after successive additions of solute in amount sufficient to cause a depression increasing from 0·5° to 5·0°. These depression "constants" were then plotted against the depressions, and the values of K at depressions of 1° (K_1) and of 3·5° ($K_{3\cdot5}$) were read off from the curves. A simple qualitative expression for the deviation was then obtained

by expressing the difference between these constants ($K_{3\cdot5} - K_1$) as a percentage of the depression constant at 1° (K_1). The "percentage deviations," $100(K_{3\cdot5} - K_1)/K_1$, so obtained are numerically equal to approximately one-third of Robertson's "rate" of association.

Table I contains the values obtained for K_1, $K_{3\cdot5}$, and the percentage deviation for alcohols, phenols, anilines, anilides, and amides, also pyridine and quinoline, in phenol solution.

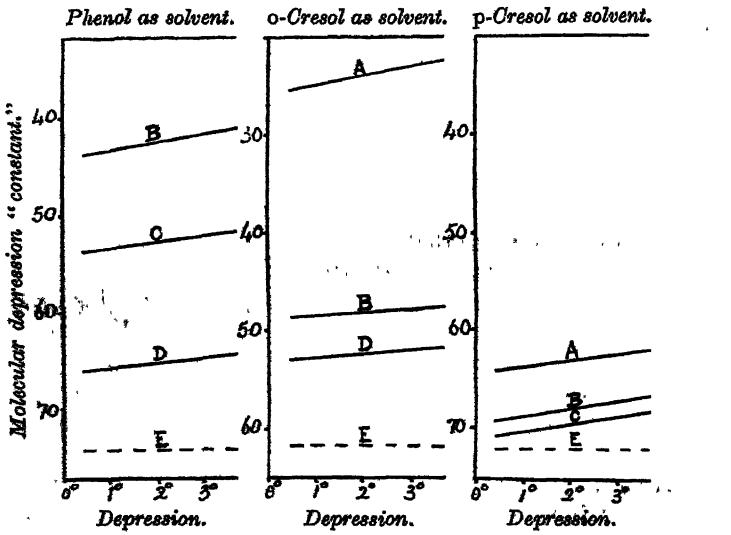
* Owing to the limited solubility of tribromoaniline this figure is for a depression of 3°. For the percentage deviation a correction has been made.

A general perusal of these deviations reveals two main tendencies: (1) As an homologous series is ascended, deviations of K increase at first in a positive direction, but at the fourth carbon atom a reversal occurs until in the long-chain carbon compounds deviations finally become negative (compare alcohols and anilides); (2) substitution by a phenyl group produces no regular change of deviation, but substitution by a halogen atom tends to produce negative deviation (compare aniline with *p*-bromo- and *s*-tribromo-aniline; anilides with *p*-bromoanilides; chloroacetanilide and chloroacetamide with the unsubstituted compounds).

These tendencies, noted already by Robertson in his investigations on acids and esters, would seem to be general in all homologous series, and to point to a differentiation of the effect on percentage deviation of the hydrocarbon chain and of the attached polar group. In the view of Hildebrand (*J. Amer. Chem. Soc.* 1916, **38**, 1452), osmotic phenomena are considered to be the,

observable expression of intermolecular forces induced (*a*) by the internal pressure and (*b*) by the polarities of the interdiffused liquids. Since relative internal pressure among homologues presumably varies as the size of the molecule, whereas polarity is largely dependent on the attached group, this view may be regarded as receiving confirmation in these results.

Another feature of the table not so readily explained is observed with the cresols, where, although noticeable parallelism is shown by the depression curves, the molecular depression constants are markedly dissimilar whatever the concentration. Bruni's explanation involving the separation of solid solutions is not applicable here even if we accept his analytical technique (see Robertson, *loc. cit.*, 1906); for, first, van Bijlert (*Z. physikal. Chem.*, 1891, **8**, 352), using this technique, found no separation of solid solution whatever with *m*-cresol, whereas in its depression constant this is the most irregular phenol; secondly, crystallographic data reveal marked divergence in crystal structure among compounds found to exhibit very similar molecular depressions; and finally, while morphotropic considerations indicate that *p*-substitution, in affecting least the symmetry of the molecule, favours similarity of crystal structure between the simple and substituted compounds, in this investigation the greatest deviation is found with *o*- and *m*-substituted compounds. A theory of active molecules propounded by Brown and Bury (*J. Physical Chem.*, 1926, **30**, 694) provides no better explanation, since it involves regularity at infinite dilution and has no explanation for parallel depression curves.



Further light was sought by investigating *o*- and *p*-cresol as solvents for simple phenols; the curves shown in Fig. 1 were obtained. The remarkable parallelism of curves would seem to indicate the formation of solid solutions, as would also the fact that phenol–*o*-cresol and phenol–*p*-cresol mixtures show abnormalities of like extent whichever component be in excess. However, the characteristically greater abnormality of *m*-cresol, as compared with *o*- or *p*-cresol, in each of the structurally different solvents is incompatible with this conclusion, and the previous criticisms have been in no wise invalidated.

The smaller abnormalities disappear almost completely if a mean depression constant (69) for the homologous series investigated is used for comparison in preference to the van 't Hoff theoretical constant ($K = 0{\cdot}02T^2/L = 74$). Hence the explanation of abnormality may be that in phenolic solutions the van 't Hoff equation requires considerable modification to include some theory of active molecules, though the theory of Brown and Bury cannot be accepted in its present form.

Variations of Molecular Volume.

Calculation of Results.—The alteration of molecular volume of the solute is expressed as the ratio (Molecular solution volume)/(Molecular volume), where the molecular volume is derived from the density of the pure liquid at 40°, and the molecular solution volume is calculated on the simple mixture law from the solution density at 40° of that solution which produces a depression of 4·5° in the freezing point of phenol. Thus the solutions are of approximately the same molecular concentration, but the assumption is made that the

FIG. 1.

whole change of volume upon solution takes place in the molecules of the smaller component.

The molecular volume changes in the various binary liquid mixtures are tabulated in Tables IIa and *b*, where *p* is the percentage composition required to produce a depression of 4·5°. Direct determinations of density at 40° were made except for the molecular volumes of the pure simple alcohols, which were obtained by extrapolation of their known densities at other temperatures. Figures for a hydrocarbon, an ester, and an acid are also included, since each of these types shows a characteristic deviation curve.

It is noted from Table II (*a*) that the alcohols show a typically low ratio of M.S.V./M.V., whereas the phenols (omitting the not unexpected exceptional values for halogen derivatives) show little volume

TABLE II.

change. Benzyl alcohol, though alcoholic in cryoscopical behaviour, behaves in volume change as a benzene derivative. The absence of volume change in mixtures of phenols is confirmed in Table II (*b*), so that, whatever the nature of the molecular environment producing such divergent magnitudes for K, it has no effect on molecular volumes. It is therefore not surprising that the depression curves of these phenolic mixtures are found to be parallel.

To strengthen any conclusions based on volume changes, molecular volume changes were determined with the unassociated toluene, *m*-xylene, and *iso*amyl acetate as solvents. These figures, together with those for the phenols, are in Table III, where both solutes and solvents are arranged in order of their "degree of association" in the liquid state. It would appear that unassociated solvents have the effect of increasing the molecular volume of solutes in solution. Yet generalisations based on concepts of molecular association require solutes in normal solvents to be associated, and to have, almost certainly, smaller molecular volumes, so that these figures enlarge the increasing mass of evidence which

FIG. 2.

discredits the widespread use of "association" concepts to explain irregular behaviour in intermolecular phenomena (see Brown and Bury, *loc. cit.*, p. 702). It is significant that *iso*propyl alcohol and acetic acid, which would commonly be regarded as the most "associated" of the solutes, show this contrary result in molecular volume change to the greatest extent.

General Discussion.

Results for solutes of the three types, alcohol, ester, and hydrocarbon, in the three phenolic solvents are compared in Fig. 2. (Type phenols have already been discussed, and comparison with type acids is invalidated by large polar effects.) The figures placed on each curve represent the ratio M.S.V./M.V., and it seems obvious that each typical deviation is accompanied by an equally typical

alteration of the molecular volume. Hence it becomes significant to enquire whether the intermolecular forces causing this volume change are also capable of governing the cryoscopic deviations.

Referring first to volume changes and to Table III, we find that the anomaly there remarked vanishes if we explain the results in terms of internal pressures, since a solute of internal pressure similar to that of its solvent will be dissolved without volume change, whereas a solute of smaller internal pressure would be compressed on solution, or *vice versa*. By forming a general estimate of internal pressures in this way, we find that their descending order for our compounds is: acetic acid, *iso*propyl alcohol, the phenols and ethyl malonate, the hydrocarbons and amyl acetate—a good agreement with generalisations from Mortimer's internal-pressure data (*J. Amer. Chem. Soc.*, 1923, 45, 633). The marked irregularity of phenols and acetic acid when dissolved in amyl acetate is a good illustration of specific disturbing influences which may arise out of polar groups.

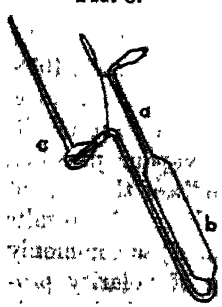
Referring now particularly to the solutes of Fig. 2, we find that in toluene and xylene solutions, ethyl malonate and *iso*propyl alcohol are expanded and toluene is normal, whereas in phenolic solutions, the ester is normal and toluene and *iso*propyl alcohol are compressed. This anomalous behaviour with alcohol–phenol mixtures is satisfactorily attributed to the tendency towards chemical combination of the molecules resulting in a closer binding and a smaller molecular volume.

Correlation between the deviation of the cryoscopic constant and these demonstrated internal-pressure differences is now sought. Hildebrand (*J. Amer. Chem. Soc.*, 1916, 38, 1473; 1919, 41, 1078) finds that in mixed liquids difference of internal pressure produces positive deviation from Raoult's law, since such a mixture results in smaller molecular attractions and increased vapour pressure, thereby reducing the "lowering of vapour pressure" and the amount of change in boiling point or freezing point. This diminution results in that increase of molecular weight (or decrease of K) so commonly stated to be due to "association." Inequality of polarity produces a like effect, but with two highly polar liquids deviation is found to be negative.

Toluene and phenol show differences in both internal pressure and polarities (as estimated qualitatively from dielectric constants); they reveal a marked decrease of K with concentration. Ethyl malonate and phenol possess similar internal pressures and are both highly polar; K increases markedly with concentration. *Iso*-Propyl alcohol and phenol possess different internal pressures and polarities, but show a tendency to unite; the expected decrease

in K is balanced by the increase due to a tendency to solvate formation. The cresols have internal pressures similar to that of phenol, but lower polarities; for each solute, the cresols show deviations of a slightly less positive character than phenol.

Thus a very interesting relation between deviations from cryoscopic normality and changes in molecular volume seems to have been established, and to be correlated with a difference of internal pressures and polarity of the intermixed liquids; but until further data have accumulated it is impossible to formulate more trustworthy conclusions. Since throughout the investigation great care was taken to eliminate as far as possible any error due to the hygroscopic nature of the solvents or other experimental sources of irregularity, it is considered that the deviations observed were conditioned by the forces governing interaction of solvent and solute.



Finally, we append a table of densities ($d_{40°}^{40°}$) of various liquids :

Acetic acid ...	1·0291	Phenol	1·0586	*o*-Chlorophenol	1·2416
*iso*Amyl acetate	0·8524	*o*-Cresol	1·0290	*p*-Chlorophenol	1·2651
Ethyl malonate	1·0349	*m*-Cresol	1·0184	Toluene	0·8498
Allyl alcohol ...	0·8166	*p*-Cresol	1·0186	*m*-Xylene	0·8487
Benzyl alcohol	1·0303				

Experimental.

The Beckmann apparatus with magnetic stirring device was employed in the cryoscopic work. Determinations were made with considerable care, and by adopting special precautions—notably a cooling bath insulated with cotton-wool and maintained at 35° over a steam boiler—highly comparable results were obtained.

Fig. 3.

Density determinations of pure liquids in amounts of about 3 c.c. were made in a specially constructed pyknometer of volume known at 40° (Fig. 3). With the trap *c* turned downwards, the liquid was aspirated into the weighed pyknometer *b* until it reached the scale on the arm *a*, which was next closed with a rubber cap. Then the pyknometer, inserted in its containing vessel in the position shown in the figure, was immersed in the thermostat at 40°; when equilibrium was reached, the vessel was tilted to displace the liquid in the trap from the mouth of the pyknometer, the volume was read to 1/10,000 c.c. from the scale, and cooling was allowed in this position. Then the trap was removed and the second weighing made.

Solution densities were determined in a special long-necked

specific-gravity bottle, graduated at 40° to read to 0·001 c.c. over the range 13·5—14·0 c.c. The final solution from the Beckmann apparatus was transferred directly to the bottle by means of a long-pointed pipette of the same capacity, the volume was read off after equilibrium was attained in the thermostat, and weighings were made. It is believed that through the use of these methods, the experimental error in the final ratio M.S.V./M.V. is no greater than 0·5%.

The best materials obtainable commercially were used. Liquids were further purified by drying and repeated fractionation until the b. p. of the accepted sample varied by no more than ± 0·1°. Solids were successively recrystallised, generally from aqueous alcohol, until the correct m. p.'s were obtained. The amido- and anilido-compounds were prepared from pure constituents by treating the base directly with the acid chloride of the appropriate acid (prepared by use of thionyl chloride). In certain instances this method was not applicable, and the methods indicated in the literature were adopted. The phenol, *o*-cresol, and *p*-cresol used as solvents were twice fractionated and twice recrystallised with the rejection of one-third during each operation, and gave final freezing points in good agreement with the literature. Suitable methods for successive deliveries of about 15 g. of solvent to the Beckmann tube without contact with the atmosphere were adopted.

Summary.

(1) The van 't Hoff equation ($K = 0{\cdot}02T^2/L$) does not hold for the solutes investigated, even at low concentrations.

(2) The observed deviations seem to depend on internal pressure and polarity in accordance with the theory of Hildebrand.

(3) Derived phenols have been found to show in their binary mixtures marked divergences not traceable to these causes. The theories of solid solutions and of activity (as formulated by Brown and Bury) have been shown to be unsatisfactory as explanations, but some theory of activity seems to be required.

(4) A general relation is shown between changes in molecular volume upon solution and cryoscopic behaviour, and this relation is in agreement with deductions drawn from internal-pressure data.

(5) Densities of various phenols and other compounds have been determined at 40°.

CCXXVIII.—*The Alkaline Hydrolysis of Esters in Aqueous Alcoholic Solution. Part II. The Interaction of Phenoxides and Aliphatic Esters.*

By ERIC STEPHEN GYNGELL.

IT was shown in Part I (J., 1926, 2484) that the reaction between ethyl acetate and potassium phenoxide, in alcoholic solution, did not follow the usual bimolecular law, as required by the equation $C_6H_5{\cdot}OK + CH_3{\cdot}CO_2Et \longrightarrow C_6H_5{\cdot}OEt + CH_3{\cdot}CO_2K$, but was due to small amounts of potassium hydroxide produced by hydrolysis of the phenoxide by water present in the alcoholic solution. Alcoholysis of the phenoxide did not appear to be a cause of reaction.

A mathematical expression was deduced which gave satisfactory constants for the ester hydrolysis; the value of this constant, however, was the product of the velocity coefficient and an equilibrium constant, but it was not possible to determine these two factors separately with any degree of certainty.

Smith (J., 1927, 170) extended this work to the interaction of potassium *m*-tolyloxide and ethyl acetate in aqueous alcoholic solution, and obtained similar results. Numerous esters of the aliphatic series have now been studied, and in all cases, except for esters of oxalic acid, the reaction has been found to proceed as a result of hydrolysis of the phenoxide.

EXPERIMENTAL.

The following experiment is typical of the whole series. Time is expressed in minutes and concentrations in milliequivs. per litre.

Potassium phenoxide, $N/4$; ethyl propionate $N/4$; H_2O, 2%; Temp., 70°.

Time.	Titre.	x.	$a - x$.	$b - x$.	$Kk \times 10^6$.
0	20·0	0·0	500·0	1111	—
70	13·8	155·0	345·0	956	1·04

$n\text{-}C_3H_7 \cdot CO_2Bu\beta$	—	0·51	0·47	0·44	0·31	0·23	0·24
$n\text{-}C_3H_7 \cdot CO_2C_5H_{11}(iso)$	—	—	—	—	—	1·17*	0·90

* $Kk \times 10^6 = 1·12$ at 15%.

Relative Activities of the Esters.—The values of Kk for the different esters do not appear to be strictly in order of the atomic weights. There is, however, a distinct decrease in the values of the constants from acetate to butyrate.

In conclusion, I should like to thank Dr. J. C. Crocker for his continued interest in the work.

CHELSEA POLYTECHNIC, S.W. [*Received, April 16th*, 1928.]

CCXXIX.—*Pseudo-ternary Systems containing Sulphur. Part III. The System Sulphur–Sulphur Monochloride.*

By DALZIEL LLEWELLYN HAMMICK and MICHAEL ZVEGINTZOV.

IT was noticed by Aronstein and Meihuizen (*Proc. K. Akad. Wetensch. Amsterdam*, 1898, **1**, 1) that a saturated solution of sulphur in sulphur monochloride, S_2Cl_2, after being heated to 170° and chilled, not only failed to deposit sulphur at its saturation temperature but was even capable of dissolving a further amount. This phenomenon was more fully investigated by Aten (*Z. physikal. Chem.*, 1913, **84**, 257). He pointed out that the behaviour of the sulphur solutions could be explained either by the formation of a new modification of sulphur as a result of the rise in temperature, or by the formation of a subchloride as a result of interaction between the dissolved sulphur and the solvent. Both effects could, of course, operate simultaneously. He heated saturated solutions of non-equilibrium sulphur (S_λ) to various temperatures between 50° and 170° and, after chilling them to 25°, 0°, and — 60°, determined the very considerable amounts of S_λ that the solutions would now dissolve before they became once more saturated. As a result of a somewhat elaborate

phase-rule analysis of the data obtained, he excluded the possibility of subchloride formation. Further, having found that insoluble or amorphous sulphur is insoluble in cold sulphur monochloride, and assuming that such sulphur is identical with S_μ (the form of sulphur present in equilibrium with S_λ in liquefied sulphur), he concluded that the increase in the amount of sulphur that the solutions would hold after heating could only be explained on the supposition that a new liquid form, S_π, was present. Aten subsequently estimated the amounts of S_π present in liquid equilibrium sulphur at various temperatures (*Z. physikal. Chem.*, 1913, **86**, 10) and found a maximum of 6·7% at 160°. This amount is quite insufficient to account for the large increases in the solvent power of sulphur–sulphur chloride mixtures found when such mixtures are heated and subsequently chilled. For instance, a solution of sulphur in sulphur chloride saturated at 20° contains 17% of S_λ; this solution, after being heated at 100° for a few hours, chilled, and again saturated at 20°, will contain 31% of dissolved S_λ. On Aten's view, this exaltation of the solvent power must be due to the solvent's effect on the internal equilibrium of the dissolved sulphur, considerable amounts of S_π being formed.

The validity of Aten's contention that subchlorides are not formed in sulphur–sulphur monochloride mixtures becomes doubtful in the light of the work of Ruff and Golla (*Z. anorg. Chem.*, 1924, **138**, 33) and of Bruni and Amadori (*Atti R. Accad. Lincei*, 1919, **28**, 217), who obtained indirect evidence for the existence of subchloride molecules. We have therefore sought for direct phase-rule evidence on the question from a detailed study of solid–liquid equilibria in the system, and have determined (i) the solubility curve of sulphur in sulphur monochloride under conditions such that the solutions might be expected to contain only S_λ, and (ii) the temperatures at which the solutions used in (i) were in equilibrium with solid after having been heated to various temperatures until internal equilibrium had been reached and then chilled.

Experimental.

The sulphur used was twice recrystallised from carbon disulphide or toluene and dried at 90°. The sulphur monochloride was distilled in an all-glass apparatus from excess of sulphur, to ensure absence of dichloride, and dried over calcium chloride; it distilled constantly at 138°.

Temperatures of equilibrium between solid phases and solutions were determined by the synthetic method used in previous work on sulphur systems (J., 1926, 1995; 1927, 493). The glass tubes were about 2 cm. in diameter and contained about 3 c.c. of solution. The

true solubilities of sulphur in sulphur monochloride (S_λ only in solution) were determined by warming the bulbs in a mechanically stirred paraffin-bath and finding in the usual way the temperatures at which the last small crystal was in equilibrium with the solution. Each bulb was then heated until internal equilibrium had been established at 100°, 148°, 178°, and 230—235° in thermostatic oil-baths. Equilibrium (as indicated by unchanged solid–liquid equilibrium temperatures) was established in 4—5 hours at 100°, 1·5 hours at 148°, and less than an hour at 178° and 230°. After the bulbs had been chilled by plunging them into ice and water (the 230—235° bulbs were chilled for 5 seconds at 100° and then put into ice), crystallisation was induced by cooling, in many cases seeding being necessary as well. A few of the solutions heated to 148°, and many of those heated to 178° and above, deposited monoclinic sulphur on cooling; this could be made to pass into rhombic by warming gently until almost all the crystals had disappeared and then recooling. The data obtained are given below. Solubilities are recorded as g. per 100 g. of solution.

TABLE I.

Solubility of Sulphur in Sulphur Chloride.

Temp.	−9°	2°	4°	10°	21°	28·7°	35·7°	36·8°

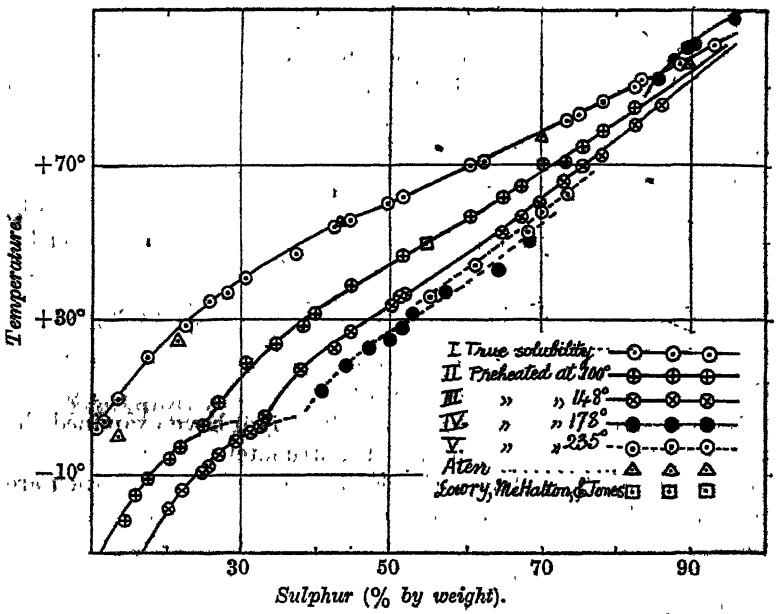
The above results are plotted in the diagram; some points have been omitted on the sulphur side in order to avoid confusing the curves.



Discussion of Results.

It is necessary that the significance of the curves in the diagram should be made quite clear. Curve I is taken to be the true solubility curve for sulphur in sulphur monochloride, complications due to compound formation or shift of internal equilibrium having been avoided by rapid working. The curve is in good agreement with that of Aten (*loc. cit.*), whose points are indicated on it. Curve II is related to I as follows: At any temperature $t°$ a point on Curve I gives the amount of sulphur that must be added to saturate sulphur monochloride without complications. When such a solution is heated at 100° and then chilled, the temperature at which it is now just saturated with sulphur (or other substance capable of giving a crystalline solid phase) is given by a point on Curve II vertically below the first point on Curve I. Curves III, IV, and V are similarly related to Curve I.

It will be seen that Curves II and III show definite breaks in the neighbourhood of 0°. The lower portions in each case appear to be

making for a maximum at a composition of about 34 parts of sulphur added to 66 parts of sulphur monochloride. This composition corresponds to a chloride S_4Cl_2. The solid phases that separate from solutions below 0° do not differ markedly in appearance from rhombic sulphur. That sulphur and sulphur monochloride are not the only substances present in the bulbs was shown, however, by opening them and removing the sulphur monochloride by means of a mercury–vapour pump and an activated-charcoal trap cooled in liquid air. A viscous, yellow oil was obtained, together with crystals of rhombic sulphur. On treatment with water, the oil gave hydro-

FIG. 1.

chloric acid with separation of sulphur, thus showing the presence of a chloride of sulphur. This could not be sulphur monochloride, which by itself is entirely volatilised and absorbed under the experimental conditions.

Confirmatory evidence that the portions of the Curves II and III correspond to a solid phase other than rhombic or monoclinic sulphur was obtained as follows. A bulb containing 30 parts of sulphur to 70 parts of monochloride was sealed and maintained at 148° for 2 hours. It was then chilled in cold water and placed in liquid air, a transparent glass being obtained. The bulb was opened and the mixture seeded with crystals of rhombic and monoclinic sulphur. No crystallisation occurred on warming and cooling

several times. A portion of the liquid contents of the bulb was now placed in a Dewar flask and stirred with a few drops of liquid air. After the latter had evaporated, the glassy mass softened and finally crystallised. A small portion of this crystalline mass was rapidly transferred to the bulb, which had been kept in liquid air. The contents of the bulb now crystallised on warming, a precipitate of small prisms melting at about 0° being obtained. Cooling of the bulb after these crystals had melted did not lead to separation of solid phase unless the liquid was seeded as before; the small crystals of rhombic and monoclinic sulphur originally added to induce crystallisation persisted, however, throughout. The same results were obtained on repetition several times with each of two separate bulbs.

It would thus appear to be established that at least one subchloride of sulphur is formed in heated solutions of sulphur in sulphur monochloride, and it is no longer necessary to suppose with Aten that unusually large amounts of forms of sulphur other than S_λ are formed in such solutions.

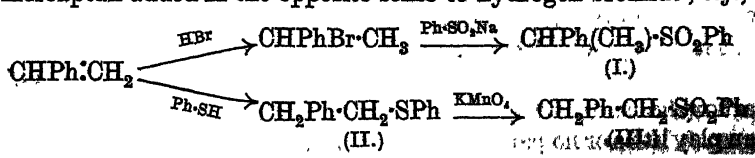
It is suggested that the formula of the new subchloride is S_4Cl_2, although there is no information available as to its molecular weight. The simplest formula S_2Cl may be excluded on valency grounds; S_4Cl_2 may reasonably be regarded as $\begin{matrix} S\leftarrow S-Cl \\ S\leftarrow S-Cl \end{matrix}$, in support of which its low volatility may be noted (compare Sidgwick, "The Electronic Theory of Valency," p. 123).

Lowry, McHatton, and Jones (J., 1927, 746) have examined the whole system sulphur–chlorine. Unfortunately their results for the portion of the system with which we have been concerned are given as a diagram without numerical data. We have calculated one solubility from a point on their graph and find that it lies on our curve for solutions that have been preheated at 100° (see diagram), as would be expected from the fact that their solutions were heated at 96° for a time before equilibrium temperatures were determined (*loc. cit.*, p. 753). Aten's solubilities (*Z. physikal. Chem.*, 1913, **81**, 274) are shown in the diagram, where it will be seen that his points lie satisfactorily on our curve at the higher temperatures. It may be noted that the statement of Lowry, McHatton, and Jones that, after being heated to 170°, sulphur dissolves permanently in sulphur monochloride (*loc. cit.*, p. 753) is incorrect in the light of the data given in Table II (*c* and *d*). Even after preheating at 230—235°, it was possible to determine equilibrium temperatures down to 36·6°. The new chloride, S_4Cl_2, could not, however, be obtained as a solid phase from solutions preheated at 178° or 235°.

The data from the experiments with mixtures preheated at 178° and 235° show that the enhanced solubility effect falls off as the preheating temperature rises, and that it is actually reversed at the highest temperature. The following table gives the solubility of rhombic sulphur at 50° in solutions that have been preheated at $T°$:

$T°$	—	100°	148°	178°	235°
S, %	39·5	54·5	62	68	66

In conclusion, it may be mentioned that solutions containing 25—40% of sulphur developed a distinct cloudiness when supercooled to — 75° after preheating at 148°. The opacity disappeared at about — 60° to — 50° on raising the temperature and appeared to be due to the separation of minute liquid droplets. It is thus possible that a metastable two-phase (liquid–liquid) region had been entered. The high viscosity of the solutions prevented adequate agitation of the liquid, so the clearing temperatures could not be accurately observed.



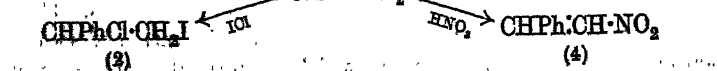
The authors wish to acknowledge a grant from Messrs. Brunner Mond and Co. which has partially defrayed the cost of this investigation.

THE DYSON PERRINS LABORATORY,
OXFORD. [*Received, May 16th,* 1928.]

CCXXX.—*Effects induced by the Phenyl Group. Part I. The Addition of Polar Reagents to Styrene and the Behaviour of the Halogenated Ethylbenzenes.*

By FRANK ASHWORTH and GEORGE NORMAN BURKHARDT.

ONE of the most striking exceptions to the Markownikoff rule was described by Posner in his work on the addition of phenyl mercaptan to double bonds (*Ber.*, 1905, **38**, 646). He allowed various unsymmetrical unsaturated compounds to remain in contact with phenyl mercaptan and oxidised the sulphides produced to sulphones. These he compared with the sulphones obtained by the action of sodium benzenesulphinate on the bromide which was formed by the addition of hydrogen bromide to the respective unsaturated hydrocarbons. In each case the products from the two methods were different. He assumed each to be a pure substance and deduced that phenyl mercaptan added in the opposite sense to hydrogen bromide; *e.g.*,

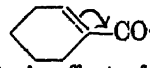


He does not record tests to establish whether any of the products were mixtures, and assumes that the Markownikoff rule holds perfectly for the addition of hydrogen bromide. It is not clear, in the cases of trimethylethylene and camphene, that his initial material was pure and he notes that the same product was obtained in good yield from crude amylene as from trimethylethylene. The present investigation was primarily designed to test his conclusions in the case of styrene, where the pure hydrocarbon was readily available, but it was also necessary to examine the evidence on the effects induced in the side chain by the phenyl group, and particularly the mode of addition of hydrogen bromide and other polar reagents to styrene.

The addition of hydrogen bromide to styrene gave, as stated by Schramm (*Ber.*, 1893, **26**, 1710), only α-bromoethylbenzene. The product was compared with the bromides obtained from phenylmethylcarbinol and phenylethyl alcohol.

The addition of sodium bisulphite to styrene had previously been effected at 100° by Miller (*Annalen*, 1877, **189**, 340), but he did not identify the product. The reaction of ammonium bisulphite in cold dilute aqueous solution with styrene emulsified in it with kieselguhr (Kolker and Lapworth, J., 1925, **127**, 307) gave in 10 days a 10% yield of pure ethylbenzene-α-sulphonate, identified by comparison with the synthetic sulphonates obtained by the action of boiling ammonium sulphite on the α- and β-bromoethylbenzenes.

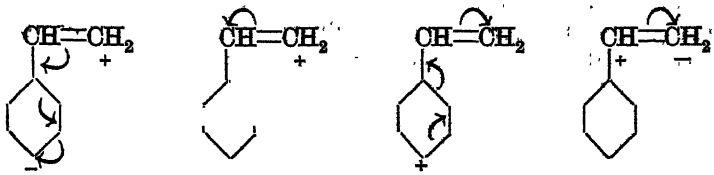
These additions are considered to take place by the combination of proton with the more anionoid carbon atom in the hydrocarbon (Kolker and Lapworth, *loc. cit.*; Lapworth, *Mem. Manchester Phil. Soc.*, 1925, **69**, xix; Robinson, J., 1926, 402). It must be assumed that the more anionoid centre in styrene is the ω-carbon atom in order to explain these additions and also such reactions as:



(1) Tiffeneau, *Compt. rend.*, 1907, **145**, 811; (2) Ingle, *J. Soc. Chem. Ind.*, 1902, **21**, 581; (3) Koenigs, *Ber.*, 1901, **34**, 3894; (4) Hofmann, *Annalen*, 1845, **53**, 297.

and a discussion of the origin of this selective anionoid activity shows what secondary effects are likely to be observed.

It is widely accepted that the general electrical effect of a group is to be estimated by a consideration of the dissociation constants of carboxylic acids, particularly those of acids in which conjugation can play little or no part (Flürscheim, J., 1909, **95**, 718; G. N. Lewis,



J. Amer. Chem. Soc., 1916, **38**, 762; Allan, Oxford, Robinson, and Smith, J., 1926, 406). The constants of a suitable group of acids make it clear that, unlike saturated aliphatic or alicyclic groups, phenyl has a stronger attraction than hydrogen for electrons (negative general effect):

	$K \cdot 10^{-5}$.		$K \cdot 10^{-5}$.
Acetic	1·82	Benzoic	6·5
Propionic	1·31	Phenylacetic (?)	5·3
*cyclo*Hexanecarboxylic	1·32	Phenylpropionic	2·3

The general effect on the constant of benzoic acid will be greatly reduced by the conjugation  CO·OH (IV), but may be somewhat increased by the steric effect of the phenyl group. The steric effect is, however, comparable in benzoic and *cyclo*hexanecarboxylic acids and both the steric and the conjugative effect are probably negligible in β-phenylpropionic acid, although here the general effect is also reduced by the length of the chain.

The chief result of this general effect on the side chain, apart from the conjugative effects which it may start, would be to make the β-electrons more available than those on the α-atom, but it is superimposed on any conjugative electronic displacements, in the manner discussed by Lapworth and Robinson (*Mem. Manchester Phil. Soc.*, 1928, **72**, 43) in their consideration of the $o : p$ ratio in aromatic substitution.

Four types of conjugative electronic displacement affecting the reactions of the side chain are possible:

(A) (B) (C) (D)

None of the known addition reactions (with the possible exception of that with phenyl mercaptan, which will be discussed later) requires phase (B) (the direction of polarisation which would be initiated by the general effect due to the phenyl group); which would be relatively inactive to kationoid reagents, as the anionoid activity of the α-carbon would be reduced by the holding in of the electrons on that atom by the attraction of the phenyl group (general effect) and also by the steric effect of the phenyl group. One would also anticipate that in this phase and in (D) the α-atom would reduce its charge by conjugation with the nucleus, although the work of Fourneau

and Thorpe on conjugated systems, of Scarborough, of Turner and of Kenyon and their collaborators on substituted diphenyl compounds, suggests that the transmission of such polarisations is not necessarily very complete.

The polarisation in (D) is directly opposed to the general effect and if it is initiated by an increase of covalency between the nuclear and the α-carbon atoms it approximates to phase (C). These are the phases which have the anionoid ω-carbon atom indicated by the reactions of the side chain, and something approximating to (C) must be considered the normal active phase of styrene.

This polarisation will not, however, explain the *o*-*p*-substitution in styrene and its derivatives, and the general effect of the vinyl group will tend to inhibit *o*-*p*-substitution, as this group has a greater attraction than hydrogen for electrons. This is clearly shown by the dissociation constants:

	$K \cdot 10^{-5}$.		$K \cdot 10^{-5}$.
Acetic acid	1·82	Vinylacetic acid	3·8
Butyric acid	1·47	Crotonic acid	2·2

(N.B. The general effect in crotonic acid is reduced by conjugation as in benzoic acid; compare above.)

Both the tendency to conjugate in the direction of (C) and (D) and the attraction of the side chain for electrons will be increased in such derivatives of styrene as ω-nitrostyrene and cinnamic ester and yet even in these cases *o*-*p*-substitution predominates. It can only be assumed that in styrene and all these derivatives there is some tendency to polarise in the manner (A) and this will have an activating effect on the *o*-*p*-positions, whereas the opposite polarisation (C) and the general effect will reduce the activity of all the positions. Hence the polarisation of type (A) will facilitate ordinary substitution in the nucleus and those of type (C) will be more inert in the nucleus and substitution will be facilitated only in the ω-position. This is in keeping with the fact that styrene is nitrated in this position first.

It is anticipated that the detailed application of these theoretical considerations will be made clearer by experiments which are in progress with derivatives of styrene containing substituents both in the side chain and in the nucleus.

Another type of evidence on the effects induced by the phenyl group was obtained by the action of boiling aqueous-alcoholic caustic potash on the halogenated ethylbenzenes. Under these conditions α-bromoethylbenzene gave quantitatively phenylmethylcarbinol; β-bromoethylbenzene gave only styrene; and styrene dibromide gave pure α-bromostyrene. The last fact was proved by hydrolysing the product with formic acid, isolating the aceto

phenone produced in 92% yield, and showing that ω-bromostyrene, which is inert towards formic acid, was absent from the residue. This is contrary to much previous work summarised by Nef (*Annalen*, 1899, **308**, 273) as follows:

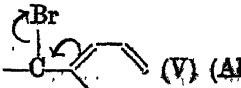
"It is obvious that alcoholic potassium acetate, water at 190°, and alcoholic potash with styrene dibromide all give a mixture of α- and ω-bromostyrene, since the product has not a constant boiling point and gives phenylpropiolic acid on treatment with sodium and carbon dioxide. This can only be derived from ω-bromostyrene."

It was found, in the present investigation, that the boiling point rose rapidly from that of α-bromostyrene to that of unchanged styrene dibromide. The residue of the latter would account for the production of phenylpropiolic acid.

Neither α- nor β-bromoethylbenzene was reduced by hydriodic acid at 150° after four hours.

Ward has shown (J., 1927, 445) that the displacement of halogen in α-chloroethylbenzene is independent of the concentration of sodium hydroxide used and up to 50° gives phenylmethylcarbinol with optical inversion, but at 100° styrene, phenylmethylcarbinol, and αα′-diphenyldiethyl ether are formed. These facts he explains on the basis of a slow unimolecular reaction formulated in the way suggested by Nef:

$$C_6H_5\cdot CHCl\cdot CH_3 \longrightarrow C_6H_5\cdot \overset{\diagup\ \diagdown}{C}\cdot CH_3 + HCl$$



a step supposed to be followed by either (1) the addition of water, or (2) isomerisation to styrene, or (3) addition of phenylmethylcarbinol. He comments on the mechanism previously discussed by Phillips (J., 1925, **127**, 2567) dependent on the production of $\begin{matrix} R_1 \\ R_2 \\ R_3 \end{matrix}\!\!\diagdown\!\!\overset{+}{C}\!-$ from a halogen compound by the removal of the halogen ion, but he retains the conception that, in such an ionisation, the hydrogen atom R_1 accompanies the halogen ion.

$$R_3{:}\overset{\displaystyle R_2}{\overset{\cdot\cdot}{C}}{:}H \longrightarrow R_3{:}\overset{\displaystyle R_2}{\overset{\cdot\cdot}{C}}\cdot + H{:}\overset{\cdot\cdot}{Cl}{:} \quad \text{not} \quad R_3{:}\overset{\displaystyle R_2}{\overset{\cdot\cdot}{C}}{:}H + :\overset{\cdot\cdot}{Cl}:$$
$$:\underset{\cdot\cdot}{Cl}:$$

The inversion in the formation of phenylmethylcarbinol could be accounted for (compare Fischer, *Ber.*, 1907, **40**, 489; Lapworth and Mottram, *Mem. Manchester Phil. Soc.*, 1927, **71**, 63) if the removal of the halogen ion were dependent on one of the frequent approaches of the water or other solvent molecules, to the side of the α-carbon atom away from the halogen, occurring simultaneously with a rare

polarisation of the molecule sufficient to ionise the halogen under these conditions. This mechanism would also account for other observations which Ward discusses, namely, that solutions of potassium cyanide, ammonia, and potassium acetate in ethyl alcohol all give α-phenyldiethyl ether as the main product.

Many investigators (compare Conant and Kerner, *J. Amer. Chem. Soc.*, 1924, **46**, 232) have observed that phenyl and carbonyl groups have similar effects on the halogen atoms in systems of the form R·[CH_2]$_n$·Cl (R=phenyl, carbethoxyl, etc.), phenyl being less powerful than any carbonyl group, and the results of the present investigation also show such similarities. It is to be noted from a theoretical point of view, however, that while the general effect of phenyl and carboxyl is in the same direction relative to hydrogen, the conjugative effects will depend on the nature of the side chain and the various factors may operate in different ways in different reactions of halogen atoms in the side chain. The α-halogen in alkylbenzenes forms with the nucleus a type of allyloid system

(V) (Allan, Oxford, Robinson, and Smith, *loc. cit.*) in which the polarisation of the nucleus assists the tendency of the halogen atom to separate with a negative charge. This is in accord with the results of the investigations on the hydrolysis of substituted benzyl halides (*Ann. Reports*, 1927, **24**, 155), and also with the capacity of the phenyl group for stabilising a positively charged α-carbon atom which is clearly shown in the positive triphenylmethyl ion. The opposite polarisation (type A, p. 1793) and the general effect may account for its less powerful effect in stabilising a negative charge in the sodium derivative of triphenylmethyl.

In the case of the β-halogenated ethylbenzenes the effect of the phenyl group on the halogen atom, here separated from it by two single bonds, appears to be slight, judged by the low reactivity to potassium iodide in acetone (Conant and Kerner, *loc. cit.*). Assuming that the separation of the halogen ion is the first process in the production of styrene by the action of aqueous-alcoholic potassium hydroxide on ω-bromostyrene, this reaction will be dependent on the ease with which the electrons of the α-carbon atom co-ordinate with the ω-atom to form the double bond, as well as on the ease with which the halogen atom is removed. The conjugation with the nucleus (type C, p. 1793) will facilitate such co-ordination and the removal of the proton will follow. On the other hand, this reaction may be dependent on the tendency of the α-hydrogen to ionise, which will be increased by the opposite type of polarisation and the general effect.

The repetition of Posner's experiments gave the products which he obtained, and the sulphone from the addition of phenyl mercaptan to styrene was identical with that obtained by the action of sodium benzenesulphinate on β-bromoethylbenzene. The sulphide obtained from the addition was also shown to contain less than 2% of the α-isomeride, by comparing the boiling point and refractive index with those of the two synthetic sulphides. It is therefore clear that phenyl mercaptan adds to styrene in the opposite sense to hydrogen bromide and other polar reagents, and the theoretical considerations which satisfactorily correlate those normal additions will not serve in this case if the reaction takes place between the polarised ethylene bond and the hydrogen and thiophenoxide ions.

In a search for other evidence in favour of a special mechanism for this reaction the course of the addition of phenyl mercaptan to styrene was followed by observations of the very large contraction in volume which takes place during the reaction and also by determinations of the depression of the freezing point of benzene caused by mixtures of phenyl mercaptan and styrene. The rate of addition is greatly dependent on the intensity of illumination, and the increase in rate produced by exposure to sunlight continues for some time after the reaction vessel is returned to diffused light; but the reaction was not stopped in the dark and the product was always phenyl β-phenylethyl sulphide. A small percentage of piperidine had such a powerful retarding action on the addition that no change in volume was observed in diffused daylight even after several days, although a contraction took place in sunlight. The action of light is well known to produce or enhance abnormal polarisations and depolarisations in a wide range of reactions, and experiments are in progress with a view to obtaining evidence in favour of one or other of the possible alternative mechanisms for the interaction of mercaptans with ethylenic hydrocarbons.

A remarkable isomerisation was observed in an attempt to prepare phenyl-β-phenylethylsulphone (III) by reducing phenacylphenylsulphone (VI) with zinc amalgam and hydrochloric acid: a liquid sulphide was obtained which on oxidation with hot chromic acid was converted into phenyl-α-phenylethylsulphone (I). A similar migration of groups takes place when ω-bromoacetophenone is heated with yellow ammonium sulphide (Willgerodt, *Ber.*, 1889, 22, 534).

(VI.) $COPh\cdot CH_2\cdot SO_2Ph \longrightarrow$ (II.) or $CHPh(CH_3)\cdot SPh$ (VII.) $\longrightarrow$ (I.)

EXPERIMENTAL.

Preparation of the Monohalogen Derivatives of Ethylbenzene.—Phenylmethylcarbinol (b. p. 100°/15 mm.; 3 : 5-dinitrobenzoate

m. p. 95°), made by the action of magnesium phenyl bromide on acetaldehyde, was converted by gaseous hydrogen bromide into α-bromoethylbenzene. This, by the action of silver acetate suspended in ether, readily yielded phenylmethylcarbinyl acetate which on hydrolysis gave the carbinol free from any detectable proportion of β-phenylethyl alcohol, as was shown by the properties of its 3 : 5-dinitrobenzoate and the entire absence of the fragrance associated with the isomeric compound.

The β-chloroethylbenzene used in some of the experiments described later was made by converting glycol chlorohydrin into its *p*-toluenesulphonate and leaving this in contact with a cold ethereal solution of magnesium phenyl bromide for 36 hours; about an equal weight of a liquid, which was probably ethylene chlorobromide, was also produced (see Ferns and Lapworth, J., 1912, **101**, 273).

β-Bromoethylbenzene was made by heating β-phenylethyl alcohol with constant-boiling hydrobromic acid for 24 hours; it had b. p. 97°/12 mm., and was quite free from the pungent odour characteristic of the α-bromo-compound.

Action of Aqueous-alcoholic Potassium Hydroxide on the Isomeric Bromoethylbenzenes.—The two bromo-compounds, when heated on the water-bath under precisely similar conditions with aqueous-alcoholic potassium hydroxide (about 0·4*N*), lost all the halogen (as determined by the decrease in alkaline titres) within 30 minutes. In the product from the α-bromo-compound, no styrene whatever could be detected. The product from the β-bromo-compound was almost pure styrene and absorbed bromine (1 mol.), yielding styrene dibromide.

Addition Reactions of Styrene.—The styrene was made by Howard's method from cinnamic acid (J., 1861, **13**, 136).

(A.) *Addition of hydrogen bromide.* A mixture of styrene and a cold saturated solution of hydrogen bromide in glacial acetic acid was kept over-night and then poured into water, and the oil obtained was distilled (b. p. 95°/15 mm.). The product was nearly pure α-bromoethylbenzene, as it was converted, by means of silver acetate and alkali successively, into phenylmethylcarbinol which gave the characteristic 3 : 5-dinitrobenzoate (m. p. 95°) and had no detectable odour of the isomeric β-phenylethyl alcohol (3 : 5-dinitrobenzoate, m. p. 108°).

(B.) *Addition of ammonium hydrogen sulphite.* An emulsion of styrene (20 g.) with *N*/4-ammonium hydrogen sulphite (2 l.) and kieselguhr (100 g.) was kept with frequent shaking for 10 days. After filtration the liquid was boiled with excess of barium hydroxide until ammonia was expelled and worked up for soluble salts (compare J., 1925, **127**, 307); 8 g. (yield, about 16%) of colourless *barium α-phenylethanesulphonate* were obtained in bundles of small

needles [Found: H_2O, 6·8; Ba (in anhydrous salt), 27·1. $(C_8H_9SO_3)_2Ba,2H_2O$ requires H_2O, 6·6%. $(C_8H_9SO_3)_2Ba$ requires Ba, 27·0%]. No alkyl sulphite could be detected (compare *loc. cit.*). A portion of the salt was converted into the amide, which separated from alcohol in feathery crystals, m. p. 121°.

The sulphonic derivatives were identical with those obtained from the ammonium salt produced when α-bromoethylbenzene was heated with aqueous ammonium sulphite for several hours (Found for the barium salt: H_2O, 6·9; Ba, in the anhydrous salt, 26·8%. Amide, feathery crystals, m. p. 121°, mixed m. p. 121°).

As α-bromoethylbenzene shows little or no tendency to become converted into styrene, the foregoing results indicate clearly that the sulphonic salt from styrene and hydrogen sulphite is the α-derivative of ethylbenzene. The conclusion, however, was checked by preparing the β-sulphonic acid.

β-Bromoethylbenzene (8 g.) was boiled with aqueous ammonium sulphite, and the solution worked up as usual with barium hydroxide. *Barium β-phenylethanesulphonate* (5 g.) was isolated in large, glistening plates [Found: H_2O, 3·4; Ba (in anhydrous salt), 26·8. $(C_8H_9SO_3)_2Ba,H_2O$ requires H_2O, 3·4%. $(C_8H_9SO_3)_2Ba$ requires Ba, 27·0%]. The sulphonamide melted at 124°.

(C.) *Addition of phenyl mercaptan.* The product obtained from styrene and phenyl mercaptan by Posner's method (*loc. cit.*) gave, on oxidation with cold dilute potassium permanganate solution and excess of sulphuric acid, the pure β-sulphone, m. p. 56—57°, identical with that prepared from β-bromoethylbenzene.

Phenyl α- and β-phenylethyl sulphides and the sulphide obtained by fractionating the addition product were unattacked by hot or cold neutral potassium permanganate, even when it contained manganese dioxide in suspension. The addition of bromine or of excess of dilute sulphuric acid caused rapid reduction of the permanganate. If the oxidation was carried out hot, a mixture of phenacylphenylsulphone (VI), m. p. 94—95°, and phenyl-β-phenylethylsulphone was obtained.

Phenyl-β-phenylethylsulphone (III) was prepared from β-bromoethylbenzene by boiling with an alcoholic solution of sodium benzenesulphinate for 12 hours and separated from carbon tetrachloride in feathery crystals, m. p. 56—57° (Found: S, 13·2. Calc. for $C_{14}H_{14}O_2S$: S, 13·0%). The sulphones could not be prepared from the chloroethylbenzenes, as the α-chloro-compound was converted into styrene and the β-isomeride was unchanged.

Pure phenyl α- and β-phenylethyl sulphides were prepared by heating sodium thiophenoxide (1·1 mols.) in alcoholic solution with α- or β-bromoethylbenzene (1·0 mol.), pouring the mixture into

water, and extracting the product with carbon tetrachloride. The sulphides were distilled, heated for ½ hour under reduced pressure at 100° in a stream of carbon dioxide, and redistilled. The α-compound had b. p. 163—164°/15 mm. and n_D 1·6042; the β-compound, b. p. 188—189°/15 mm. and n_D 1·6082.

The whole product of the reaction between styrene and phenyl mercaptan was washed with alkali, dried, and fractionated. The distinction between unchanged styrene, sulphide, and a small residue (probably metastyrene) was clearly marked. The middle fraction (yield, 90%), b. p. 187—190°/15 mm., heated in a stream of carbon dioxide under reduced pressure at 100° and refractionated, gave the following refractive indices: first 6 drops, 1·6079; 9 c.c., 1·6082; 2 drops, 1·6085; residue, 1·6088. Fractions 1 and 2 after refractionation gave: first 2 drops, 1·6073; 10 drops, 1·6081; thirteenth drop and the remainder, 1·6082. This indicates less than 2% of α-isomeride in the product.

Experiments on the velocity of the reaction and photocatalysis. During the reaction of styrene and phenyl mercaptan a 10% contraction takes place, and the course of the reaction was followed by cooling a mixture of styrene (11 c.c.) and phenyl mercaptan (10 c.c.) in a glass tube (0·2 to 0·5 cm. bore) in running water, marking the level of the meniscus, sealing the tube, and marking the level from time to time. As the velocity is influenced by light, the two reagents were distilled in only the light of a Bunsen flame (the mercaptan was distilled in hydrogen to prevent the formation of disulphide), and two tubes were prepared as described above, marked and sealed in a similar light, and left in a dark room. The part of each tube containing the liquid was kept inside rubber tubing down which water was running and the subsequent marks were made with a minimum of light in the dark room. The two reactions proceeded at the same rate. After 17½ hours one tube was taken into sunlight, the water-cooling being continued. The contraction was nearly doubled in the next 15 minutes and was practically complete after 1 hour. The other tube in the dark showed no signs of reaching the same limit after 3 weeks.

Time (hrs.)	0·1	1·5	2·5	14·0	17·5	17·75	18·0	18·25
Contraction (cm.) in tube I in dark	0·5	0·75	1·05	2·15	2·35	4·0*	4·4*	4·7*
Contraction (cm.) in tube II in dark	0·6	0·8	1·1	2·15	2·3			
Time (days)	1·5	2·5	3·5	4·5	6·5	8·5	22·5	25·5
Contraction (cm.) in tube I in light	4·9	4·9				4·9		
Contraction (cm.) in tube II in dark	2·6	2·95	3·25	3·4	3·6	3·75	3·8	3·8

* In sunlight.

The phenyl mercaptan remaining in the reaction carried out in the dark was extracted in alkali and the sulphide which was distilled out of the residue was shown to contain no detectable amount of the α-isomeride by determinations of the refractive index and boiling point.

A side tube was inserted about 70 cm. from the lower end of the reaction tube, the mixture was introduced until it overflowed from the side tube, and a similar experiment was carried out entirely in the dark. The speed was similar to that in the previous experiments before taking into sunlight.

Cryoscopic evidence on the course of the reaction [with CECIL ROBINS]. The freezing points were taken of solutions of phenyl mercaptan and of styrene in suitable amounts of benzene, and also the freezing points of the mixed solutions, with a view to determining whether any considerable amount of association took place quickly, followed by a photocatalytic depolarisation. No such association was observed and the rate of combination appeared to be in agreement with the velocity measured by contraction. In this case, however, it was clear that the reaction did not slow down again at once when the tube was returned to diffused light.

Action of Alcoholic Potassium Hydroxide on Styrene Dibromide.—Styrene dibromide (Glaser, *Annalen*, 1870, **154**, 164) (26·4 g.) was boiled in alcoholic solution with potassium hydroxide (1 mol.), the alcohol removed by distillation, and the oily product distilled in a vacuum. No fraction was obtained between α-bromostyrene and styrene dibromide.

The product was almost instantly attacked by boiling formic acid, the odour of acetophenone becoming perceptible. As β-bromostyrene was found to be very stable towards boiling formic acid, undergoing but slight hydrolysis after 20 minutes, this observation, which finds a parallel in the ready hydrolysis of α-chlorostyrene by hydrochloric acid, suggested a means of detecting β-bromostyrene when mixed with the α-isomeride.

0·774 G. of the lower-boiling portion of the product from styrene dibromide was boiled for about 5 minutes with formic acid, and sodium acetate and semicarbazide hydrochloride were then added; acetophenonesemicarbazone (0·653 g.; 92% of the theoretical yield) was deposited. It is evident that at least 92% of the oil consisted of α-bromostyrene. No trace of β-bromostyrene (easily detected by its powerful hyacinth-like odour) could be found in the liquor after the acetophenone had been removed. As a small quantity of unchanged styrene dibromide was present, having escaped the fractionation process, it is clear that removal of hydrogen

bromide from styrene dibromide takes place almost solely in one direction.

The authors gratefully acknowledge their indebtedness to Professor Lapworth for suggesting this investigation and for his advice and interest in it.

THE UNIVERSITY, MANCHESTER. [*Received, March 29th*, 1928.]

CCXXXI.—*The Influence of the Intensity of Illumination on the Velocity of the Photochemical Union of Bromine and Hydrogen, and the Determination of the Mean Life of a Postulated Catalyst.*

By FRANK BRIERS and DAVID LEONARD CHAPMAN.

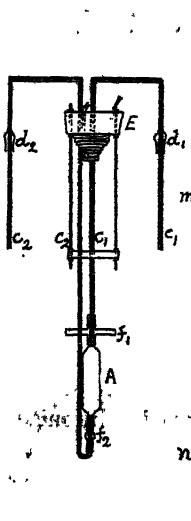
IN a previous communication (Briers, Chapman, and Walters, J., 1926, 562) experimental evidence was submitted in support of the contention of Berthoud and Bellenot (*Helv. Chim. Acta*, 1924, **7**, 307) that the rate of photochemical interaction of iodine and potassium oxalate in aqueous solution is proportional to the square root of the intensity of illumination. Formerly, it seemed to be not improbable that all photochemical changes would be found to be strictly proportional to the intensity of the light (*vide* Draper, *Phil. Mag.*, 1843, **23**, 401; M. C. C. Chapman, J., 1923, **123**, 3062; 1924, **125**, 1521; Kornfeld and Müller, *Z. physikal. Chem.*, 1925, **117**, 242), and clearly this must always be the case when the "quantum efficiency" is a true constant. However, Bodenstein and Lütkemeyer (*Z. physikal. Chem.*, 1924, **114**, 208) have recently announced that the rate of union of hydrogen and bromine in the light is proportional to the square root of the energy absorbed when the intensity of the light is kept constant. It is therefore not improbable that the rate of this gaseous reaction is also proportional to the square root of the intensity of the light. We shall show that this assertion of Bodenstein and Lütkemeyer is true without considerable error under suitable conditions. In addition to investigating the dependence of the rate of the change on the intensity of illumination, we have, as in the action of iodine on potassium oxalate, determined the mean life of the postulated catalyst on the concentration of which the rate of the change depends, and the principle of the method employed for this purpose has been the same as that adopted in the case of the other reaction.

EXPERIMENTAL.

The mean life of the catalyst was estimated by determining the hydrogen bromide formed when a mixture of bromine and hydrogen,

of constant composition and enclosed in an appropriate actinometer, was exposed to intermittent light of constant intensity in such a manner that the period during which the mixture was in light bore a constant ratio to the period during which it was in darkness. In these circumstances, the amount of chemical change per unit of radiant energy supplied is dependent on the length of the equal short periods of illumination. From the quantitative relation between the frequency of illumination and the chemical change per unit of energy supplied, the mean life of the catalyst can be determined.

FIG. 1.



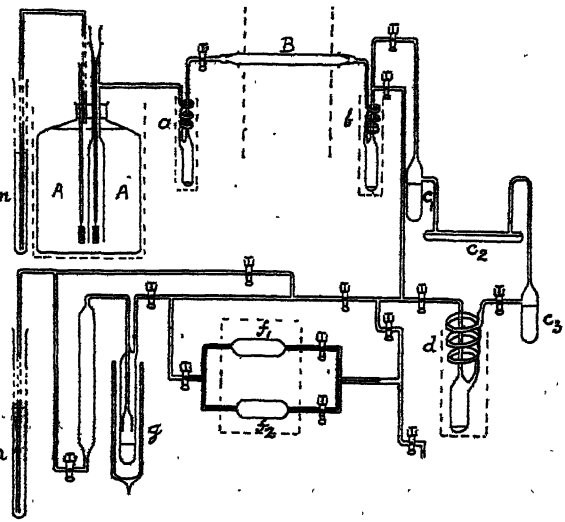


FIG. 2.

The actinometer (Fig. 1) was made from a wide glass tube, A, of 2·20 cm. internal diameter and 8 cm. long. The mixed gases entered the actinometer through the capillary tube, c_1, and escaped through the capillary tube c_2. The ground glass joints at d_1 and d_2 served to connect the actinometer with the apparatus employed to analyse its contents at the end of an experiment. During an exposure of the actinometer to light it was immersed in the vapour of boiling dimethylaniline contained in a wide tube of pyrex glass (not shown in the figure) which was kept in position by the stopper E. The ends of the glass crosses at f_1 and f_2 touched the sides of the pyrex tube and served to keep the actinometer centrally in the same fixed position.

After the actinometer had been filled, its exposure to intermittent light was accomplished in the following manner. The insolation tube was screened by blackened asbestos board so that no light could

enter it except that which had passed through sectors cut out of a rotating disc of stout cardboard and through a plate-glass window of the same shape as each of the sectors. The disc was provided with eight equal sectors, each being 8 cm. long and situated at a mean distance of 21 cm. from the centre. The sectors were at equal distances from one another, but the angle subtended by each sector at the centre was changed whenever it was desired to alter the ratio of the periods of darkness and illumination. The pyrex jacket was placed as near as possible to the plate-glass window in such a position that the whole of the mixture in the actinometer was equally illuminated. The source of illumination was a 1000-watt incandescent-filament lamp, placed at a horizontal distance of 30 cm. from the reaction vessel. The light from the lamp passed through an aperture of appropriate shape in a large piece of stout sheet-iron which was placed immediately in front of the lamp, the aperture being of such a size that its penumbra was outside the plate-glass window. The current supplied to the lamp was maintained constant with a rheostat worked by hand, and was recorded by a mirror galvanometer. The rotating disc was placed as near as possible to the plate-glass window. The shadow cast by the edge of a sector was quite sharp, but there was some error, which could neither be avoided nor estimated, occasioned by reflexion from the inner wall of the glass bulb of the lamp. The lamp itself was placed in such a position that its incandescent wire subtended in a plane at right angles to the top edge of the window the minimum angle at a point in the actinometer. The disc was kept in rotation by means of a geared motor, and in some of the experiments in which the rotation was slow, by a clock.

The filling of the actinometer with the mixture of hydrogen and bromine was accomplished with the apparatus shown in Fig. [illegible]. The hydrogen was prepared by the electrolysis of an aqueous solution of baryta contained in the large electrolytic cell, A, and was freed from excess of water vapour by passage through a glass worm, a, surrounded by water at a temperature 2° below that of the laboratory. The oxygen was removed by passing the gas through a quartz tube, B, filled with palladised asbestos and heated to redness, and the water formed was condensed in the worm, b, which was kept at the same temperature as a. The moist hydrogen then passed slowly over a large surface of pure liquid bromine contained in glass vessels, three of which are shown diagrammatically at c_1, c_2, and c_3. The hydrogen thus saturated with bromine and almost saturated with water vapour then passed through a long glass worm d immersed in a thermostat kept at 12°. The issuing hydrogen, which thus contained a constant proportion of water vapour and

bromine, streamed through two almost identical actinometers (shown diagrammatically at f_1 and f_2) which, during the filling, were kept at a constant temperature of 25°. The bromine in the escaping hydrogen was recovered by condensation in a freezing mixture contained in the thermos flask g. While the actinometers were being filled, the pressure in the apparatus was kept constant by adjusting the height of the columns of water in m and n. At the end of a filling, the pressure in the actinometers was reduced to 50 cm. of mercury and the actinometers were then sealed off at the points c_1 and c_2 (Fig. 1). The two almost identical actinometers, thus filled under exactly the same conditions, were subsequently used to compare the rates of formation of hydrogen bromide per unit of radiant energy absorbed under different conditions of illumination.

The analysis of the contents of the actinometers at first presented a difficulty, since the ordinary procedure was found not to be sufficiently accurate. The bromine and hydrogen bromide had to be separated before their amounts were estimated. In principle, the method adopted was to admit into the actinometer a limited amount of pure water and to distil the bromine from the solution of hydrogen bromide and thence into a cooled solution of potassium iodide, the distillation being conducted in such a manner that the hydrobromic acid was retained in the actinometer and in a trap inserted between it and the bulbs containing the potassium iodide solution. The liberated iodine was titrated with standard sodium thiosulphate, and the hydrobromic acid with standard baryta in an atmosphere of hydrogen.

All the bromine used was purified from chlorine and iodine as well as from organic matter by the method recommended by Scott (J., 1913, **103**, 847), and the water used in the electrolytic cell and in the analyses was purified by the following method. Ordinary distilled water was saturated with chlorine and boiled for several hours in a large flask provided with a fused-on reflux condenser. At the end of this operation sufficient potassium bromide was added to interact with the small amount of chlorine still present, and the liberated bromine was removed by boiling under reduced pressure. A few drops of pure potash solution were then added, and after it had been heated, the water was distilled in dust-free air, and the distillate collected in carefully cleaned glass-stoppered bottles.

Discussion.

The experimental results show clearly that if, with a constant intensity of illumination, the disc is made to rotate at different rates, the amount of chemical change in a given time is greater when

the rate of rotation of the disc is greater, the increase in the amount of change being such that it tends to a limit as the rate of rotation is made more rapid. When the disc rotates very slowly, the amount of hydrogen bromide formed in a given time is, of course, independent of the rate of rotation, and becomes the same as that produced by continuous illumination for the same total length of time. The mean life of the postulated catalyst is calculated from the result of a determination of the rate of rotation of the disc for which the mean velocity of chemical change is mid-way between the mean velocities of chemical change previously found for a very rapid and for a very slow rate of rotation of the disc.

That the photochemical union of hydrogen with chlorine and bromine is attributable to ephemeral catalysts (either atoms or active molecules) is now commonly assumed, and the assumption is supported by the fact, now established for the interaction of hydrogen and bromine, that the total amount of chemical change is not solely dependent on the total time of illumination by light of a constant intensity, but alters when the supply of the light is rendered intermittent. In adopting this theory we shall make the following assumptions concerning the catalyst:

(1) For light of a given quality, the rate of formation of the catalyst is proportional to the energy absorbed.

(2) The rate of destruction of the catalyst is the sum of two terms, one being proportional to the first power and the other to the second power of its concentration.

(3) The rate of formation of hydrogen bromide is directly proportional to the concentration of the catalyst.

Taking for granted (1) and (3), we can show that if the rate of destruction of the catalyst is proportional to its concentration the rate of union of hydrogen and bromine is proportional to the intensity of the light, whereas, if the rate of destruction of the catalyst is proportional to the square of its concentration, the rate of union is proportional to the square root of the intensity of the light. Thus, on the one hand, if A represents the concentration of the catalyst, I the intensity of the light, t the time, and k and k_1 are constants, the differential equation for the variation of A is

$$dA/dt = kI - k_1A = 0 \text{ in the steady state).}$$

Therefore, in the steady state A is proportional to I. Such would be the case if the destruction of the catalyst were caused principally by the impacts of its molecules with molecules of an inhibitor. On the other hand, if

$$dA/dt = kI - k_1A^2 (= 0 \text{ in the steady state}),$$

A would be proportional to the square-root of the intensity of the light, and such would be the case if the destruction of the catalyst were caused principally by the impact of two of its molecules.

Our results indicate that the rate of interaction of hydrogen and bromine, for very high intensities of the light, approximates to values which are proportional to the square-root of the intensity, but for low intensities the rate becomes more nearly equal to values proportional to the intensity. Accordingly, we must conclude that the destruction of the catalyst is at the same time both a first- and a second-order reaction, and that the differential equation which gives the time variation of its concentration is

$$dA/dt = kI - k_1A^2 - k_2A \ (= 0 \text{ in the steady state}) \quad . \quad . \quad (1)$$

Let the units of time, energy, and concentration be so chosen that $k = 1$, $I = 1$, and $A = 1$ in the steady state when the actinometer is fully exposed to light; the values of the constants k_1 and k_2 can then be determined experimentally in the following manner. The actinometer is, in the first place, exposed to the light with the disc rotating very slowly, and the time, t_1, needed for the production of a given amount of hydrogen bromide is determined. Then with the twin actinometer a similar experiment is performed with the disc rotating very rapidly. Let us suppose that the time required for the production of the specified amount of hydrogen bromide is t_2. If α is the ratio to 2π of the sum of the angles subtended at the centre of the disc by all the sectors, then in the first experiment the actinometer was exposed to light of unit intensity for the time αt_1, whilst the result of the second experiment ought obviously to be the same as that of an exposure of the actinometer for a time t_2 to light of intensity α. But since the amount of chemical change is proportional to the product of the concentration of the catalyst and the time of exposure, we must have

$$\alpha t_1 = A_2 t_2 \text{ or } A_2 = \alpha t_1/t_2 \quad . \quad . \quad . \quad . \quad . \quad (1.1)$$

in which A_2 is the approximately constant concentration of the catalyst in the second experiment.

With the new units, equation (1) becomes

$$dA/dt = I - k_1A^2 - k_2A \ (= 0 \text{ in the steady state}) \quad . \quad . \quad (1.2)$$

In the first experiment, I and A both have by definition the value 1, and in the second experiment I has the value α, and A the value $\alpha t_1/t_2$. On substituting these values in (1.2), we obtain the following two equations from which the values of k_1 and k_2 can be deduced:

$$1 = k_1 + k_2$$

and

$$\alpha = k_1(\alpha t_1/t_2)^2 + k_2(\alpha t_1/t_2)$$

An actual experiment gave for $\alpha t_1/t_2$ the value 0·2391 when α was $\frac{1}{3}$

from which it follows that k_1 and k_2 are respectively 0·6272 and 0·3728. These were the values of the two constants adopted for the determination of the mean life of the catalyst.

The Determination of the Mean Life of the Catalyst.

In the system of units proposed above, the rate of increase of A becomes $I - k_1A^2 - k_2A_1$, and in this expression I is equal to the rate of production of the catalyst, and $k_1A^2 + k_2A$ to its rate of destruction, per unit volume. The mean life of the catalyst in the steady state is the quotient of A by the rate of production of A, *i.e.*, it is equal to A/I. But under continuous illumination the intensity has been taken as unity, and, under the same conditions, A in the steady state has also been taken as unity. Therefore in the conventional units adopted, the mean life of the catalyst is the unit of time.

Under all conditions the rate of chemical change is proportional to the mean value of A, and therefore, since A is unity when the actinometer is continuously illuminated, its mean value for a given moderate rate of rotation of the disc is the ratio of the rate of chemical change during that moderate rotation to the rate of chemical change under continuous illumination. Experiment therefore supplies us with the information that A has a certain known value when the disc is made to rotate at a known rate measured in seconds, or, in other words, when the equal intervals of illumination have a known value in seconds. It is also possible to calculate what rate of rotation of the disc measured in terms of the new unit of time (*i.e.*, the mean life of a molecule of the catalyst) would result in the same mean value of A. Accordingly, experiment furnishes the value of a rate in seconds, and calculation gives the value of the same rate in mean lives. The numerical ratio of the two values is clearly the value of a mean life in seconds.

The calculation of the rate of rotation of the disc (in mean-life units) which would result in a specified mean value of A is performed in the following way. For the purpose of the calculation it is more convenient to write the differential equation (1.2), which gives the rate of increase of A in the light, in the form $dA/d\tau = I - c_1^2A^2 - c_2A$, in which τ is written for t to indicate that the measurements of time are to be made with a unit equal to the mean life of the catalyst when the intensity of the light is unity, and c_1 and c_2 are constants. When I is taken as unity the solution of the equation is

$$\log_e \frac{\{1+(c_2/2c_1)^2\}^{\frac{1}{2}}+\{x+c_2/2c_1\}}{\{1+(c_2/2c_1)^2\}^{\frac{1}{2}}-\{x+c_2/2c_1\}} = 2c_1\{1+(c_2/2c_1)^2\}^{\frac{1}{2}}\tau + C_1 \quad . \quad (2)$$

where x is substituted for c_1A, and C_1 is the integration constant.

The same symbols being used, the differential equation for the decrease of A in the dark is $dA/d\tau = -c_1{}^2A^2 - c_2A$, of which the solution is

$$\log_e\left\{\frac{x + c_2/c_1}{x}\right\} = c_2\tau + C_2 \quad . \quad . \quad . \quad . \quad (3)$$

where C_2 is the integration constant.

For brevity, (2) is written as $f(x) = \tau$, and (3) as $F(x) = \tau$. If x_1 and x_2 are the values of x at the beginning and end of a period of illumination, and x_2 and x_3 the values of x at the beginning and end of a period of darkness, and τ_1, τ_2, τ_3, and τ_4 the corresponding values of τ

$$\frac{f(x_1) - f(x_2)}{F(x_2) - F(x_3)} = \frac{\tau_2 - \tau_1}{\tau_4 - \tau_3} = \beta$$ (a known constant when the rate of rotation is uniform).

But in the steady state, which is very rapidly approached, x_3 must be equal to x_1 since the increase in x during a period of illumination must then equal its decrease during a period of darkness, and therefore the above equation reduces to

$$f(x_1) + \beta F(x_1) = f(x_2) + \beta F(x_2) \quad . \quad . \quad . \quad . \quad (4)$$

It is easy to show that if any one of the infinite number of possible values of x_2 is introduced into this equation, the resulting equation for x_1 is satisfied by two real values, one of which is, of course, x_2. In other words, for every value of x_2 there is a corresponding value of x_1. Moreover, when x_1 and x_2 are known, the corresponding mean value of x, and also the length of a period of illumination in terms of a mean life of a molecule of the catalyst, can be computed with the aid of equations (2) and (3). By trial, a value of x_2 must be found which gives a mean value of x equal to the experimentally determined value of that constant. Then by a comparison of the calculated period of illumination in mean-life units with the period of illumination expressed in seconds, and deduced from the known rate of rotation of the disc, the mean life in seconds can be calculated.

It is obvious that the required result can also be obtained by graphical methods.

The actual experimental results are tabulated below. In column A the number of the determination is recorded; in B the rates of rotation of the disc in two comparative experiments; in C the ratio of the time of illumination to the sum of the periods of illumination and darkness; in D the times (in minutes) required to effect the same amount of chemical change in two comparative experiments; in E the ratio of these times; and in F and H the respective values of the constants k_1 and k_2.

			314 217·5	1·444		
			mean =	1·476		

For the calculation of the mean life of the catalyst the results of the determinations V and VIII were employed, the necessary figures being the mean ratios in column E, namely 1·9126 and 1·476 respectively. The mean life of the catalyst was estimated to be

0·063 second.

Under less intense illumination the mean life would be longer.

It will have been observed that certain approximations, which will affect to some extent the accuracy of the result, have been made.

Conclusion.

If the photochemical interaction of hydrogen and bromine is due to the presence of a catalyst (atoms or activated molecules), the catalyst is capable of existing for an appreciable fraction of a second.

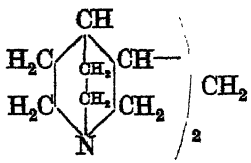
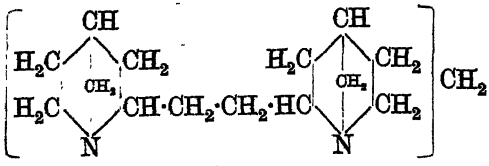
CCXXXII.—*The Lupin Alkaloids. Part I.*



By GEORGE ROGER CLEMO and GRACE CUMMING LEITCH.

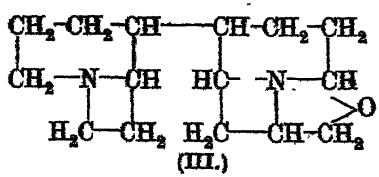
THIS group of alkaloids includes lupinine, $C_{10}H_{19}ON$, sparteine, $C_{15}H_{26}N_2$, lupanine, $C_{15}H_{24}ON_2$, and hydroxylupanine, all of which have been isolated from one or other of the different varieties of lupin seeds. Although numerous chemists have worked on these alkaloids, the present real knowledge of their structures is very scanty indeed. For instance, in spite of the fact that bridged piperidine ring systems have been postulated for these compounds, it appears that there is not a single recorded case of a monocyclic pyridine or piperidine derivative having been definitely obtained from any of them.



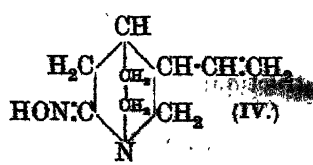
Lupinine, present in *Lupinus luteus*, was examined by Willstätter and Fourneau (*Ber.*, 1902, **35**, 1914), who concluded that it contained a primary alcoholic side chain, together with a tertiary nitrogen atom probably common to two rings as in quinuclidine. Recently, Kalle & Co. (D.R.-PP. 386,936 and 396,508) have described the production of chlorolupinine and lupinan, $C_{10}H_{19}N$; but the structural question appears to be still as left by Willstätter in 1902.

The chief workers on sparteine have been Mourèu and Valeur, who advanced the β-diquinuclidylmethane formula (I) for this alkaloid (*Compt. rend.*, 1905, **141**, 117). Germain (*Gazzetta*, 1912, **42**, i, 447) oxidised sparteine with permanganate in phosphoric acid solution,

and, obtaining some succinic acid, felt justified in advancing formula (II) for the alkaloid.



(I.)



(II.)

Lupanine occurs in the dextro- and the inactive form in *L. albus* and in the dextro-form in *L. angustifolius*, and the inactive modification can be easily isolated in a pure condition from *L. termis*, which appears to be native to North Africa and Syria. The authors are greatly indebted to Dr. R. G. A. Heathcote, of the Royal School of Medicine, Cairo, for securing the necessary seed and extracting the first batch of *i*-lupanine used in this investigation. The early workers on lupanine include Schmidt (*Arch. Pharm.*, 1897, **235**, 192), who advanced the empirical formula $C_{15}H_{24}ON_2$, and Davis (*ibid.*, p. 199), who proved the absence of a reactive carbonyl or hydroxyl group. Many chemists, including Siebert (*ibid.*, 1891, **229**, 544), Callsen (*ibid.*, 1899, **237**, 577), Soldaini (*Gazzetta*, 1903, **33**, 1428), and Beckel (*Arch. Pharm.*, 1912, **250**, 691), have studied the oxidation of the alkaloid, but except oxalic acid, no oxidation product appears to have been isolated in quantity sufficient for its characterisation. Beckel (*Arch. Pharm.*, 1911, **249**, 329) concluded from titration experiments that lupanine is a monoacidic base (see p. 1813). Molander (*Ber. Deut. Pharm. Ges.*, 1921, **31**, 265) subjected the alkaloid to drastic treatment with fuming hydrochloric acid at 210°, to fusion with caustic potash, etc., but in all cases the lupanine was recovered almost wholly unchanged. Thoms and Bergerhoff (*Arch. Pharm.*, 1925, **263**, 1) state that lupanine is recovered when its methylammonium hydroxide is distilled in a vacuum, but that when the alkaloid is distilled with zinc dust a small proportion is changed to give, together with other products, what they describe, mainly from its odour and boiling point, as α-ethylpyridine. On these grounds, they advanced the tentative formula (III) for the alkaloid.

(III.)

(IV.)

The only definitely established facts, however, are that lupanine possesses a very stable, fully saturated ring system with one reactive

tertiary nitrogen atom, and no reactive carbonyl, hydroxyl, or methoxyl groups.

It has now been found that lupanine forms a crystalline *dihydrochloride*. The basic nature of both nitrogen atoms is thus proved, but the result does not exclude the presence of a lactam group >N·CO–, for α-quinuclidones, if they were known, might be expected to be basic from the fact that α-oximino-β-vinylquinuclidine (IV) forms a methiodide (*Ber.*, 1908, **41**, 68). The presence of such a group, whilst explaining why lupanine is very much more soluble in water than deoxylupanine (see p. 1819) or sparteine, is yet difficult to reconcile with its ready solubility in ether and ligroin, with its great stability to acids and alkalis, and with the fact that it cannot be reduced electrolytically. The alternative is that lupanine has an ethereal oxygen atom. Notwithstanding its dibasic character the alkaloid yields only a *monomethiodide* and a *monomethosulphate*, in this respect resembling sparteine. Lupanine methiodide is a stable compound, crystallising unchanged after refluxing with methyl-alcoholic potash, and its quaternary ammonium hydroxide when vacuum-distilled gives lupanine and methyl alcohol. Again, when the methiodide is heated in a vacuum with caustic soda, lupanine is largely regained; but if a mixture of caustic potash and caustic soda is used, the distillate contains, in addition to some lupanine, two methyl-lupanines and a small proportion of simpler bases; and if caustic potash alone is used, the bulk of the distillate consists of simpler bases.

From what follows, it seems probable that the lupanine oxygen atom is in that part of the molecule containing the reactive tertiary nitrogen atom involved in these changes, and if the latter is in a quinuclidine system linked in either the α- or the β-position to the rest of the molecule (see I), more than two methyl-lupanines might be expected to result by the elimination of hydrogen iodide from lupanine methiodide. So far, however, only two methyl-lupanines have been obtained, one of which, *α-methyl-lupanine*, is, remarkably enough, a water-insoluble solid; the *β-compound*, apparently an oil, is easily soluble in water and has only been obtained pure in the form of its crystalline *methiodide*. The α-compound forms a *monohydrochloride* and a *monomethiodide*, and α-methyl-lupanine methylammonium hydroxide, when distilled in a vacuum, is largely converted into an isomeric oil, soluble both in water and in ether (*i.e.*, apparently $\left.\begin{matrix}-CH_2\\ \\ -NMe_2\cdot OH\end{matrix}\right\rangle \longrightarrow \left.\begin{matrix}-CH_2\cdot OH\\ \\ -NMe_2\end{matrix}\right)$, which has not yet been satisfactorily converted into a crystalline methiodide. In addition, a small proportion of α-methyl-lupanine is recovered from the distillate.

When lupanine methiodide is heated in a metal bath with caustic potash, the bulk of the distillate boils below 145°/1 mm. (b. p. of lupanine, 190°/1 mm.) and contains a mixture of bases, three of which have given crystalline derivatives: *e.g.*, a small fraction, b. p. 88—92°/1 mm. (approx.), gives mainly a *picrate* (m. p. 130°) together with a small amount of a second *picrate* which decomposes at 225°, and the fraction, b. p. 127—132°/1 mm., gives a crystalline *picrate* and a *dimethiodide*. Analytical results point to the empirical formula $C_{13}H_{22}N_2$ for the latter *base*, but the question of determining the structure of these degradation products, which are probably derivatives of quinuclidine, is rendered difficult by the fact that the literature contains few references to such compounds, and some of these, as, for instance, the observation by Koenigs (*Ber.*, 1904, **37**, 3250) that the β-ethylquinuclidine methiodide melts between 55—85°, are not very helpful for characterisation purposes. Accordingly, the detailed examination of these bases may have to be supplemented by synthetic work before their structures can be settled.

The possibility that lupanine may be an oxygen derivative of sparteine caused attention to be directed to the action of reducing agents on the base. Prolonged heating at 220° in sealed tubes with fuming hydriodic acid and red phosphorus gave *deoxylupanine*, $C_{15}H_{26}N_2$, but 25% of the lupanine was recovered unchanged. Deoxylupanine is an oil which forms a *monomethiodide* and is sparingly soluble in cold water. The question of its structural relationship to sparteine, which occurs naturally in the lævo-form, is complicated by the fact that it has not been possible to racemise the latter or resolve the former. That no ring change occurs in the preparation of deoxylupanine seems certain from the fact that sparteine can be recovered unchanged after a similar treatment. This fact indicates the presence of the quinuclidine ring system, as β-ethylquinuclidine is stable to hydriodic acid, which decomposes, for example, pyridine and coniine. Deoxylupanine and sparteine, however, differ in some respects in their chemical properties, which points to some structural dissimilarity. For instance, deoxylupanine is much more stable to air than sparteine, and it gives crystalline *mono-* and *di-picrates*, whereas sparteine only forms a crystalline dipicrate. When hydrogen sulphide is passed into an ethereal solution of deoxylupanine containing sulphur in suspension, an orange precipitate results in contrast with the dull red one given by sparteine. Both bases, however, can be readily oxidised to give *iso*lupanine and oxysparteine, respectively. Isolupanine resembles lupanine in being very easily soluble in water to give an alkaline solution, and also in organic solvents. It shows no evidence of the

presence of a reactive carbonyl group, and forms only a *monomethiodide*. Neither lupanine, *iso*lupanine, nor oxysparteine gives a precipitate in the hydrogen sulphide test.

Although, as stated, numerous chemists have unsuccessfully studied the oxidation of lupanine, it has now been found that it can be easily oxidised by permanganate in acetone solution to give *oxylupanine*, $C_{15}H_{22}O_2N_2$. Curiously enough, the action always ends when five atomic proportions of oxygen have been used up, and in addition to oxylupanine a very small amount of another oxidation product and some oxalic acid are also formed. Oxylupanine is a deliquescent compound giving an aqueous solution which is neutral to litmus. It has no reactive carbonyl, methylene, or hydroxyl group, as judged by its non-reactivity with phenylhydrazine, piperonal, and benzoyl chloride, and contains no reactive tertiary nitrogen atom. It seems certain, however, that *iso*lupanine, oxylupanine, and oxysparteine are formed by the conversion of methylene into carbonyl groups. As these are all non-reactive, the case for the presence of a carbonyl group in lupanine is strengthened. These facts can be explained if the reactive tertiary nitrogen atom of lupanine is in a quinuclidine ring, which can form at least two isomeric α-quinuclidones, whose lactam carbonyl groups might be expected to be non-reactive. On this basis, oxylupanine might be the αα′-diketo-compound with the nitrogen no longer basic. Against this inference, however, must be put the fact that no oxidation results similar to the above have been observed with the quinine alkaloids, and further the lupin alkaloids differ completely in physiological action from the latter. Again, it is unlikely that α-quinuclidones would be stable to both alkalis and acids, judging from the fact that α-oximino-β-vinylquinuclidine (IV) is hydrolysed by dilute acids, presumably *via* the α-quinuclidone, to meroquinine.

It is hoped to describe the extension of the work along the aforementioned and cognate lines, and its further bearing on the structural problem presented by these alkaloids, in a future communication.

Experimental.

l-Lupanine.—Crude lupanine sulphate* (80 g.) was dissolved in water (60 c.c.) and made alkaline with caustic potash (160 c.c.; *d* 1·25), and the liberated base was extracted with chloroform and fractionated; 41·5 g. of a colourless viscid oil passed over at 185—195°/1 mm. and 2 g. at 195—220°/1 mm. The main fraction quickly crystallised (softened at 85°; m. p. 95°), and after recrystallising from acetone (24 c.c.) gave colourless, prismatic plates (30 g.),

* The authors are much indebted to Messrs T. and H. Smith, Ltd., of Edinburgh for carrying out the extraction of the seed on a large scale.

m. p. 98—99° (Found: C, 72·7; H, 9·8; N, 11·4. Calc. for $C_{15}H_{24}ON_2$: C, 72·6; H, 9·7; N, 11·3%). *i*-Lupanine is very easily soluble in cold water, giving a strongly alkaline solution, and in the usual organic solvents.

Lupanine Mono- and Di-hydrochlorides.—The precipitate obtained by passing hydrogen chloride into a solution of lupanine (1 g.) in dry ether (20 c.c.) was collected and dissolved in absolute alcohol (10 c.c.). On dilution with ether (15 c.c.), stout colourless prisms separated, m. p. 185° (decomp.) (Found: C, 55·7; H, 7·9; Cl, 21·6. $C_{15}H_{24}ON_2,2HCl$ requires C, 56·1; H, 8·1; Cl, 22·1%). The *dihydrochloride* is deliquescent, its aqueous solution being acid to litmus. When it is heated under 1 mm. pressure, decomposition occurs and a sublimate of the very deliquescent crystalline monohydrochloride is formed (Found: Cl, 12·0. Calc. for $C_{15}H_{24}ON_2,HCl$: Cl, 12·4%).

Lupanine Monomethiodide.—When lupanine (as obtained direct by distillation; 41·5 g.), dissolved in acetone (50 c.c.), was mixed with methyl iodide (20 c.c.), the *methiodide* began to separate almost at once. The mixture was refluxed gently over-night, the crystalline precipitate collected and ground with a small volume of alcohol, and the product (62 g.; decomp. 246—250°) recrystallised from absolute alcohol, giving stout prisms (51·5 g.), m. p. 258—260° (decomp.), raised to 262—263° by a further crystallisation from alcohol (Found: C, 49·8; H, 7·1; I, 33·0. $C_{15}H_{24}ON_2,MeI$ requires C, 49·2; H, 6·9; I, 32·6%). The methiodide is very soluble in water and sparingly soluble in absolute alcohol.

Lupanine Monomethosulphate.—Methyl sulphate (1·3 g.) was added to lupanine (2·5 g.) in acetone (5 c.c.), and the solution refluxed over-night. The resulting deliquescent prisms (2·7 g.), m. p. 188°, decomp. 275°, were recrystallised from alcohol (3 c.c.) by dilution with acetone (10 c.c.); m. p. 196° (Found: C, 54·6; H, 8·0. $C_{17}H_{30}O_5N_2S$ requires C, 54·5; H, 8·0%).

Action of Alkalis on Lupanine Methiodide.—(a) α- and β-Methyllupanines. The powdered methiodide (2 g.), mixed with caustic potash (1·5 g.) and caustic soda (1·5 g.), was carefully heated under 1 mm. pressure with a free flame, an absorbent charcoal trap being placed between the receiver and the pump. Five such experiments, after the recovery of a small quantity from the trap, gave 5·7 g. of distillate, which set to a buttery mass and on fractionation gave 0·2 g., b. p. up to 145°/1 mm., 1·4 g., b. p. 145—180°/1 mm., and 3·9 g., b. p. 180—190°/1 mm. The last fraction while still an oil was stirred with cold water (25 c.c.), and the resulting colourless solid was collected—filtrate X—washed with a little water, dried on the water-bath, and crystallised (1·5 g.) from a small volume of ligroin (b. p.

60—80°); well-defined, colourless prisms then separated, m. p. 123° (Found: C, 73·7, 73·2; H, 9·7, 9·9; N, 10·2; OMe, 0; *M*, cryoscopic in benzene, 274. $C_{16}H_{26}ON_2$ requires C, 73·3; H, 9·9; N, 10·7%; *M*, 262). *α-Methyl-lupanine* is readily soluble in the usual organic solvents, but insoluble in water, and its cold acetone solution rapidly decolorises potassium permanganate. From a solution of the base in ether, hydrogen chloride precipitates the *monohydrochloride*, which crystallises from alcohol–ether in flat prisms, m. p. 209° (decomp.) (Found: Cl, 11·2. $C_{16}H_{26}ON_2$,HCl requires Cl, 11·9%).

α-Methyl-lupanine methiodide. The base (3·3 g.) was heated overnight in a sealed tube in the water-bath with methyl alcohol (4 c.c.) and methyl iodide (4 c.c.); the crystalline deposit (4·3 g.), when recrystallised from alcohol, formed stout colourless prisms, m. p. 258° (decomp.) (Found: C, 51·0; H, 7·3; N, 6·9; I, 31·4. $C_{16}H_{26}ON_2$,MeI requires C, 50·5; H, 7·2; N, 6·9; I, 31·4%). The compound was very soluble in cold water, and when distilled with caustic potash in a vacuum gave a mixture of bases apparently similar to those described under (b) below. When, however, the methyl-lupanine methylammonium hydroxide from this methiodide (4·3 g.) was distilled in a vacuum, 2·8 g. of a colourless viscid oil passed over at 190—215°/1 mm., from which 0·3 g. of α-methyl-lupanine was recovered by stirring with water. On fractionating the aqueous filtrate, 2·2 g. of oil passed over at 210—215°/1 mm. (Found: C, 69·9; H, 10·4. $C_{17}H_{30}O_2N_2$ requires C, 69·4; H, 10·2%); this *base* was readily soluble in water and in ether.

The aqueous filtrate X on fractionation gave 2·1 g., b. p. 180—195°/1 mm. This was combined with similar material to give 11 g., and then fractionated into equal first and last fractions. The former slowly set to a buttery mass of lupanine. The latter also deposited a small amount of this base, which was filtered off and the filtrate was refractionated, giving 0·8 g., b. p. up to 188°/1 mm., 2·2 g., b. p. 188°/1 mm., and 1 g., b. p. 188—190°/1 mm. The middle and last fractions were treated in acetone with methyl iodide over-night and the crystalline deposit was then collected and dissolved in absolute alcohol. On cooling, some finely divided, crystalline lupanine methiodide quickly separated. This was removed, and large compact prisms separated from the filtrate over-night. These, after recrystallisation from alcohol, had m. p. 272° (decomp). alone and m. p. below 250° (decomp.) when mixed with lupanine methiodide (Found: C, 51·9; H, 7·2; N, 6·6; I, 31·7. $C_{16}H_{26}ON_2$,MeI requires C, 50·5; H, 7·2; N, 6·9; I, 31·4%). *β-Methyl-lupanine methiodide* is very soluble in water, and more soluble in alcohol than lupanine methiodide.

(b) *The base* $C_{13}H_{22}N_2$. Lupanine methiodide (2 g.), well mixed with caustic potash (3 g.) and heated under 1 mm. pressure at 260°, decomposed, giving a solid mass. The heating at 260° was continued for 15 minutes and the temperature of the bath was then raised to 300°; an oil distilled during the next 5 to 10 minutes. The combined distillates from twelve such experiments (11 g.) were divided into the following fractions: (i) 1·2 g., b. p. 85—112°/1 mm.; (ii) 7·5 g., b. p. 112—132°/1 mm.; (iii) 0·6 g., b. p. 132—150°/1 mm.; (iv) 1·7 g., b. p. up to 170°/1 mm.

When fraction (i) was redistilled, half of it passed over at 88—92°/1 mm. (Found: C, 79·4; H, 10·5; N, 10·8%). This oily *base* was slightly soluble in cold water, giving an alkaline solution, and its cold acetone solution slowly decolorised potassium permanganate. The base (0·5 g.) was boiled with picric acid (0·9 g.) in alcohol (20 c.c.) for 1 minute; the solution was then cooled and decanted from 0·1 g. of a *product* which crystallised from acetic acid in yellow prisms, decomp. 225° after darkening at 215°. The decanted alcoholic solution was partly evaporated, and ether added; lemon-yellow plates then separated, m. p. 130—131° (Found: C, 52·7, 53·0; H, 5·0, 5·2. $C_{13}H_{20}O_7N_4$ requires C, 53·4; H, 4·9%. $C_{17}H_{18}O_7N_4$ requires C, 52·3; H, 4·6%).

When fraction (ii) was redistilled, a large proportion passed over at 127—132°/1 mm.; the portion, b. p. 130°/1 mm., was analysed (Found: C, 76·5; H, 10·4; N, 13·4. $C_{13}H_{22}N_2$ requires C, 75·7; H, 10·7; N, 13·6%). The oil is sparingly soluble in water, and its cold acetone solution decolorises potassium permanganate.

Picrate of the base $C_{13}H_{22}N_2$. An alcoholic solution of the fraction, b. p. 127—132°/1 mm. (1 g.) and picric acid (1·25 g.) was boiled for 1 minute, cooled, and decanted from a small quantity of gum; the *picrate* (1·4 g.) slowly separated in yellow prisms, and melted at 137° after recrystallisation from alcohol (Found: C, 52·3, 52·5; H, 5·8, 6·1. $C_{13}H_{22}N_2,C_6H_3O_7N_3$ requires C, 52·4; H, 5·8%).

Dimethiodide of the base $C_{13}H_{22}N_2$. When the fraction, b. p. 127—132°/1 mm. (1 g.), acetone (3 c.c.), and methyl iodide (1 c.c.) were mixed together, much heat was evolved and a solid separated. After 12 hours, the crystals that had formed were collected, and recrystallised from a solution in alcohol by dilution with acetone, giving almost colourless, compact prisms, m. p. 202°, decomp. 280° (Found: C, 37·3; H, 5·2. $C_{13}H_{22}N_2,2MeI$ requires C, 36·9; H, 5·7%).

Decahydrolupanine.—Four sealed glass tubes, each containing lupanine (1·25 g.), hydriodic acid (5 c.c.; *d* 2), and red phosphorus (1·25 g.), were heated for 36 hours at 220°, much pressure being developed. The viscid product was heated at 150° under diminished pressure to

remove the excess of hydriodic acid, the residue treated with caustic potash solution (100 c.c.; *d* 1·25), and the liberated oil extracted with chloroform and fractionated; 1·7 g. passed over at 140—170°/1 mm., followed at 170—190° by 0·8 g. which set to a soft crystalline mass of lupanine. The first fraction was seeded with lupanine and left for some days in an ice-chest, the separated lupanine was filtered off, and the filtrate fractionated; the bulk passed over at 145°/1 mm., leaving a small residue of lupanine (Found: C, 77·4; H, 11·2; N, 11·6. $C_{15}H_{26}N_2$ requires C, 76·9; H, 11·1; N, 11·9%). *Deoxylupanine* is sparingly soluble in water, giving an alkaline solution. A deliquescent *dihydrochloride* is formed when hydrogen chloride is passed into an ethereal solution of the base and can be crystallised by slowly diluting its cold alcoholic solution with ether (Found: Cl, 23·0. $C_{15}H_{26}N_2,2HCl$ requires Cl, 23·1%).

Mono- and di-picrates of deoxylupanine. When ethereal solutions containing equal weights of the base and picric acid were mixed, a yellow precipitate of the *monopicrate* was formed, which crystallised from alcohol in well-formed, yellow, hexagonal prisms, m. p. 135° (Found: C, 54·9; H, 6·3. $C_{15}H_{26}N_2,C_6H_3O_7N_3$ requires C, 54·4; H, 6·3%).

The precipitate of the *dipicrate* formed when alcoholic solutions of deoxylupanine (0·25 g.) and picric acid (0·5 g.) were mixed crystallised from alcohol in lemon-yellow needles, m. p. 206—207° (Found: C, 46·7; H, 5·1. $C_{15}H_{26}N_2,2C_6H_3O_7N_3$ requires C, 46·8; H, 4·6%). A mixture with sparteine dipicrate (m. p. 208°) melted at 198—200°.

Deoxylupanine methiodide. The base (1·3 g.) was added to acetone (2 c.c.) and methyl iodide (1 c.c.); after 12 hours, 1·8 g. of the *methiodide* had separated, which crystallised from acetone in colourless plates, m. p. 226° (Found: C, 51·5; H, 7·9. $C_{15}H_{26}N_2,MeI$ requires C, 51·1; H, 7·7%).

iso*Lupanine*.—Deoxylupanine (1·2 g.) on oxidation * gave 0·9 g. of a distillate which crystallised; on recrystallisation from ligroin (b. p. 40—60°) colourless plates, m. p. 113°, were obtained (Found: C, 72·6; H, 9·7. $C_{15}H_{24}ON_2$ requires C, 72·6; H, 9·7%). Mixed with lupanine, the substance melted at 78—80°. When heated in a sealed tube with methyl alcohol and methyl iodide, iso*lupanine* gave a crystalline *monomethiodide*, which separated from alcohol–acetone (1 : 2) in colourless plates, m. p. 208°.

Oxylupanine.—Lupanine (2·5 g.) was dissolved in acetone (30 c.c.), and powdered potassium permanganate (5·3 g.) added during about 4 hours with stirring and cooling in an ice-bath. After being left overnight, the mixture was stirred for ½ hour and filtered, and the sludge extracted with acetone. The solvent was then removed from the

* Details of the method will be published shortly.

filtrate, and the residue* distilled; at about 210°/1 mm., 1·4 g. passed over, which crystallised from acetone in stout colourless prisms, m. p. 123° (Found: C, 69·1; H, 8·3; N, 10·5; *M*, cryoscopic in benzene, 266, 275. $C_{15}H_{22}O_2N_2$ requires C, 68·7; H, 8·4; N, 10·7%; *M*, 262). *Oxylupanine* forms a *chloroplatinate* which crystallises from alcohol in brown prisms, m. p. 232° (decomp.). By means of this salt the value 266 was obtained for the molecular weight of oxylupanine. After being refluxed in alcoholic or acetic acid solution with phenylhydrazine for 24 hours, or in ethereal solution containing benzoyl chloride with sodium bicarbonate in suspension, oxylupanine was recovered unchanged. It could not be condensed with piperonal, and it was also recovered after being heated in acetic acid solution, saturated with hydrogen chloride, for 24 hours at 240°.

One of us (G. R. C.) wishes to thank the Royal Society for grants towards the cost of the seed and of the extraction of the lupanine used in this investigation.

CCXXXIII.—*Neodymium Selenate.*

By JOHN ALBERT NEWTON FRIEND and ALBERT ARTHUR ROUND.

ALTHOUGH selenates of lanthanum (Atomic No. 57), cerium (58), praseodymium (59) and samarium (62) have been described, *neodymium* (60) *selenate* does not appear to have been prepared hitherto. In the course of a search for the "missing" element, No. 61, some fairly pure neodymium magnesium nitrate was prepared by repeated fractionation from certain rare-earth residues. From this the oxalate was precipitated, ignited to oxide, and used in the preparation of the salts described below.

That the oxide thus obtained contained only traces of impurity was proved in several ways. (1) The visible absorption spectrum of a *N*/16-solution of the chloride prepared from the oxide showed close agreement with Rech's data (*Z. wiss. Photochem.*, 1905, 3, 411). (2) An *X*-ray analysis was made by Messrs. Adam Hilger with a sample of the oxide on a copper target of a Shearer *X*-ray tube, using a Müller *X*-ray spectrograph with calcite crystal. The presence of traces of praseodymium, samarium, and gadolinium was ascertained. Traces of terbium were also present, as shown by the brown tint of

* A trace of a higher oxidation product separates if this residue is redissolved in a small volume of acetone.

the ignited oxide. (3) Chemical analysis was effected by converting a weighed quantity of oxide into sulphate, and pouring the solution into an excess of oxalic acid solution. After 24 hours, the precipitated oxalate was collected on an asbestos filter and estimated by titration with permanganate. This method, which was used by Gooch and Kobayashi (*Amer. J. Sci.*, 1918, **45**, 227) for thorium, appeared to work well with neodymium, the equivalent weight of which was found to be 48·17, 48·30; mean, 48·24, the accepted value for 1925 being 144·27 ÷ 3 or 48·09.

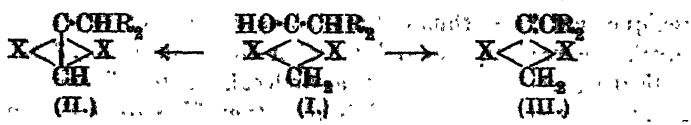
Neodymium Selenate Pentahydrate, $Nd_2(SeO_4)_3,5H_2O$.—Neodymia readily dissolves in aqueous selenic acid. A slight excess was added to the warm acid and, after filtration, the solution was concentrated on the water-bath until a good crop of pink crystals separated from the hot mother-liquor. These were dried between filter-paper and stored over sulphuric acid. Some of the dried salt was heated in a current of dry air, the evolved water being collected in a calcium chloride drying tube. If the heating was gentle, the loss in weight of the salt exactly equalled the gain of the drying tube, indicating that no reduction to selenite or change other than dehydration had taken place; but it was difficult to ensure complete desiccation without slight decomposition of the anhydrous salt [Found: H_2O, 11·47, 11·24; mean, 11·36. $Nd_2(SeO_4)_3,5H_2O$ requires H_2O, 11·15%]. Upon exposure to moist air the dry salt absorbed moisture.

Octahydrate, $Nd_2(SeO_4)_3,8H_2O$.—A solution of neodymium selenate saturated at about 15° was poured into excess of alcohol, whereupon a pink, viscous liquid separated. On agitation with a glass rod the liquid rapidly crystallised to a pink solid, which was coarsely crushed beneath the alcohol, drained, and washed with ether. After drying between filter-paper, the amount of combined water was determined as before [Found: H_2O, 17·19, 17·39, 17·26; mean, 17·28. $Nd_2(SeO_4)_3,8H_2O$ requires H_2O, 16·72. $Nd_2(SeO_4)_3,9H_2O$ requires H_2O, 18·42%]. This hydrate is also formed by prolonged exposure of the saturated solution over concentrated sulphuric acid.

Dodecahydrate, $Nd_2(SeO_4)_3,12H_2O$.—The previous salts readily absorbed moisture in a saturated atmosphere. When the semi-deliquescent mass thus obtained was dried over sulphuric acid, a break occurred in the dehydration–time curve at 23·37% H_2O, indicating the existence of a dodecahydrate (Theory: $12H_2O$, 23·14; $13H_2O$, 24·59%). This *hydrate* appears to be the one which first separates when a saturated solution is evaporated at room temperature over concentrated sulphuric acid. It rapidly loses water at the ordinary temperature, and prolonged exposure over concentrated sulphuric acid yields the octahydrate. When freed

from adherent saturated solution by pressure between filter-paper, a sample had a water content of 22·2%. This was low for a dodecahydrate, as expected, but higher than the 21·6% required for an undecahydrate.

Neodymium Selenate, $Nd_2(SeO_4)_3$.—The pink *anhydrous* salt is readily obtained by gently heating any of the hydrates in a current of dry air, or at 170—180° for a more prolonged period [Found: Nd_2O_3, 47·29, 45·49; mean, 46·39. $Nd_2(SeO_4)_3$ requires Nd_2O_3, 46·86%]. Although the mean result is in fair agreement with theory, the individual results do not agree as well as one could desire. Probably the second specimen had been imperfectly dehydrated, and the first may have been slightly overheated (see above).



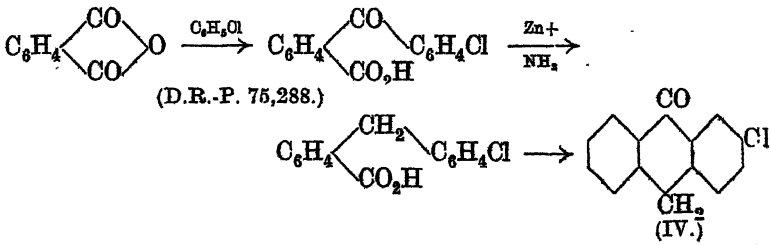
Selenates of all the elements of the cerium sub-group, save No. 61, are now therefore known. The neodymium salt is intermediate in hydrate formation between the praseodymium and samarium salts. For example, the former yields a penta- and an octa-hydrate (Scheele, *Z. anorg. Chem.*, 1898, **17**, 310), the latter yields an octa- and a dodeca-hydrate (Cleve, *Bull. Soc. chim.*, 1874, **21**, 196), and neodymium yields all three. A thorough study of the selenates of this group is in progress with a view to their possible use in the separation of rare-earth mixtures by fractional crystallisation.

THE TECHNICAL COLLEGE, BIRMINGHAM. [*Received, May 23rd*, 1928.]

CCXXXIV.—*The Synthesis of* meso-*Alkyl and* meso-*Aryl Anthracene Derivatives. Part IV.*

By EDWARD DE BARRY BARNETT and JOHN LAURENCE WILTSHIRE.

THE normal product of the action of a Grignard solution on an anthrone is the alkyl or aryl dihydroanthranol (I), from which the alkyl or aryl anthracene (II) or the alkylidene dihydroanthracene (III) is obtained by loss of water (for references, see Part II, J., 1927, 1725):



(X = C_6H_4 or substituted C_6H_4; R = alkyl, aryl or hydrogen.) The reaction, however, is profoundly affected by the presence of chlorine atoms in *o*-positions, and when these are present the synthesis either completely breaks down or gives only exceedingly

poor yields except in the cases of magnesium methyl iodide, magnesium phenyl bromide, and magnesium benzyl chloride.

It has now been found that a somewhat similar influence is exerted by a chlorine atom in a β-position, since with 2-chloro-9-anthrone (IV) satisfactory yields of the alkyl anthracene were obtained only with magnesium ethyl bromide and magnesium benzyl chloride, the other magnesium alkyl halides giving extremely poor results. The excellent yield obtained with magnesium ethyl bromide as compared with the very poor yield obtained with magnesium methyl iodide or bromide is interesting, as it is the reverse of what is the case with 1 : 5-dichloroanthrone (Barnett, Cook, and Matthews, *Ber.*, 1926, **59**, 2863).

The 2-chloro-9-anthrone employed in the above experiments was prepared according to the scheme :

It differed from the β-chloroanthrone previously isolated from the reduction of 2-chloroanthraquinone (Barnett and Matthews, *J.*, 1923, **123**, 2554), so the latter must be 3-chloro-9-anthrone.

2-Chloro-9-anthrone (apparently in an impure state) has been described by Meyer and Fischbach (*Ber.*, 1925, **58**, 1251), who obtained it by condensing ω-bromo-*o*-toluoyl bromide with benzene, and oriented it by converting it into a benzanthrone derivative.

Experimental.

4-*Chlorodiphenylmethane*-2'-*carboxylic Acid*.—4-Chloro-*o*-benzoylbenzoic acid (50 g.) was dissolved in 300 c.c. of ammonia (*d* 0·880) and 150 c.c. of water, 150 g. of zinc dust were added slowly, and finally a few c.c. of copper sulphate solution. Reduction was effected on the water-bath and was complete in about 20 hours. The product was isolated in the usual way and after recrystallisation from alcohol melted at 132° (Found : Cl, 14·1. $C_{14}H_{11}O_2Cl$ requires Cl, 14·4%).

2-*Chloro*-9-*anthrone* (IV).—The above carboxylic acid was added slowly with cooling to concentrated sulphuric acid (3 c.c. per g.) and after it had dissolved the solution was kept at the ordinary temperature for an hour and then poured on ice. The resulting

anthrone after recrystallisation from alcohol melted constantly at 155° and depressed the melting point of the β-chloroanthrone previously described (Barnett and Matthews, *loc. cit.*).

2-Chloro-9-anthranyl acetate was obtained from the above anthrone by the usual acetic anhydride–pyridine method (Barnett and Matthews, J., 1923, **123**, 389). After recrystallisation from alcohol it melted at 143° (Found: Cl, 13·2. $C_{16}H_{11}O_2Cl$ requires Cl, 13·1%).

3-Chloro-9-anthranyl acetate was similarly prepared from 3-chloro-9-anthrone. After recrystallisation from alcohol it melted at 146° and depressed the melting point of the above 2-chloro-9-anthranyl acetate (Found: Cl, 13·3%).

Action of Grignard Solutions on 2-Chloro-9-anthrone.—In all cases 7 g. of the finely powdered anthrone were added slowly to the Grignard solution prepared from 2·2 g. of magnesium (3 mols.) and the requisite amount of the halogen compound. After being kept in a freezing mixture for 3 hours, the solution was poured on a mixture of ice and solid ammonium chloride, the washed ethereal layer evaporated to dryness, and the residual oil heated on the water-bath for a short time with acetic acid containing hydrochloric acid. The following compounds were obtained, all of which, unless otherwise stated, were recrystallised from methyl or ethyl alcohol and formed pale yellow needles.

2-Chloro-9-methylanthracene, m. p. 84°. Yield, very small (Found: Cl, 15·8. $C_{15}H_{11}Cl$ requires Cl, 15·7%).

2-Chloro-9-ethylanthracene, m. p. 79°. Yield, excellent (Found: Cl, 15·0. $C_{16}H_{13}Cl$ requires Cl, 14·8%).

2-Chloro-10-bromo-9-ethylanthracene. By the action of bromine (1 mol.) on the above chloroethylanthracene in carbon disulphide solution. Yellow crystals from benzene–light petroleum; m. p. 128° (Found: Cl + Br, 36·1. $C_{16}H_{12}ClBr$ requires Cl + Br, 35·9%).

2-Chloro-9-n-propylanthracene, m. p. 82° (Found: Cl, 14·3. $C_{17}H_{15}Cl$ requires Cl, 13·9%).

2-Chloro-9-benzylanthracene, m. p. 132°. Yield, excellent (Found: Cl, 11·9. $C_{21}H_{15}Cl$ requires Cl, 11·7%).

2-Chloro-10-bromo-9-benzylanthracene. By the action of bromine (1 mol.) on the above chlorobenzylanthracene in carbon disulphide solution. Yellow needles from acetic acid or ethyl acetate; m. p. 167° (Found: Cl + Br, 30·4. $C_{21}H_{14}ClBr$ requires Cl + Br, 30·3%).

When the above chlorobenzylanthracene was kept over-night with excess (3 to 4 mols.) of bromine in carbon disulphide solution a substance was obtained (isolated by the addition of light petroleum) which after recrystallisation from benzene–light petroleum formed a cream-coloured powder; this melted and decomposed violently

at about 150°, was difficult to obtain pure, and appeared to be a *dibromide* of 2-chloro-10-bromo-9-benzylanthracene (Found: Cl + Br, 51·4. $C_{21}H_{14}ClBr_3$ requires Cl + Br, 50·9%).

CCXXXV.—*The Rotatory Dispersion of Derivatives of Tartaric Acid. Part III. Diacetyltartaric Acid and its Esters.*

By PERCY CORLETT AUSTIN.

PREVIOUS work upon diacetyltartaric acid (Austin and Park, J., 1925, **127**, 1926) revealed some anomalies, which could not be properly interpreted at the time. For instance, the lævorotations of a solution of the pure acid in dry acetone were found to be identical with those obtained when the anhydride was mixed in the same solvent with one molecular proportion of water and the mixture had been kept for 16 days until mutarotation was complete; but the presence of increasing amounts of water led to greatly increased lævorotations, a fact which pointed to some further change in structure. Moreover, the values calculated for the velocity coefficients of the hydration of the anhydride indicated that the reaction could be regarded neither as unimolecular nor as bimolecular. Nevertheless, the measurements of rotatory dispersion corresponded well with the values calculated from a simple one-term Drude formula, although the dispersion constant ($\lambda_0^2 = 0{\cdot}0833$) was unusually high. The result was unexpected and the conclusion was drawn that this acid afforded the first instance of simple dispersion in the tartaric acid series which was independent of ring formation.

This conclusion was regarded with some suspicion, however, in view of the fact that Patterson's value of the ratio $\alpha_{4358}/\alpha_{5461}$ for the *iso*butyl ester (J., 1916, **109**, 1170) is less than the theoretical minimum for a simple dispersion, *viz.*, 1·57 (compare Lowry and Austin, *Phil. Trans.*, 1922, *A*, **222**, 249), so that the rotatory dispersion of this ester is obviously complex. This ester was therefore prepared, and purified by repeated distillation under low pressures. Since the liquid could not be induced to crystallise, its rotatory dispersion was measured without a solvent in a 4-dcm. tube, whereby an undoubted maximum was detected about 56 Å.U. beyond the blue mercury line. The lower esters of the acid were then prepared by the action of an excess of acetic anhydride on the corresponding esters of tartaric acid, in the presence of a few drops of concentrated

sulphuric acid. The methyl and *iso*propyl esters were easily crystallised, the ethyl ester somewhat less readily, the *n*-propyl ester only with difficulty, and the *n*-butyl and *iso*butyl esters refused to solidify. Readings were therefore taken of the pure liquid *n*-propyl and the two butyl esters and of solutions in the other cases. The *n*- and *iso*-butyl and -propyl esters gave maxima in the visible region, and a solution of the ethyl ester in acetone showed a reversal of sign in the red; but the rotatory dispersion of a solution in acetone of the methyl ester was so nearly simple in the visible region that there was at first some uncertainty as to whether the dispersion was simple or complex. The readings in acetone could not be prolonged beyond 3720 Å.U., and the ester is not sufficiently soluble to be examined in ether; the deviations from a simple formula become marked, however, in the early photographic region. Finally, the complexity of the free acid was established by using dry ether in place of dry acetone as solvent, whereupon it was found that photographic readings could be prolonged considerably farther into the ultra-violet region. The fact that the values of $[\alpha]$ are considerably lower in ether than in acetone may be due to a partial interaction between the acid and acetone to form a definite compound, which would presumably give simple dispersion.

The equations used in Tables I—VIII show that, whereas the dispersion of the other esters is anomalous, that of the methyl ester and of the acid is *complex but normal*, since $\lambda_1^2 < \lambda_2^2$ when $k_1^2 < k_2^2$ (compare Lowry, J., 1915, **107**, 1195). The dispersion constants λ_1^2 and λ_2^2 are 0·0507 and 0·0691, respectively, for the acid and its methyl ester, and 0·0457 and 0·0507 for the other esters. Although, therefore, the rotatory dispersion of most of the esters is obviously anomalous, the dispersion constants of the two terms of Drude's equation differ by an amount corresponding to a separation of only about 114 Å.U. between the characteristic frequencies at 2138 and 2252 Å.U. of the higher esters, and of 377 Å.U. between the characteristic frequencies at 2252 and 2629 Å.U. of the acid and its methyl ester. Under these conditions, as Lowry and Dickson pointed out (J., 1913, **103**, 1075; compare also Hunter, J., 1924, **125**, 1296), it is exceptionally difficult to distinguish between a simple and a complex dispersion, and this distinction would have been quite impossible if the terms had been of similar sign. The rotatory dispersion of the free acid is, indeed, so nearly simple that the calculation of the curves of complex rotatory dispersion which are developed during the hydrolysis of the anhydride (Austin and Park, *loc. cit.*) still holds good without alteration.

It will be seen that the acetyl derivatives give *two* low-frequency terms, where the corresponding hydroxy-compounds are governed

by one term of low frequency and one term of much higher frequency. The increased lævorotations observed on increasing the proportion of water in the mutarotation experiments of diacetyltartaric anhydride (Austin and Park, *loc. cit.*) may therefore be ascribed, as in the case of tartaric acid itself, to an alteration in the equilibrium between two components of opposite sign. The calculation of the true values of the velocity coefficients during mutarotation would then depend on a detailed knowledge, which is not yet available, of the effect of water upon this equilibrium.

An attempt to prolong the region of investigation in the case of diacetyltartaric anhydride by employing ether as solvent was unsuccessful owing to insufficient solubility. The dispersion constant in this case is, however, only 0·0507, and there is no reason to doubt the simple character of the compound on account of the oxygen bridge between the two acid groups.

EXPERIMENTAL.

Preparation of Diacetyltartaric Acid.—In the earlier work great difficulty was experienced in obtaining crystals of the acid which resulted from the slow mutarotation of the anhydride in acetone to which exactly the calculated quantity of water had been added. It is advantageous to concentrate the acetone solution, after mutarotation, by evaporation in a desiccator to a small bulk and to add the residue to boiling benzene, instead of eliminating the acetone. The solubility is thereby greatly increased and much larger crops of crystals can be obtained.

Preparation of the Esters.—These esters have been prepared previously by Anschütz and Pictet (*Ber.*, 1880, **13**, 1175) and by Freundler (*Ann. Chim. Phys.*, 1894, **3**, 454) by the action of acetyl chloride on the tartaric esters. McCrae and Patterson used acetic anhydride with ethyl tartrate and boiled the mixture (J., 1900, **77**, 1098). I have found that the addition of a trace of concentrated sulphuric acid to a mixture of the tartaric ester with a considerable excess of acetic anhydride is sufficient to catalyse the reaction without boiling, since the mixture rapidly becomes hot (compare Chattaway and Parkes, J., 1923, **123**, 663). After standing in the desiccator, the methyl ester soon crystallised, but the ethyl ester crystallised only after several weeks. The methyl ester was washed with ether and recrystallised from the same solvent; m.p. 103°. It is very soluble in acetone. The ethyl ester dissolved readily in both ether and acetone, but could be recrystallised from hot ligroin. As the crystals were slightly coloured, they were melted and the liquid was distilled at 17 mm. pressure; it then boiled at 179°, giving a colourless distillate, which solidified at 67°.

In the remaining cases, the excess of acetic anhydride was carefully distilled off after the mixture had stood for 12 hours, the sulphuric acid neutralised with calcium or barium carbonate, and the distillation continued under reduced pressure. It was found necessary to use flasks with wide side tubes (10—12 mm. diameter) and to heat them in an oil-bath in order to obtain colourless distillates. The first portions were rejected in each case. On cooling, the *iso*propyl ester soon solidified to a mass of crystals, m. p. 31·4°, but the *n*-propyl ester refused to solidify for several months. Eventually crystallisation took place in the polarimeter tube during the course of a set of readings. The substance was then refraction-

ated and crystallised by seeding. It melted at 21·5°,* but observations could be made with the supercooled liquid. For the purpose of comparison with older results, the observed melting points, boiling points, densities, and specific rotations for the sodium line are summarised in Table I, which also shows the wave-lengths λ_μ of maximum rotations.

The remaining tables show the observed and the calculated values of the specific rotations over a wide range of wave-lengths. The concentration of the solution of diacetyltartaric acid in ether (Table II) is the same as that in acetone, given in Part II. 10·8334 G. of the acid are equivalent to 10·0 g. of the anhydride.

CCXXXVI.—*The Rotatory Dispersion of Derivatives of Tartaric Acid. Part IV. Propyl and Butyl Tartrates.*

By PERCY CORLETT ADSHEAD.

SINCE the investigation of the esters of diacetyltartaric acid recorded in Part III (preceding paper) involved the preparation of *n*-propyl, *iso*propyl, *n*-butyl, and *iso*butyl tartrates, measurements of the rotatory dispersions of these esters were made in order that they might be compared with values previously obtained by Lowry and Abram for methyl tartrate (J., 1915, **107**, 1187) and by Lowry and Cutter for the ethyl ester (J., 1922, **121**, 542). It has been found that in every case the rotatory dispersion is both complex and anomalous, but although the same dispersion constants are used throughout the series, no simple relation appears to exist between the rotation constants. These are recorded in Table I, which also shows the melting points, boiling points, and densities, where ascertained, and the wave-lengths λ_μ calculated for maximum rotations. For comparison, the published values for the methyl and ethyl esters are included. The value of λ_μ for methyl tartrate is exceptionally high,

TABLE I.

*iso*Butyl	66	171°/11 mm.	—	24·985	18·741	5374	25% in ether.

* Dimorphous.

Preparation of the Esters.—The preparation of the propyl esters was more troublesome than that of the butyl esters, since in the latter case the boiling points of the alcohols are sufficiently high to enable one to eliminate the water produced by slowly distilling off a constant-boiling mixture of the alcohol and water through a long fractionating column. When the propyl alcohols were used, it was necessary to use a dehydrating agent. Hydrogen chloride was first used, but in order to avoid possible contamination of the final product with chlorinated compounds (compare Lowry and Cutter, *loc. cit.*), calcium chloride was substituted later. The solubility of calcium chloride in the alcohol renders its subsequent removal troublesome, but fairly satisfactory yields could be obtained. The powdered tartaric acid dissolved much more rapidly in *n*-butyl than in *iso*butyl alcohol. The esters were carefully distilled and fractionated under low pressure. An oil-bath was used for heating the distillation flasks. This was particularly necessary in the case of *iso*propyl tartrate, which decomposes somewhat readily.

The results are in the following tables. The rotations are all positive, except the one case recorded.

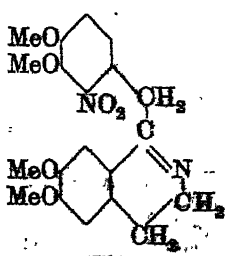
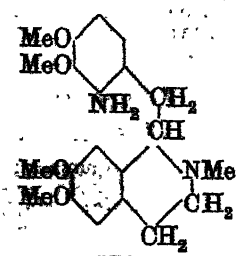
CCXXXVII.—*Synthetical Experiments on the Aporphine Alkaloids. Part III. A Synthesis of Corytuberine Dimethyl Ether.*



By JOHN MASSON GULLAND and ROBERT DOWNS HAWORTH.

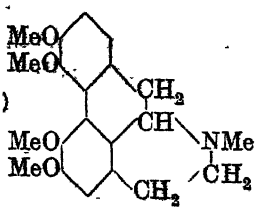
THE method described in Parts I and II of this series (this vol., pp. 581, 1132) has now been applied to the synthesis of 3 : 4 : 5 : 6-tetramethoxyaporphine (IV), the *d*-form of which is identical with corytuberine dimethyl ether (corydine and *iso*corydine monomethyl ether).



2'-*Nitro*-3' : 4'-*dimethoxyphenylaceto*-β-3 : 4-*dimethoxyphenylethylamide* (I) was prepared from 2-nitro-3 : 4-dimethoxyphenylacetyl chloride and β-veratrylethylamine, and converted into 2'-*nitro*-6 : 7 : 3' : 4'-*tetramethoxy*-1-*benzyl*-3 : 4-*dihydroisoquinoline* (II) by the action of phosphorus pentachloride. This pale yellow, crystalline base, which forms a crystalline *hydrochloride*, was converted into its *methiodide*, and the latter was reduced with zinc dust and hydrochloric acid to 2'-*amino*-6 : 7 : 3' : 4'-*tetramethoxy*-1-*benzyl*-2-*methyltetrahydroisoquinoline* (III). This oily base, which yields a crystalline *dihydrochloride*, diazotises readily and the diazonium salts couple with β-naphthol in alkaline solution.

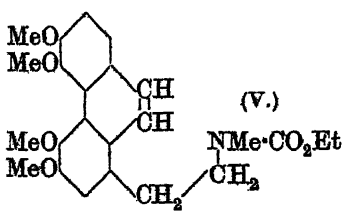
(I.)

(II.)



(III.)

The base (III) was diazotised in a mixture of methyl alcohol and sulphuric acid and converted into 3 : 4 : 5 : 6-*tetramethoxyaporphine* (IV) by warming. This *dl*-base is a pale yellow oil from which a crystalline *methiodide* has been prepared. The *dl*-base (IV) was resolved by means of *d*-tartaric acid, and 1-*corytuberine dimethyl ether* d-*bitartrate* was thus obtained in crystalline



condition. *d*-Corytuberine dimethyl ether *l*-bitartrate was then prepared by liberating the base from the mother-liquors and combining it with *l*-tartaric acid. The *d*- and *l*-bases were obtained from the bitartrates in the form of oils. These gave the colour reactions described by Gadamer (*Arch. Pharm.*, 1911, **249**, 547) for the oily corytuberine dimethyl ether, which he prepared by methylating naturally occurring *d*-corytuberine.

As we do not possess a sample of the natural product, direct comparison has not been possible, but the melting points, solubilities, and rotation values of the *l*-bitartrate and the methochloride of the synthetical *d*-base are in close agreement with those which Gadamer (*loc. cit.*) records for the corresponding derivatives of the *d*-base obtained from natural sources. Further, the optically inactive carbethoxycorytuberine dimethyl ether (V), prepared by the action of sodium hydroxide and ethyl chloroformate on the synthetical *d*- or *dl*-base, appears to be identical with the product obtained by Osada (*Arch. Pharm.*, 1924, **262**, 501) in a similar manner from the *d*-base of natural origin.

(IV.)

(V.)

This synthesis confirms the structure which Gadamer (*loc. cit.*) suggested for corytuberine dimethyl ether (corydine and *iso*corydine monomethyl ether), and we hope to determine by analogous syntheses the positions of the phenolic hydroxyl groups in these alkaloids.

Experimental.

2'-Nitro-3' : 4'-dimethoxyphenylaceto-β-3 : 4-dimethoxyphenylethylamide (I).—A benzene solution of 2-nitro-3 : 4-dimethoxyphenylacetyl chloride (prepared from 5 g. of acid as described in this vol., p. 1134) and β-veratrylethylamine (3·7 g.) was cooled and shaken with a slight excess of 15% sodium hydroxide solution. The benzene layer was washed with dilute hydrochloric acid and dried with sodium sulphate, and the solvent removed. The residual oil was dissolved in a little methyl alcohol (in which it is very soluble) and mixed with ether, the alcohol was removed by washing with water, and the ether was dried and allowed to evaporate slowly; the *amide* separated in almost colourless nodules, m. p. 64—66°, containing solvent of crystallisation which is lost at 100° (found in material dried at 110°: C, 60·2; H, 6·2. $C_{20}H_{24}O_7N_2$ requires

C, 59·6; H, 5·7%). This amide is very soluble in the usual organic solvents with the exception of light petroleum.

2'-Nitro-6 : 7 : 3' : 4'-tetramethoxy-1-benzyl-3 : 4-dihydroisoquinoline (II).—A solution of the amide (I) (5 g.), chloroform (50 c.c.), and phosphorus pentachloride (6 g.) was allowed to remain at room temperature for 36 hours. The solvent was removed in a vacuum from the buff-coloured solid, the residue was dissolved in hot water, and the filtered solution made alkaline with ammonia. The solid base, collected after 3 hours, crystallised from ethyl alcohol in pale yellow prisms (3·9 g.), m. p. 159—160° (Found: C, 61·9; H, 5·9. $C_{20}H_{22}O_6N_2$ requires C, 62·2; H, 5·7%). This *base* is almost insoluble in light petroleum, sparingly soluble in ether and cold alcohol, but readily soluble in benzene and chloroform. It dissolves in hot dilute hydrochloric acid, and on cooling, the *hydrochloride* separates in very pale yellow needles, m. p. 227° (decomp.). The *methiodide* was prepared by allowing the base to react with an excess of methyl iodide at room temperature for 12 hours. The excess of methyl iodide was then removed, and the residue crystallised from ethyl alcohol, in which it was readily soluble. It forms rosettes of yellow needles, which contain solvent of crystallisation and melt at 105—107°, resolidify, and decompose gradually between 180° and 190° (Found in material dried at 100°: C, 47·7; H, 5·0. $C_{21}H_{25}O_6N_2I$ requires C, 47·7; H, 4·7%).

2'-Amino-6 : 7 : 3' : 4'-tetramethoxy-1-benzyl-2-methyltetrahydroisoquinoline (III).—A hot solution of the methiodide (2·3 g.) in water (25 c.c.) and concentrated hydrochloric acid (25 c.c.) was reduced by the gradual addition of zinc dust (7·5 g.). The liquid having been filtered and made alkaline with ammonia, the base was extracted with ether and dried, and the solvent removed. The residual oil was dissolved in chloroform and saturated with dry hydrogen chloride; the *dihydrochloride* of the base (III) separated in colourless needles (1·7 g.), m. p. 188—190° (Found in material dried at 100°: C, 56·8; H, 6·7. $C_{21}H_{28}O_4N_2,2HCl$ requires C, 56·6; H, 6·7%). The dihydrochloride was hygroscopic and dissolved readily in ethyl alcohol. The addition of sodium nitrite to an aqueous solution of the dihydrochloride produced a bright yellow solution which coupled with alkaline β-naphthol, yielding a vermilion azo-dye which became deep port-wine in colour when dissolved in concentrated sulphuric acid.

dl-Corytuberine dimethyl ether (IV).—The dihydrochloride of the base (III) (2 g.), dissolved in methyl alcohol (10 c.c.) and sulphuric acid (10 c.c. of 2*N*), was diazotised by the gradual addition of the calculated amount of 2*N*-sodium nitrite. The bright yellow liquid became deep red after boiling for ½ hour; zinc dust (1 g.) and con-

centrated hydrochloric acid (3 c.c.) were then added, and the boiling was continued for 15 minutes. The mixture was filtered, and the residue extracted with boiling water. The combined filtrate and washings were rendered alkaline with ammonia and extracted with ether, the extract was washed with sodium hydroxide solution and dried, and the ether was removed. *dl*-Corytuberine dimethyl ether (0·3 g.) remained as a pale yellow oil which did not crystallise. The *hydrochloride* was very soluble in water and alcohol, and the *hydriodide* separated as a gum when potassium iodide was added to an aqueous solution of the hydrochloride. The *methiodide*, which was obtained by heating the *dl*-base with an excess of methyl iodide, crystallised from ethyl alcohol in colourless prisms which darken slightly at about 220° and decompose at 248° (Found: C, 52·9; H, 5·5. $C_{22}H_{28}O_4NI$ requires C, 53·1; H, 5·6%).

Resolution of dl-*Corytuberine Dimethyl Ether*.—When *dl*-corytuberine dimethyl ether (1 g.) in absolute ethyl alcohol (15 c.c.) was mixed with an absolute-ethyl-alcoholic solution of *d*-tartaric acid (3 c.c. of 2*N*), a gum separated. This dissolved on boiling, and the colourless crystals of l-*corytuberine dimethyl ether* d-*bitartrate* which rapidly separated were collected by filtering the boiling solution and recrystallised from rectified spirit, forming colourless needles, m. p. 219—221° (decomp.) (Found in material dried at 100°: C, 59·2; H, 6·3. $C_{25}H_{31}O_{10}N$ requires C, 59·4; H, 6·1%). In aqueous solution: $l = 1$, $c = 1·005$, $\alpha_D = -1·49°$, whence $[\alpha]_D = -148·2°$. On cooling, the hot filtrate deposited a gum; the clear supernatant liquid was decanted and evaporated to dryness and the base was liberated by the action of sodium hydroxide solution and extracted with ether. The ethereal extract was dried, the solvent removed, and the residual oil was dissolved in absolute ethyl alcohol (15 c.c.) and mixed with an absolute-ethyl-alcoholic solution of *l*-tartaric acid (3 c.c. of 2*N*). *d*-Corytuberine dimethyl ether *l*-bitartrate separated; it crystallised from rectified spirit in colourless needles, m. p. 219—222° (decomp.). Gadamer (*loc. cit.*) gives 219—224° (decomp.) (Found: C, 59·3; H, 6·3. Calc. for $C_{25}H_{31}O_{10}N$: C, 59·4; H, 6·1%). In aqueous solution, $l = 1$, $c = 1·017$, $\alpha_D = +1·53°$, whence $[\alpha]_D = +149·7°$. Gadamer (*loc. cit.*) gives $[\alpha]_D = +150°$.

The *d*- and the *l*-base were liberated as oils from the bitartrates by the action of sodium hydroxide solution. With concentrated sulphuric acid, concentrated nitric acid, Erdmann's reagent, Fröhde's reagent, Mandelin's reagent, and a solution of selenic acid in concentrated sulphuric acid, the *d*- or the *l*-base gave colour reactions which were in agreement with those described by Gadamer (*loc. cit.*) for *d*-corytuberine dimethyl ether.

d-Corytuberine dimethyl ether methochloride was prepared by refluxing the *d*-base with an excess of methyl iodide for 1 hour, removing the excess of methyl iodide, digesting the residual methiodide with an aqueous suspension of silver chloride for 2 hours, filtering the solution, and evaporating the filtrate to dryness. When ether was added gradually to a solution of the gummy residue in a little absolute ethyl alcohol, the methochloride separated in slender needles, m. p. 243° (decomp.). Gadamer gives m. p. 234—237° (decomp.). In aqueous solution: $l = 1$, $c = 1{\cdot}112$, $\alpha_D = +2{\cdot}17°$, whence $[\alpha]_D = +196°$. Gadamer gives 197·6°.

Carbethoxycorytuberine dimethyl ether (V), m. p. 93°, was prepared from the synthetical *d*- or *dl*-base by the process described by Osada (*loc. cit.*) and appeared to be identical with that obtained from natural sources.

Our thanks are due to the Research Fund Committee of the Chemical Society for grants.

[*Received, May 15th*, 1928.]

CCXXXVIII.—*Syntheses in the Diphenyl Series.*

By LEONARD ERIC HINKEL and DONALD HOLROYDE HEY.

THE view (this vol., p. 1200) that 4 : 5 : 5-tribromo-1-phenyl*cyclo*hexan-3-one, when heated alone or with alcoholic potassium hydroxide, decomposes into 5-bromo-3-hydroxydiphenyl and 4 : 5-dibromo-3-hydroxydiphenyl has now been shown to be correct. The constitutions of the two compounds have been proved by their syntheses from 5-bromo-3-nitro-4-aminodiphenyl through 5-bromo-3-nitrodiphenyl and 5-*bromo*-3-*aminodiphenyl* in the first case, and through 4 : 5-*dibromo*-3-*nitrodiphenyl* and 4 : 5-*dibromo*-3-*aminodiphenyl* in the second.

No trace of 4 : 5-dibromo-3-nitrodiphenyl was obtained from 5-bromo-3-nitro-4-aminodiphenyl by diazotisation in hydrobromic acid solution as described by Crossley (J., 1904, 85, 278): the amino-group appeared to be unaffected, but the bromine formed by the interaction of the nitrous and hydrobromic acids reacted readily with the base, giving rise to 5 : 4′-dibromo-3-nitro-4-aminodiphenyl. This formed golden-orange needles, m. p. 154°. Scarborough and Waters (J., 1927, 1138), who obtained this compound by the bromination of 5-bromo-3-nitro-4-aminodiphenyl, describe it as red needles, m. p. 158°. We have repeated their experiment,

carrying out the heating process for only 2 hours, and obtained the dibromo-derivative as golden-orange needles, m. p. 154°; longer heating, as carried out by them, not only diminished the yield but also produced small quantities of darker-coloured substances. Acetylation of the dibromo-compound gave a product, m. p. 153°, which was identical with a specimen kindly provided by Bell and Robinson, who prepared it by the bromination of 3-nitro-4-acetamidodiphenyl (J., 1927, 1130). Reduction of the base gave 5 : 4′-*dibromo*-3 : 4-*diaminodiphenyl*.

EXPERIMENTAL.

5-*Bromo*-3-*nitro*-4-*aminodiphenyl*.—3-Nitro-4-aminodiphenyl was brominated as described by Scarborough and Waters (*loc. cit.*). By slow crystallisation from methyl alcohol the product was obtained pure as deep orange needles, m. p. 100° (Found: Br, 27·2. Calc.: Br, 27·3%).

Acetylation of the base gave 5-bromo-3-nitro-4-acetamidodiphenyl, which crystallised from alcohol in orange-yellow needles m. p. 95°, and was identical with the compound described by Bell and Robinson (*loc. cit.*) as (5?)-bromo-3-nitro-4-acetamidodiphenyl, m. p. 94—95°.

5-*Bromo*-3-*aminodiphenyl*.—5-Bromo-3-nitrodiphenyl (Scarborough and Waters, *loc. cit.*) was reduced in alcoholic solution with sodium hydrosulphite. After removal of the alcohol under reduced pressure, the *base* was extracted with ether. It crystallised from light petroleum (b. p. 40—60°) in light brown prisms, m. p. 88° (Found: Br, 32·1. $C_{12}H_{10}NBr$ requires Br, 32·3%).

The *acetyl* derivative, prepared in the usual manner, crystallised from alcohol–light petroleum in white prisms, m. p. 140° (Found: Br, 26·9. $C_{14}H_{12}ONBr$ requires Br, 27·6%).

5-*Bromo*-3-*benzoyloxydiphenyl*.—5-Bromo-3-aminodiphenyl was diazotised in the usual manner in an 80% solution of sulphuric acid at 0°. After remaining for 1 hour at this temperature, the solution was gradually heated to boiling, then diluted, and extracted with ether. The dark oil remaining after removal of the ether was treated with sodium hydroxide solution. Acidification of the alkaline solution precipitated 5-bromo-3-hydroxydiphenyl as an oil which owing to the small amount available was not further purified but converted directly into its benzoyl derivative; this crystallised from alcohol in clusters of small needles, m. p. 108°, unchanged by admixture with the benzoyl derivative of 5-bromo-3-hydroxydiphenyl (this vol., p. 1203).

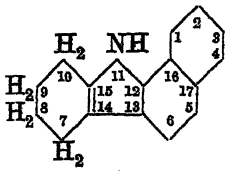
4 : 5-*Dibromo*-3-*nitrodiphenyl*.—4 G. of 5-bromo-3-nitro-4-aminodiphenyl were diazotised as described above. The solution was

diluted with ice-water, poured into a cold solution of cuprous bromide in hydrobromic acid, and gradually heated to boiling. Extraction of the solution with ether gave a solid which crystallised from methyl alcohol in pale yellow needles, m. p. 125° (Found: Br, 44·6. $C_{12}H_7O_2NBr_2$ requires Br, 44·8%). Oxidation with chromic acid in glacial acetic acid solution gave 4 : 5-dibromo-3-nitrobenzoic acid (m. p. 182°).

4 : 5-*Dibromo*-3-*acetamidodiphenyl*.—4 : 5-Dibromo-3-nitrodiphenyl was reduced with sodium hydrosulphite, and the brown semi-solid base obtained was converted by the usual method into the *acetyl* derivative, which crystallised from aqueous alcohol in white needles, m. p. 177° (Found: Br, 43·5. $C_{14}H_{11}ONBr_2$ requires Br, 43·4%).

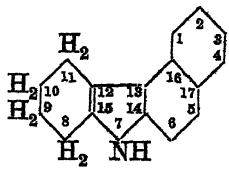
On hydrolysis of the acetyl derivative with concentrated hydrochloric acid and subsequent treatment with ammonia, the base was obtained as a dark semi-solid mass, which was converted into 4 : 5-dibromo-3-hydroxydiphenyl by the diazo-reaction. This crystallised from light petroleum (b. p. 40—60°) in fine needles, m. p. 81°, and its benzoyl derivative, prepared in the usual manner, crystallised from alcohol in small, white needles, m. p. 104°. These m. p.'s were unchanged by admixture with the corresponding compounds described in this vol., p. 1203.

5 : 4′-*Dibromo*-3 : 4-*diaminodiphenyl*, obtained by reducing 5 : 4′-dibromo-3-nitro-4-aminodiphenyl with sodium hydrosulphite, crystallised from alcohol in white needles, m. p. 120° (Found: Br, 46·9. $C_{12}H_{10}N_2Br_2$ requires Br, 46·8%). The *dibenzoyl* derivative, prepared in the usual manner, was sparingly soluble in boiling alcohol, from which it separated in microscopic crystals, m. p. 278° (Found: Br, 29·2. $C_{26}H_{18}O_2N_2Br_2$ requires Br, 29·1%).



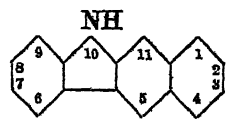
UNIVERSITY COLLEGE, SWANSEA. [*Received, May 22nd*, 1928.]

CCXXXIX.—*Derivatives of* 7 : 8 : 9 : 10-*Tetrahydro*-αβ-*naphthacarbazole and of* 8 : 9 : 10 : 11-*Tetrahydro*-α′β′-*naphthacarbazole*.



By STEPHEN HELLICAR OAKESHOTT and SYDNEY GLENN PRESTON PLANT.

THE reactions observed with tetrahydrocarbazole and its 9-acyl derivatives, especially those with nitric acid which involve the addition of OH and NO_2 or OH and OH to the double linkage (Perkin and Plant, J., 1921, **119**, 1825; 1923, **123**, 676), made it probable that the investigation of 7 : 8 : 9 : 10-tetrahydro-αβ-naphthacarbazole (I) and 8 : 9 : 10 : 11-tetrahydro-α′β′-naphtha-



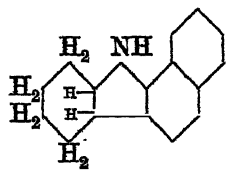
carbazole (II) along similar lines would present many interesting points.

(I.)

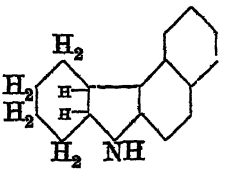
(II.)

(III.)

These two compounds (named $\Delta^{1(6)}$-tetrahydrobenzo-α- and -β-naphthindole) have already been prepared by Borsche, Witte, and Bothe (*Annalen*, 1908, **359**, 64) from *cyclo*hexanone-α- and -β-naphthylhydrazone respectively, and these authors have established the constitution of (I) by oxidising it to αβ-naphthacarbazole with lead oxide. There could be no reasonable doubt concerning the structure of (II), but it has now been confirmed by dehydrogenation with sulphur to α′β′-naphthacarbazole, thus disposing of the alternative ββ-naphthacarbazole skeleton (III).



Attempts to acetylate 7 : 8 : 9 : 10-tetrahydro-αβ-naphthacarbazole directly with acetic anhydride failed, but the action of acetyl chloride on magnesium 11-7 : 8 : 9 : 10-tetrahydro-αβ-naphthacarbazyl bromide yielded 11-*acetyl*-7 : 8 : 9 : 10-*tetrahydro*-αβ-*naphthacarbazole*. The 11-*benzoyl* compound was similarly obtained. An investigation of the action of nitric acid on 7 : 8 : 9 : 10-tetrahydro-αβ-naphthacarbazole and its acetyl and benzoyl derivatives has yielded no crystalline substance, with the exception of a *trinitro*-derivative from the benzoyl compound.



The action of hot acetic anhydride on 8 : 9 : 10 : 11-tetrahydro-α′β′-naphthacarbazole in the presence of a few drops of concentrated sulphuric acid gives first 7-*acetyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole*, but a *diacetyl* derivative is soon formed in which one of the acetyl groups must be attached to carbon and the other to nitrogen. On boiling with aqueous-alcoholic potassium hydroxide, the acetyl group attached to nitrogen is removed with the production of C-*monoacetyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole*, the nature of which is confirmed by the fact that it gives an *oxime*. The point of attachment of the *C*-acetyl group has not been determined. 7-*Acetyl*- and 7-*benzoyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole* can be most conveniently obtained by means of the Grignard reaction in processes similar to those used for the isomeric derivatives of αβ-naphthacarbazole. From the product of the action of nitric acid in glacial acetic acid solution on each of these acyl derivatives of (II), a *mononitro*-derivative has been isolated; but from none of the acyl derivatives studied in the naphthacarbazole

series have products formed by the addition of OH and NO_2 or OH and OH to the double linkage been isolated. It is not possible to state definitely that such reactions do not occur, since in many experiments a considerable portion of the product could not be crystallised nor its nature determined.

Compounds (I) and (II) have been reduced to 7 : 8 : 9 : 10 : 14 : 15-*hexahydro-αβ-naphthacarbazole* (IV) and 8 : 9 : 10 : 11 : 12 : 15-*hexahydro-α'β'-naphthacarbazole* (V) respectively. Theoretically

(IV.)

(V.)

each of these hexahydro-derivatives should exist in two stereoisomeric forms (*cis-* and *trans-*) analogous to the two forms of hexahydrocarbazole (Gurney, Perkin, and Plant, J., 1927, 2676), but the formation of the *trans*-modification in other than very small quantities in each case is not to be expected on account of the much greater strain in these configurations. Therefore the two hexahydronaphthacarbazoles here described almost certainly have the *cis*-configurations (IV and V). The former can be prepared by the electrolytic reduction of the corresponding tetrahydro-compound, but a similar method for (V) gave a very poor yield, hydriodic acid and phosphorus being used finally for the reduction.

Experimental.

7 : 8 : 9 : 10-*Tetrahydro-αβ-naphthacarbazole* (I).—α-Naphthylhydrazine hydrochloride, prepared from α-naphthylamine (100 g.) by the method of Fischer (*Annalen*, 1886, **232**, 236), was mixed with alcohol (1000 c.c.) and shaken for a short time at 50—60° with crystallised sodium acetate (80 g.); *cyclo*hexanone (60 c.c.) was then added and, after ½ hour, the solution was diluted with water (2000 c.c.). The hydrazone separated as a sticky mass which was washed with water and warmed with 1100 c.c. of 14% sulphuric acid (by vol.); the compound (I) then separated in good yield. It was recrystallised from glacial acetic acid and obtained in colourless needles, m. p. 139—140° (compare Borsche, Witte, and Bothe, *loc. cit.*). It can also be obtained by boiling the alcoholic mixture of crude α-naphthylhydrazine hydrochloride, sodium acetate, and cyclohexanone. The product soon begins to separate, and can be isolated in a pure condition by adding an equal volume of water and cooling the mixture. Its *picrate* separates from benzene in very dark brown prisms, m. p. 172° (decomp.). All attempts to

nitrate the compound (I) in either acetic acid or sulphuric acid solution failed to yield any crystalline substance.

Oxidation of 7 : 8 : 9 : 10-*Tetrahydro-αβ-naphthacarbazole.*—A mixture of this compound (6·8 g.), sulphur (2 g.), and quinoline (20 c.c.) was boiled for 45 minutes, cooled, and poured into a mixture of ice and dilute hydrochloric acid. The sticky product was washed with dilute hydrochloric acid, dried, mixed with a little iron filings, and distilled. The αβ-naphthacarbazole obtained crystallised from benzene–petroleum in colourless needles, m. p. 225—226°. It dissolved in concentrated sulphuric acid to give a yellow solution, which changed to a dark green on the addition of a drop of concentrated nitric acid. There is no doubt that this product is identical with the αβ-naphthacarbazole previously described (compare, *e.g.*, Japp and Maitland, J., 1903, **83**, 267; Borsche, Witte, and Bothe, *loc. cit.*; Bucherer and Schmidt, *J. pr. Chem.*, 1909, **79**, 384).

11-*Acetyl*-7 : 8 : 9 : 10-*tetrahydro-αβ-naphthacarbazole.*—Magnesium (4·8 g.) was dissolved in a mixture of ethyl bromide (16 c.c.) and ether (150 c.c.). When a solution of the compound (I) (25 g.) in dry ether was slowly added, a brisk evolution of ethane occurred and a dark oil separated. The mixture was treated gradually with acetyl chloride (15 c.c.), warmed on the water-bath for a few minutes, and then cautiously treated with ice and dilute hydrochloric acid. The whole was extracted with more ether, and the extract was washed with aqueous sodium carbonate and dried over potassium carbonate. After removal of the solvent, the residue was crystallised from glacial acetic acid or methyl alcohol, from which 11-*acetyl*-7 : 8 : 9 : 10-*tetrahydro-αβ-naphthacarbazole* separated in colourless needles, m. p. 125° (Found : N, 5·2. $C_{18}H_{17}ON$ requires N, 5·3%). This acetyl derivative is slightly soluble in cold ether and alcohol, readily soluble in benzene, and practically insoluble in petroleum.

11-*Benzoyl*-7 : 8 : 9 : 10-*tetrahydro-αβ-naphthacarbazole* was prepared similarly, benzoyl chloride being used in place of acetyl chloride. The crude product was a dark yellow syrup, which crystallised on treatment with glacial acetic acid, and after recrystallisation from petroleum (b. p. 100—120°) 11-*benzoyl*-7 : 8 : 9 : 10-*tetrahydro-αβ-naphthacarbazole* separated in short, yellow needles, m. p. 146—147° (Found : N, 4·3. $C_{23}H_{19}ON$ requires N, 4·3%).

When a solution of the benzoyl derivative (1 g.) in glacial acetic acid (10 c.c.) at 95° was treated with nitric acid (5 c.c. of *d* 1·4), left at 100° for ½ hour, and then kept over-night, *trinitro*-11-*benzoyl*-7 : 8 : 9 : 10-*tetrahydro-αβ-naphthacarbazole* separated; after recrystallisation from acetone, it was obtained in yellow needles, m. p. 255° (decomp.) (Found : C, 60·8; H, 3·3; N, 12·2. $C_{23}H_{16}O_7N_4$

requires C, 60·0; H, 3·5; N, 12·2%). Attempts to control this reaction in order to isolate simpler products yielded no crystalline material.

7 : 8 : 9 : 10 : 14 : 15-*Hexahydro*-αβ-*naphthacarbazole*.—A solution of the compound (I) (10 g.) in a mixture of sulphuric acid (100 c.c. of *d* 1·5) and alcohol (100 c.c.) at 80° was submitted to electrolytic reduction during 20 hours, lead electrodes and a current of 5 amps. (0·03 amp. per sq. cm. of cathode) being used. The mixture was diluted with water (300 c.c.), filtered, and made alkaline with concentrated aqueous ammonia. Ether extracted an oil which solidified when left in contact with petroleum. On recrystallisation from a small quantity of methyl alcohol, 7 : 8 : 9 : 10 : 14 : 15-*hexahydro*-αβ-*naphthacarbazole* was obtained in colourless needles, m. p. 88° (Found: C, 86·2; H, 7·7. $C_{16}H_{17}N$ requires C, 86·1; H, 7·6%). The base soon develops a mauve colour on exposure to the air, is readily soluble in ether with a blue fluorescence, and gives with mineral acids salts which are only slightly soluble in water.

A solution of the base (2·2 g.) in glacial acetic acid (7 c.c.), after being treated with concentrated nitric acid (2 c.c., previously treated with urea nitrate) dissolved in acetic acid (3 c.c.), was diluted with water (10 c.c), and made alkaline with ammonia. Ether extracted a syrup which was crystallised from alcohol, *dinitro*-7 : 8 : 9 : 10 : 14 : 15-*hexahydro*-αβ-*naphthacarbazole* separating in small, yellow needles, m. p. 139—140° (Found: N, 13·6. $C_{16}H_{15}O_4N_3$ requires N, 13·4%).

11-*Acetyl*-7 : 8 : 9 : 10 : 14 : 15-*hexahydro*-αβ-*naphthacarbazole*.—A mixture of 7 : 8 : 9 : 10 : 14 : 15-hexahydro-αβ-naphthacarbazole (2 g.) and acetic anhydride (10 c.c.) was boiled for 5 minutes, allowed to cool, diluted with water, and left over-night. The product crystallised from a small quantity of petroleum (b. p. 80—100°) in long, colourless needles, m. p. 132° (Found: N, 5·3. $C_{18}H_{19}ON$ requires N, 5·3%).

11-*Benzoyl*-7 : 8 : 9 : 10 : 14 : 15-*hexahydro*-αβ-*naphthacarbazole*.—The base (5 g.) was shaken with aqueous sodium hydroxide and benzoyl chloride (6 g.). The product separated as a crystalline mass and after recrystallisation from methyl alcohol was obtained in colourless needles, m. p. 148—149° (Found: N, 4·3. $C_{23}H_{21}ON$ requires N, 4·3%).

8 : 9 : 10 : 11-*Tetrahydro*-α′β′-*naphthacarbazole* (II).—This substance was obtained by a process similar to that described for compound (I), but using β-naphthylhydrazine hydrochloride. It separated from glacial acetic acid in colourless prisms, m. p. 137° (Found: C, 86·9; H, 7·0. Calc.: C, 86·9; H, 6·8%). Borsche, Witte, and Bothe (*loc. cit.*) give the m. p. 152°. When equal

quantities of the compound (II) and picric acid were mixed in hot alcohol, the solution filtered and allowed to cool, the *picrate* separated in black needles, m. p. 194° (decomp.). Attempts to nitrate the compound (II) yielded nothing crystalline.

Oxidation of 8 : 9 : 10 : 11-*Tetrahydro-α′β′-naphthacarbazole.*—This was carried out as described on p. 1843. The semi-solid distillate was dissolved in toluene and the solution was dried over calcium chloride, filtered, and treated with a toluene solution of picric acid. The crimson picrate, m. p. 165—168°, which separated was decomposed by grinding with dilute aqueous sodium hydroxide, and the product was dried and recrystallised from benzene–petroleum; α′β′-naphthacarbazole then separated in colourless plates, m. p. 134—135° (Found: C, 88·7; H, 5·1. Calc.: C, 88·5; H, 5·1%). The mixture with compound (II) melted completely below 110°. α′β′-Naphthacarbazole, prepared in this way, dissolved in concentrated sulphuric acid to give a yellowish-brown solution which turned yellowish-green on addition of a drop of concentrated nitric acid (compare Ullmann, *Annalen*, 1904, **332**, 102), and gave a picrate which separated from toluene in crimson plates, m. p. 175° (compare Japp and Maitland, *loc. cit.*). There can be no doubt, therefore, that this product is identical with the α′β′-naphthacarbazole previously described. The isomeric ββ′-naphthacarbazole melts at 330° (Graebe and Knecht, *Annalen*, 1880, **202**, 1).

Acetyl Derivatives of 8 : 9 : 10 : 11-*Tetrahydro-α′β′-naphthacarbazole.*—Boiling acetic anhydride alone has no action on the compound (II). When, however, the substance (10 g.) was boiled for 45 minutes with acetic anhydride (60 c.c.) containing a few drops of concentrated sulphuric acid, a dark green solid separated. After recrystallisation from glacial acetic acid containing some charcoal, a C-*acetyl*-7-*acetyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole* separated in greenish-yellow prisms, m. p. 185° (Found: C, 78·8; H, 6·2; N, 4·7. $C_{20}H_{19}O_2N$ requires C, 78·7; H, 6·2; N, 4·6%). This diacetyl derivative (4 g.) was heated on the water-bath for ½ hour with potassium hydroxide (8 g.) dissolved in aqueous alcohol, the alcohol distilled off, and the residue treated with water; C-*acetyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole* then remained and after crystallisation from alcohol was obtained in yellow plates, m. p. 213° (Found: N, 5·2. $C_{18}H_{17}ON$ requires N, 5·3%). This regenerated the diacetyl compound (m. p. 185°) when treated with acetic anhydride and a drop of concentrated sulphuric acid on the water-bath, and when boiled for an hour with an excess of hydroxylamine hydrochloride and sodium acetate in alcohol, yielded an oxime which crystallised from aqueous alcohol in pale yellow plates, m. p. 213—216° (Found: N, 10·2. $C_{18}H_{18}ON_2$ requires N, 10·1%).

When the compound (II) was warmed on the water-bath with acetic anhydride containing a few drops of concentrated sulphuric acid for 5 minutes only and the mixture cooled and diluted with water, the product, after crystallisation from alcohol and then from glacial acetic acid, yielded 7-*acetyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole* in colourless plates, m. p. 162° (Found : N, 5·2. $C_{18}H_{17}ON$ requires N, 5·3%). Owing to the readiness with which the diacetyl derivative (m. p. 185°) is produced, it is, however, difficult to prepare 7-acetyl-8 : 9 : 10 : 11-tetrahyro-α′β′-naphthacarbazole in any quantity by this method, and a much more satisfactory process is to use the Grignard reagent as described above for the preparation of 11-acetyl-7 : 8 : 9 : 10-tetrahydro-αβ-naphthacarbazole. In this case the product was practically insoluble in either the ether or the aqueous layer, and was collected by filtration and recrystallised from glacial acetic acid. 7-Acetyl-8 : 9 : 10 : 11-tetrahydro-α′β′-naphthacarbazole was hydrolysed to the compound (II) on boiling its alcoholic solution with potassium hydroxide for ½ hour, the product being obtained on diluting the solution with water.

7-Acetyl-8 : 9 : 10 : 11-tetrahydro-α′β′-naphthacarbazole (5 g.), dissolved in glacial acetic acid (50 c.c.) at 95°, was treated gradually with nitric acid (2 c.c. of *d* 1·4) in a little acetic acid. Almost immediately a yellow product (2·5 g.), melting indefinitely at about 190°, separated. It was collected after a few hours and crystallised from toluene and then from *cyclo*hexanone. After further recrystallisation from *cyclo*hexanone a *mononitro*-7-*acetyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole* was obtained in bright yellow needles, m. p. 222° (Found : N, 9·0. $C_{18}H_{16}O_3N_2$ requires N, 9·1%). It was evident that this is not the only product of this reaction, but efforts to isolate any other substance in a pure condition have so far been unsuccessful.

7-*Benzoyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole*.—This derivative was obtained by a process similar to that described for the corresponding 11-benzoyl-7 : 8 : 9 : 10-tetrahydro-αβ-naphthacarbazole. After crystallisation from glacial acetic acid, it separated in clusters of yellowish prisms, m. p. 139° (Found : N, 4·3. $C_{23}H_{19}ON$ requires N, 4·3%).

7-Benzoyl-8 : 9 : 10 : 11-tetrahydro-α′β′-naphthacarbazole (2 g.) was dissolved in glacial acetic acid (40 c.c.) at 80° and treated with nitric acid (1·5 c.c. of *d* 1·5) in a little glacial acetic acid. The mixture was cooled and kept for some days and the product was then collected and crystallised from acetone, from which *mononitro*-7-*benzoyl*-8 : 9 : 10 : 11-*tetrahydro*-α′β′-*naphthacarbazole* separated in yellow needles, m. p. 208—209° (Found : C, 74·8; H, 5·1. $C_{23}H_{18}O_3N_2$ requires C, 74·6; H, 4·9%).

8 : 9 : 10 : 11 : 12 : 15-*Hexahydro-α′β′-naphthacarbazole*.—A mixture of the compound (II) (10 g.), red phosphorus (7 g.), and hydriodic acid (70 c.c. of *d* 1·9) was boiled for 18 hours, cooled, made alkaline with aqueous sodium hydroxide, and extracted with ether. The extract was washed with water and dried over potassium carbonate and then dry hydrogen chloride was passed into it. 8 : 9 : 10 : 11 : 12 : 15-*Hexahydro-α′β′-naphthacarbazole hydrochloride* separated; after recrystallisation from hot water, it was obtained in small, buff-coloured prisms, m. p. 265° with sublimation (Found : C, 73·7; H, 7·0. $C_{16}H_{17}N$,HCl requires C, 73·9; H, 6·9%). The base, liberated by treating the hydrochloride with aqueous sodium hydroxide and isolated by means of ether, was obtained only as a syrup, b. p. 198—202°/10 mm.

7-*Acetyl*-8 : 9 : 10 : 11 : 12 : 15-*hexahydro-α′β′-naphthacarbazole* was obtained by boiling the base with acetic anhydride for 5 minutes and then diluting the solution with water. It separated from dilute alcohol in colourless plates, m. p. 120° (Found : N, 5·2. $C_{18}H_{19}ON$ requires N, 5·3%).

7-*Benzoyl*-8 : 9 : 10 : 11 : 12 : 15-*hexahydro-α′β′-naphthacarbazole*.—A mixture of the base (2 g.) and benzoic anhydride (2·4 g.) was heated at 150°, cooled, dissolved in chloroform, washed with aqueous sodium carbonate, and dried over potassium carbonate; the solvent was then removed and on crystallisation from petroleum (b. p. 60—80°) the product was obtained in colourless prisms, m. p. 131° (Found : N, 4·3. $C_{23}H_{21}ON$ requires N, 4·3%).

One of us (S. H. O.) desires gratefully to acknowledge the receipt of a grant from the Department of Scientific and Industrial Research which has enabled him to take part in this work.

CCXL.—*The Preparation and Properties of Pure Phosphorus Trioxide.*

By CHRISTINA CRUICKSHANK MILLER.

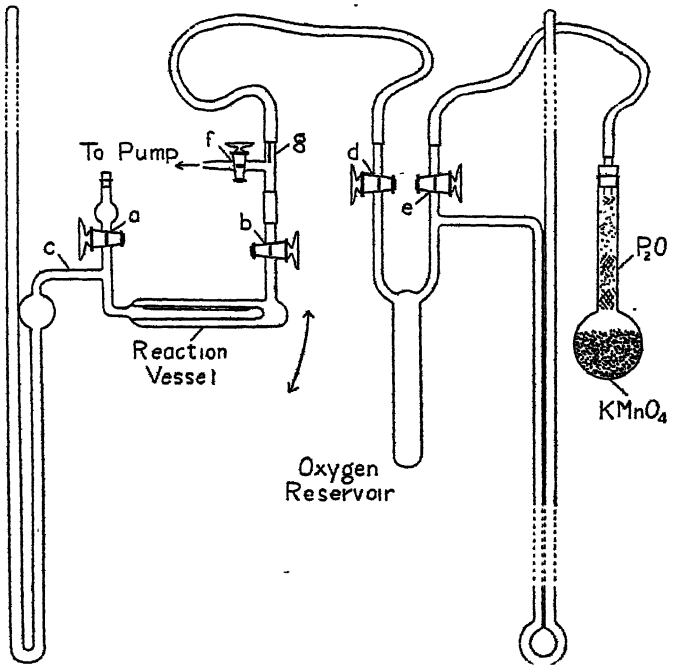
THE luminescence exhibited by slowly oxidising phosphorus trioxide has been frequently commented on and studied since the preparation of the oxide by Thorpe and Tutton (J., 1890, **57**, 545) and their study of its properties. Many have been the attempts to find the relation between the glowing of phosphorus and the glowing of its oxide. Although the best conditions for production of the glow in the two cases are by no means the same, there are several striking

points of resemblance; for example, Emeléus (J., 1925, **127**, 1362) established the identity of the ultra-violet band spectra, and Downey (*ibid.*, 1924, **125**, 347) showed that the light from each is capable of ionising oxygen; also Scharff (*Z. physikal. Chem.*, 1908, **62**, 179) found that substances which inhibit the glow of phosphorus likewise inhibit that of the trioxide.

The possibility of the glow being due to phosphorus in the oxide was considered by Thorpe and Tutton but rejected as unlikely. It is now shown, however, that Thorpe and Tutton did not study an oxide free from phosphorus, and that many properties supposed to be characteristic of phosphorus trioxide may, indeed, be due to dissolved phosphorus.

In an earlier paper (Miller, *Proc. Roy. Soc. Edin.*, 1926, **46**, 76) it was shown that there was a connexion between the glowing of phosphorus trioxide and the presence of water vapour. The effect on phosphorus trioxide, in evacuated bulbs, of water vapour derived from certain salt–hydrate mixtures was such as to indicate the possibility of formation of hydrides of phosphorus. It has since been found, however, that the use of hydrated chlorides and sulphates leads to erroneous results owing to the liberation of hydrogen chloride from chlorides and of sulphur dioxide from sulphates. When chlorides are used, gaseous hydrogen phosphide has been definitely proved to be amongst the final products, but its formation is due to complicated reactions which ensue between the hydrochloric acid and the phosphorus trioxide, not to direct action of aqueous vapour on the trioxide. When sulphates are used no hydrogen phosphide is produced. The very slight increase of pressure observed when water itself was the source of moisture is now attributed to carbon dioxide initially dissolved in the oxide and liberated in part by the conversion of phosphorus trioxide into phosphorous acid. In subsequent experiments water vapour at various pressures was obtained by the use of aqueous solutions of orthophosphoric acid, which produced no pressure change in presence of phosphorus trioxide in evacuated bulbs.

The Rate of Oxidation of Phosphorus Trioxide.



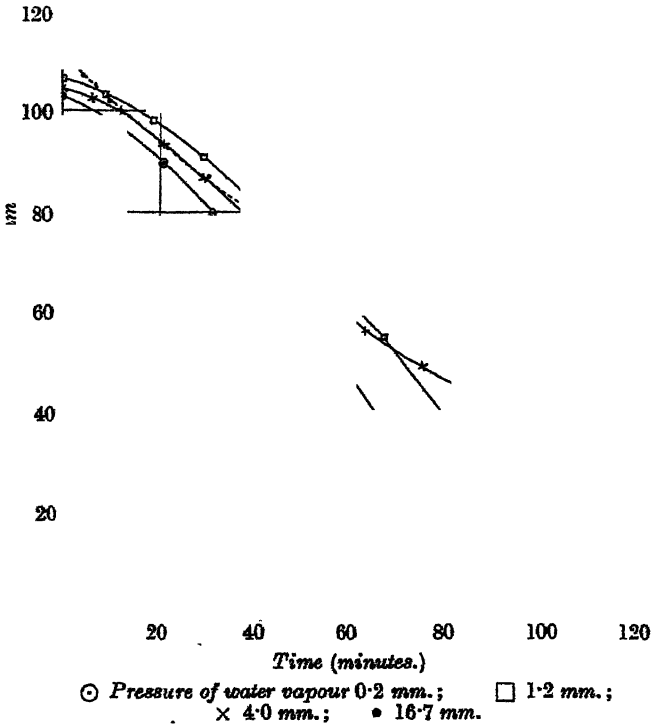
The rate of oxidation in oxygen, at 25°, of phosphorus trioxide, prepared according to Thorpe and Tutton's method and distilled at low pressure over reduced copper gauze, was studied in presence of the following solutions of phosphoric acid:

H_3PO_4 (g. per 100 g. of solution) ...	50	80	90	97
Density at 25°	1·335	1·629	1·743	1·845
Aqueous tension at 25° (mm.)	16·7	4·6	1·2	0·2

(If moisture was excluded from the apparatus oxygen was absorbed at an extremely slow rate.)

The apparatus (shown to the left in Fig. 1) was a slight modification of that used with hydrate mixtures (*loc. cit.*) and consisted of a bulb into one end of which was sealed a glass boat. Phosphorus trioxide was run into the boat at *a* and phosphoric acid into the wide tube at *b*. On to the apparatus was sealed a mercury manometer, and the whole was held pivoted at *c* so that an up and down movement could be effected as shown by the arrow. The volume of the bulb was a minimum, 30 c.c., so as to maintain the saturated vapour pressure of phosphorus trioxide, and the shaking device prevented film formation on the liquids.

FIG. 1.



In all experiments the same quantities of liquids were used, *viz.*, 0·2 c.c. of phosphorus trioxide and 8 c.c. of a phosphoric acid solution, a choice which did not introduce a marked change in the pressure of water vapour as the oxide was used up. The apparatus containing phosphoric acid was evacuated, and oxygen, generated by heating potassium permanganate, passed in till its partial pressure was 100—110 mm. After the apparatus had been heated to 25°, liquid phosphorus trioxide was run into the boat and pressure readings were made at intervals. The pressure-time curves (Fig. 2) illustrate the nature of the results.

Experiment 1. When the pressure of water vapour was very

low—0·2 mm.—oxygen was absorbed at a slowly increasing rate until all had gone in 1½ hours. During oxidation, glowing and flashing took place in the vapour phase, the luminescence always tending to be away from the phosphorus trioxide source, *i.e.*, not above the boat. Luminescence was all the time of the same nature, but brighter at lower pressures, and it faded and disappeared abruptly when nearly all the oxygen was used up. Most of the phosphorus trioxide seemed to be oxidised.

FIG. 2.

Experiment 2. The rate of absorption of oxygen in presence of 1·2 mm. pressure of water vapour was similar to that in Expt. 1, but the rate fell off after about 70 minutes. The glow phenomena up to this point were also similar, except that glowing took place to a slight extent above the boat. After 90 minutes, when the rate of oxidation was slower, there was permanent glowing round numerous solid particles in the boat. This was not observed when the pressure of water vapour was very low. No phosphorus trioxide remained.

Experiment 3. When the pressure of water vapour was 4 mm. the rate of oxidation for 40 minutes was similar to that in the two

preceding experiments. The glow tended very early to pass above the boat, and steady glowing showed at numerous points in the boat, earlier than in Expt. 2. The passing of the glow to the boat coincided with a reduction in the rate of absorption of oxygen and with the disappearance of phosphorus trioxide.

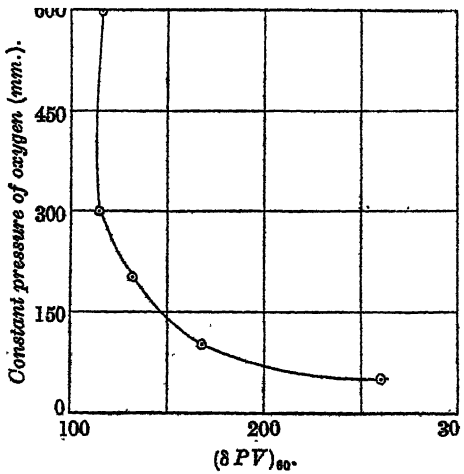
Experiment 4. With a high pressure of water vapour, flashing occurred after a few minutes above the boat, and in 10 minutes steady glowing took place in the boat. The phosphorus trioxide was practically all used up. After ½ hour the only glowing was that round the solid particles in the boat, and the fairly rapid initial rate of oxygen absorption had given way to a very slow absorption.

In these experiments it was found that the bulk of the phosphorus trioxide was converted into phosphorous acid, which did not absorb oxygen under the conditions prevailing. When the pressure of water vapour was high, this conversion was very rapid, and the subsequent slow rate of oxygen absorption was therefore not due to phosphorus trioxide. In all experiments, after the oxygen was used up, a small, insoluble residue, consisting of minute particles surrounded by liquid, remained in the boat; this was apparently phosphorus, for it glowed in air. The glowing previously observed in the boat was around these particles. As a test, 40 mg. of phosphorus were disintegrated in 2 c.c. of a 50% solution of phosphoric acid and part of the mixture was oxidised as in Expts. 1—4. Glowing took place round the solid particles and the pressure fell at a measurable rate, depending on the quantity of mixture present and on the amount of liquid surrounding the particles. The appearance of phosphorus in the boat in Expts. 1—4 was attributed to phosphorus originally dissolved in the phosphorus trioxide and set free by the conversion of the oxide into phosphorous acid. As the phosphorus trioxide might contain 1% of phosphorus, as judged by results of analysis, its rate of oxidation was compared with that of a 1% solution of phosphorus in paraffin oil. With the latter the pressure of oxygen fell 100 mm. in 3—4 minutes. This rapid rate of oxidation therefore bore no resemblance to the rates found for phosphorus trioxide. Glowing appeared only at the surface of the paraffin solution.

The rate of oxygen absorption by phosphorus trioxide, with low water-vapour pressure, was examined at constant pressure and volume. The boat tube was connected as shown in Fig. 1 with a 45—55 c.c. oxygen reservoir, to which were attached a mercury manometer, reading up to 800 mm. pressure, and a flask in which oxygen was generated by heating potassium permanganate, and dried by passage through a short column of phosphoric oxide,

The boat apparatus was provided with a manometer, registering up to 600 mm. pressure, which on account of its weight was attached at *c* by means of rubber tubing to the reaction bulb. The latter was moved up and down as before. The boat apparatus and as much as possible of the reservoir were put in a thermostat at 25°. The volumes of the reaction vessel and of the reservoir between *b* and *e* were known for all pressures.

In an experiment, the reservoir was charged with oxygen at a pressure about 300 mm. above the constant pressure required; 8 c.c. of a 97% solution of phosphoric acid and 0·5 g. of phosphorus trioxide were run into the reaction bulb and the apparatus was quickly evacuated between *a* and *d*. Tap *f* was closed and oxygen admitted to the evacuated bulb through tap *b* until the pressure was just below that required. The rate of inflow was controlled by means of the narrow capillary, *g*. When the apparatus had been 10 minutes in the thermostat, the pressure in the reaction vessel was carefully adjusted to the constant-pressure mark by admitting oxygen from the reservoir. Immediately after closing tap *b*, the time was noted and the pressure in the reservoir read off. Pressure in the reaction bulb was next allowed to fall not more than 5 mm. and then raised by admission of oxygen to about 5 mm. above the constant-pressure mark. The pressure fell again from this point, and the times of reaching the constant-pressure mark and the pressure of the reservoir were noted. Readings were made at intervals for 1½ hours or until the phosphorus trioxide was exhausted. From the change in PV, the product of the pressure and the volume of the reservoir, the amount of oxygen absorbed in a given time could be determined. For an experiment performed at 25° and at constant pressure (100 ± 4 mm.) the following results were obtained:



t (mins.).	P (cm.).	V (c.c.).	PV.	$(PV)_0 - (PV)_t = (\delta PV)_t$.
0	31·35	50·5	1583	0
7·5	31·0	50·5	1566	17
25	30·15	50·4	1520	63
29·5	29·9	50·4	1507	76
36	29·55	50·35	1487	96
42	29·2	50·3	1469	114
49	28·85	50·3	1451	132
57	28·35	50·25	1425	158
67	27·8	50·2	1396	188
75	27·4	50·15	1374	209
82·5	26·9	50·1	1348	235
90·5	26·4	50·1	1323	260

The change in PV in the time t, $(\delta PV)_t$, was equivalent to the volume of oxygen absorbed (in c.c. at 25° and 1 cm. pressure). Except for a slight initial retardation, the rate of absorption was

practically constant. Experiments performed with the pressure of oxygen constant at 600, 300, 200, and 50 mm. gave results of the same type, but showing different rates of absorption of oxygen. In order to compare the rates, the amount of oxygen absorbed in 60 minutes, $(\delta PV)_{60}$, was determined for each and the corresponding curve constructed (Fig. 3). It was unnecessary to correct for the change in volume of the reaction vessel with pressure, for the reaction only took place in the bulb part, which was the same for all.

An experiment at 25 mm. pressure was unsatisfactory, as the rate of oxidation on two occasions suddenly increased considerably. Fig. 3 indicates that the rate of oxygen absorption may become very great at pressures below 50 mm., an indication, probably, of ignition.

FIG. 3.

The results, which were all obtained with one specimen of phosphorus trioxide, showed that the rate of absorption of oxygen between 600 and 300 mm. pressure was practically constant but increased regularly as the pressure fell below 300 mm. This bore a resemblance to the rate of oxidation of phosphorus in moderately dried oxygen (see Russell, J., 1903, **83**, 1263).

In all experiments the position of the luminescence was striking. Bright flashing occurred principally below the boat, just above the acid surface, or at the end of the tube beyond the boat, *i.e.*, away from the source of phosphorus trioxide and near the water-vapour source. Attention has already been directed to the appearance of luminescence at sources of moisture at considerable distances from the oxide (Miller, *Proc. Roy. Soc. Edin.*, 1926, **46**, 239). Owing to the ease with which phosphorus trioxide took up water vapour in a

partially evacuated apparatus, it was difficult to imagine that in every instance phosphorus trioxide existed where luminescence appeared. Could the luminescence have been due to dissolved phosphorus? And if so, why did not luminescence appear at the surface of the liquid oxide as in the case of phosphorus dissolved in paraffin oil? The only explanation seemed to be that phosphorus trioxide prevented the luminescence of phosphorus. Phosphorus trioxide vapour containing phosphorus would therefore only luminesce if something were present to destroy the phosphorus trioxide. Water vapour, which is essential for the luminescence at the ordinary temperature, has this effect. One would then expect phosphorus trioxide to destroy the glow of slowly oxidising phosphorus. The following experiment was performed. Below the boat of the apparatus in Fig. 1, 5 c.c. of a solution of phosphorus in paraffin oil were introduced. Oxygen was present initially at 50 mm. pressure, and the solution glowed quite brightly at the surface. The pressure fell 29 mm. in 28 minutes. The experiment was started afresh, and after a minute 0·5 g. of phosphorus trioxide was run into the boat. The glow was immediately extinguished, and the pressure afterwards fell only 16 mm. in 170 minutes. This was not further studied, but the observation favoured the foregoing explanation that the glowing of phosphorus trioxide might be due to dissolved phosphorus.

Owing to its mode of preparation, the crude phosphorus trioxide contained phosphorus, which was no doubt partly removed by distillation. When the distillation proceeded too far, small globules of phosphorus accompanied the liquid phosphorus trioxide into the receiver and appeared not to dissolve to any extent. The phosphorus trioxide ordinarily used was therefore probably a saturated solution of phosphorus in phosphorus trioxide. Distillation over copper was not specially effective in removing phosphorus. Analysis, as previously mentioned, suggested the presence in the oxide of 1% of phosphorus. The well-known reddening of phosphorus trioxide in light has also been attributed to dissolved phosphorus. It is significant that the actual extent of decomposition is slight; for instance, Thorpe and Tutton (J., 1891, 59, 1019) found only 1% of red phosphorus in a sample of oxide exposed for 7 months to light.

In order to determine the part, if any, played by phosphorus in the luminous oxidation of phosphorus trioxide, it was obvious that the preparation of a phosphorus-free oxide was desirable. An unsuccessful attempt was made to dehydrate pure phosphorous acid. In another attempt phosphorus trioxide was exposed to light in an evacuated bulb, and the oxide was volatilised from the red solid at 25° into a second bulb where it was again exposed. Reddening occurred as before and the process was once more repeated. The

reddening effect was purely a superficial one. The light seemed to affect the white, opaque phosphorus trioxide, not the transparent crystals which sometimes formed. If the latter were melted and resolidified, they gave a white opaque solid which was affected by light. As there was apparently no diminution in the amount of reddening in the third bulb, this attempt to separate phosphorus was abandoned.

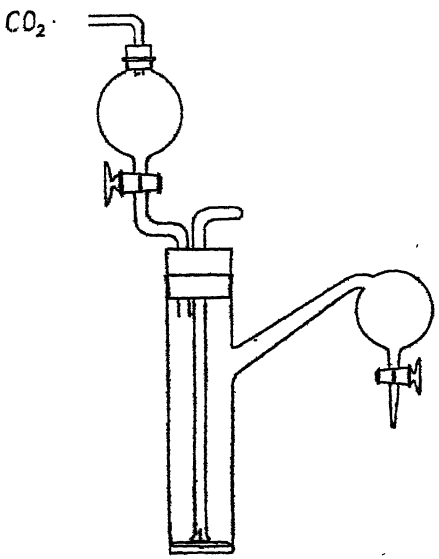
The next method adopted was the recrystallisation of freshly distilled phosphorus trioxide from a suitable solvent. Carbon disulphide is by far the best solvent for phosphorus but phosphorus trioxide also dissolves readily. A preliminary trial showed, however, that it could be employed if the temperature of recrystallisation was about $-18°$ and the amount used was small. The solvent was dried and distilled over mercury before use. Carbon disulphide is known to be a strong inhibitor of the glow of phosphorus, but it was found that there was no diminution of the glowing of a specimen of phosphorus trioxide after it had been dissolved in carbon disulphide and the solvent removed by evaporation, finally with the aid of a pump.

The Recrystallisation of Phosphorus Trioxide.—As a trial a small quantity of freshly distilled phosphorus trioxide was recrystallised four times from carbon disulphide in an atmosphere of carbon dioxide. The solvent was then expelled by a fairly rapid stream of carbon dioxide, and the purified oxide, about 25% of the original bulk, transferred to a boat apparatus (Fig. 1) and oxidised at 25° in presence of a 97% solution of phosphoric acid and oxygen at a constant pressure of 100 mm. (compare p. 1851). At first no glowing was seen, but after a time there were occasional bright flashes without pressure change in 50 minutes. It was suspected that a trace of carbon disulphide was responsible for the lack of oxidation. The apparatus was therefore re-evacuated and fresh oxygen passed in. Slight glowing occurred and the pressure fall corresponded to $(\delta PV)_{40} = 5{\cdot}2$. After a further evacuation and addition of oxygen the pressure fall was practically the same. The rate of oxidation of ordinary distilled phosphorus trioxide was previously found to be represented by $(\delta PV)_{40} = 108$ (see table, p. 1852), therefore the rate of oxidation of the purified oxide was reduced to one-twentieth of the original, probably corresponding to a similar reduction in the amount of dissolved phosphorus. The phosphorus trioxide obtained from the mother-liquor was found to oxidise at the normal rate.

These results showed that greater care had to be taken in eliminating solvent from the purified oxide. The apparatus shown in Fig. 4 was designed for recrystallisation experiments. It consisted

of a flat-bottomed tube provided with a side tube through which the mother-liquor from the crystals could be poured. It was further provided with a rubber stopper holding a small tap-funnel, and with a glass rod to which was attached by platinum at the lower end a perforated porcelain disc of nearly the same diameter as the tube. The disc could be moved up and down the tube like a piston. Dry carbon dioxide was passed into the apparatus as shown. Freshly distilled phosphorus trioxide and carbon disulphide were mixed by stirring in the tube and cooled to $-18°$, the perforated disc being moved up and down to prevent formation of crystals

FIG. 4.



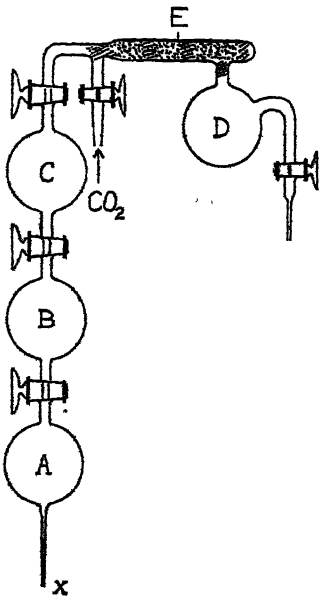


FIG. 5.

on the walls. The crystals were then allowed to settle and the disc was pressed down to force out the liquor. The latter was quickly poured off into the side bulb and thence removed. The recrystallisation was repeated and the crystals were finally washed with cooled carbon disulphide. The purified oxide was melted, transferred to a small tube, and solvent removed by evacuation with an oil pump, the oxide meanwhile being many times melted and resolidified. The yield of oxide was slightly higher than before. The specimen glowed when rubbed on the fingers, and in ozonised oxygen, but did not ignite on cotton wool. When oxidised according to the usual method the amount of oxygen absorbed was $(\delta PV)_{40} = 9$, slightly more than before, and there was quite bright flashing at intervals.

The maximum amount of oxygen absorbed by this oxide corresponded to little more than 0·1% of dissolved phosphorus.

Light petroleum (b. p. 40—60°) was tried in case the preceding results were due to carbon disulphide. Recrystallisation was effected five times and the solvent removed as before. The amount of oxygen absorbed by a portion of the oxide was equivalent to $(\delta PV)_{40} = 27$, three times the value found above. If the oxidation was due to phosphorus alone, this result indicated that there was three times as much phosphorus left in the oxide as in the preceding experiment and one-quarter of the amount present in the ordinary distilled oxide for which $(\delta PV)_{40}$ was 108. One might expect to obtain identical results for the rate of absorption of oxygen by the three specimens of phosphorus trioxide obtained by saturating the two purified oxides and the unpurified oxide (if not already saturated) with phosphorus at 25°. For the first two the values of $(\delta PV)_{40}$ were found to be 92 and 90, and for the last, 100. The two lower values were attributed to the fact that only minimum quantities of the solutions were prepared and phosphorus separated slightly while the oxides were being measured out. This did not happen with the third specimen. The value 100 was lower than that previously obtained for phosphorus trioxide, *viz.*, 108. The latter value was due to the use of oxide melted at 30—40°, which contained sufficient phosphorus to saturate it at a temperature above 25° and more than enough to saturate it at 25°.

The recrystallisation of a much larger quantity of phosphorus trioxide was attempted. Light petroleum was apparently not so effective as carbon disulphide in removing phosphorus, but it had the advantage that larger quantities could be used. A combination of methods was therefore adopted, the recrystallisation being effected with carbon disulphide and the crystals washed with light petroleum. 40 C.c. of freshly distilled phosphorus trioxide were mixed with one-third of the volume of pure carbon disulphide and recrystallised at −18°. The crystals were pressed as free as possible of liquor and washed with 15 c.c. of cooled light petroleum. The process was twice repeated with diminishing quantities of the solvents, and followed by two final washings with light petroleum (5 c.c. and 10 c.c.). The crystals were melted and filtered through glass-wool into a bottle from which air was displaced by dry carbon dioxide. The yield was about one-third of the original bulk.

The oxide in the mother-liquors was recovered, excess of phosphorus removed, and the oxide distilled and recrystallised as before. In all, three products were obtained and put in one bottle from which the remaining solvent was carefully removed as before. The phosphorus trioxide in the last mother-liquor was recovered from

solution in the usual manner and distilled in a vacuum to give a clear phosphorus-saturated solution of phosphorus trioxide.

A little of the purified oxide was oxidised in presence of 4 mm. of water vapour. The total amount of oxygen absorbed corresponded to about 0·02% of dissolved phosphorus. Bright flashing occurred under the boat during the first ½ hour; after 3 hours no glowing was seen and the pressure remained steady. This experiment indicated further removal of phosphorus from the oxide. A drop of this purified material when rubbed on the fingers gave a bright but momentary glow, whereas a drop of the ordinary oxide gave a glow sufficiently bright and lasting to illuminate the whole hand. It was supposed that the purified oxide glowed and absorbed a minute quantity of oxygen because of the retention of a trace of phosphorus. Elimination of this trace by further recrystallisation was impracticable, but it was thought that it might be eradicated by exposure of the oxide to sunlight, a process in which there was no further introduction of substances with an inhibitory effect on the glow. According to expectations the oxide reddened in sunlight, but not to the extent shown by the unpurified oxide. The apparatus shown in Fig. 5 was designed. Initially only that part was used which consisted of the three glass bulbs joined together as indicated. Phosphorus trioxide was drawn into bulb *A* and *x* was sealed off. The three bulbs were then thoroughly evacuated and the taps closed. As large a surface as possible of the phosphorus trioxide was exposed to light for a few hours and considerable reddening took place. The apparatus was re-evacuated and the phosphorus trioxide in bulb *A* volatilised into bulb *B* by heating *A* to 40° and cooling *B*. The oxide was again exposed to light, whereupon further reddening occurred, and then transferred to bulb *C* for a third exposure. In bulbs *B* and *C* the reddening was not so extensive as in bulb *A*. The second part of the apparatus, which had not been contaminated with phosphorus trioxide vapour containing phosphorus, was now sealed on to the three bulbs, and the tube *E* charged with phosphoric oxide. The whole apparatus was evacuated and the phosphorus trioxide in bulb *C* volatilised through the phosphoric oxide into the receiving bulb *D*. The drying tube and the bulb *D* were then filled with pure, dry carbon dioxide to atmospheric pressure, and portions of the oxide removed as required.

The Properties of Purified Phosphorus Trioxide.—1. At the ordinary temperature the oxide was a transparent, crystalline solid, lacking the opaque, waxy appearance of the unpurified product, caused probably by the separation of phosphorus from solution, on solidification.

2. A clear, colourless sample of purified phosphorus trioxide

contained in an evacuated bulb was exposed to light for 10 weeks in a well-lit laboratory, but, although it was several times melted and resolidified, it remained colourless and transparent. Crude phosphorus trioxide similarly treated was readily affected by light (see p. 1854). A second sample of purified oxide, which was kept in an atmosphere of carbon dioxide and used for the following experiments, was also exposed to light. The colourless crystalline mass assumed, during the first few hours' exposure, a faint pink tinge which did not deepen on further exposure for 6 weeks. The colour was due to the separation of a very small quantity of red substance.

3. When rubbed on the fingers the purified oxide gave no glow, and for a short time there was a pungent acid smell resembling that of hydrochloric acid. The phosphorus smell so readily detected with ordinary phosphorus trioxide was entirely absent. The pure oxide when spread on cloth did not ignite as does the ordinary product, but when mixed with a small proportion of the crude oxide, or with phosphorus, glowing and ignition were restored.

4. The m. p.'s of the purified and unpurified oxides were determined in a vacuum in small melting-point tubes, the oxide in each case having been initially volatilised through phosphoric oxide. The values found were: Purified oxide, 23·8°; unpurified oxide, 22·4°.

5. In order to obtain an indication of the amount of phosphorus dissolved in the unpurified oxide, the depression constant of the pure oxide was found by determining by Rast's method (*Ber.*, 1922, **55**, 1051) the lowering of freezing point produced by naphthalene as solute. With solutions containing 1·98 and 2·67% of naphthalene the lowerings were 1·85° and 2·4° respectively, giving for the depression constant the values 11,700 and 11,200. For the lowering of freezing point produced by phosphorus, *viz.*, 1·4°, a depression constant of 11,000 gives 1·6 g. as the amount of phosphorus (as P_4) dissolved in 100 g. of trioxide.

6. The pure oxide and the oxide saturated with phosphorus at 25° were analysed quantitatively: 0·15—0·25 g. was melted under water in a small flask and heated at 40—50° till converted into phosphorous acid. The pure oxide left no residue, whereas the unpurified oxide left a residue of phosphorus. An excess of liquid bromine was added and then 3—4 c.c. of 4*N*-sodium hydroxide, since hypobromite is known to oxidise phosphorous acid. Phosphorus was also completely oxidised. After a short time 5 c.c. of concentrated nitric acid were added and the solution was boiled to free it from bromine. The phosphoric acid was precipitated twice as magnesium ammonium phosphate, which was converted into pyrophosphate

(Found, for purified oxide: 100·04, 100·05; for unpurified oxide: 101·37, 101·47%). On the assumption that the purified oxide was entirely free from phosphorus, the last two results correspond respectively to 1·74 g. and 1·87 g. of free phosphorus in 100 g. of trioxide.

7. The solubility of phosphorus in the purified oxide at 25° was determined by shaking a weighed excess of purified phosphorus with about 1 g. of phosphorus trioxide in a small stoppered tube, in an atmosphere of carbon dioxide. The tube was first heated sufficiently to melt the phosphorus and then allowed to stand at 25°. The excess of phosphorus collected into a globule which was easily removed, washed, and weighed. The weight of phosphorus dissolved corresponded to 1·71 g. per 100 g. of trioxide. Experiments 5, 6, and 7 therefore showed satisfactory agreement.

8. The behaviour of the purified oxide in oxygen was studied. At 25° and in presence of 4 mm. of water vapour, the oxide neither glowed nor absorbed oxygen at 100 mm. or 18 mm. pressure, in contradistinction to the absorption of oxygen, accompanied by luminescence, exhibited by impure phosphorus trioxide (see Expt. 3, p. 1859). In presence of concentrated sulphuric acid it gave no deposition of oxides at 25° in oxygen at 600 mm. pressure, whereas unpurified phosphorus trioxide, under similar conditions, deposited phosphorus tetroxide (see Miller, *Proc. Roy. Soc. Edin.*, 1926, **46**, 239). At higher temperatures, the following phenomena were noticed. 0·2—0·3 G. of oxide was mixed with phosphoric oxide and volatilised into a 6 c.c. bulb into which pure dry oxygen was passed to a pressure of 300 mm. The bulb was sealed and heated gradually, but no glowing or fuming was seen below 200°. At about 220°, fuming was observed, accompanied by a very faint glow. The action was not brisk, for after ½ hour's heating at this temperature oxygen was still present. With undried phosphorus trioxide and moist oxygen the result was much the same, but in a second similar experiment oxidation appeared at 130°. Unpurified phosphorus trioxide gave an entirely different result, igniting at 40° in dry oxygen at 300 mm. pressure and using up all the oxygen. When ozonised oxygen containing 1% of ozone was passed at a slow rate over the pure phosphorus trioxide at 25°, oxidation occurred without luminescence. Under similar conditions, ordinary phosphorus trioxide glowed brightly and difficulty was experienced in preventing ignition.

9. When the purified oxide was melted under excess of water and heated gradually, it was simply converted into phosphorous acid, until a temperature of 75—80° was reached. At this point decomposition set in, bubbles of gas passed up through the water

from the oxide, and yellow and red solid products were formed. The gas fumed at the surface of the water and gave bright flashes. Unpurified phosphorus trioxide exhibited the same phenomena at a somewhat lower temperature.

When purified phosphorus trioxide in excess was sealed in an evacuated bulb with a small quantity of water, a clear yellow syrup formed, which after several days became opaque. The bulb was opened under water, but no gas was present. The amount of yellow solid was so small that accurate analysis was impossible—it is possibly a suboxide.

10. When the purified oxide was heated in a vacuum at 300°, red, yellow, and white decomposition products were formed, phosphorus tetroxide being amongst them. The thermal decomposition of ordinary phosphorus trioxide gives a similar result.

11. A portion of the pure trioxide was saturated with purified phosphorus at 25°. The oxide so obtained assumed on solidification the white, opaque appearance of unpurified phosphorus trioxide, glowed in air, ignited on cloth, and reddened in light.

Summary.

A study of the rate of absorption of oxygen by phosphorus trioxide in presence of water vapour at various pressures led to the conclusion that the luminescence of the oxide was essentially connected with the presence of dissolved phosphorus.

Phosphorus trioxide, as prepared by Thorpe and Tutton's method, invariably contained phosphorus, the bulk of which could be removed by several low-temperature recrystallisations from carbon disulphide. The remainder was removable by exposure of the oxide to light and subsequent volatilisation from the red product.

The pure oxide so obtained melted at 23·8°, *i.e.*, 1·4° higher than the unpurified product, and lacked many of the properties formerly attributed to phosphorus trioxide. For instance, it neither glowed nor oxidised in moist or dry oxygen at the ordinary temperature and was unaffected by sunlight. When it was heated in a sealed bulb with dry oxygen at 300 mm. pressure, fuming and very faint glowing were observed at about 200°. By addition of pure phosphorus to the pure oxide the properties previously regarded as characteristic of phosphorus trioxide were restored.

The trioxide was found to dissolve 1·7 g. of phosphorus per 100 g. when saturated at 25°.

It is not yet known if the absorption of oxygen by the impure oxide is due to phosphorus alone or to phosphorus and phosphorus trioxide together, but this point is being investigated.

A study of the oxidation products of phosphorus in oxygen and

of phosphorus trioxide in oxygen and ozonised oxygen is being continued.

The author wishes to thank Professor Sir James Walker, F.R.S., for the interest he has taken and the encouragement he has given her in the prosecution of this investigation.

UNIVERSITY OF EDINBURGH. [*Received, May 19th*, 1928.]

CCXLI.—*The Action of Fluorine upon Aqueous Solutions of Chromium and Manganese Salts.*

By FRIEDRICH FICHTER and ERNST BRUNNER.

OUR researches on electrochemical oxidation of organic compounds have fully demonstrated the efficiency of a platinum anode as a powerful oxidising agent, and we noted especially the formation of organic peroxides and peracids, which are the intermediate products in the different forms of the Kolbe reaction. Since this effect is to be attributed to oxygen formed under a very high potential, and since there is no fundamental difference between electrochemical oxidation and ordinary chemical oxidation, we anticipated that similar results could be achieved by purely chemical means if the reagents furnished oxygen of the same high potential.

The positive end of the table of electrochemical potentials (first supplement, Deutsche Bunsen-Gesellschaft, 1915), measured in *N*-solutions of the respective salts, represents a number of such oxidising agents, several of which (*e.g.*, hydrogen peroxide, quadrivalent lead, and ozone) are frequently employed:

Lower stage of oxidation.		Higher stage of oxidation.	Potential.
$2H_2O$	$\longrightarrow$	$H_2O_2 + 2H^{\cdot}$	+ 1·8 volts
$Co^{\cdot\cdot}$	$\longrightarrow$	$Co^{\cdot\cdot\cdot}$	+ 1·8 ,,
$Pb^{\cdot\cdot}$	$\longrightarrow$	$Pb^{\cdot\cdot\cdot\cdot}$	+ 1·8 ,,
$O_2 + H_2O$	$\longrightarrow$	$O_3 + 2H^{\cdot}$	+ 1·9 ,,
$2F'$	$\longrightarrow$	F_2	+ 1·9 ,,

The figures in the table are somewhat uncertain, and the value for fluorine is probably too low. Von Wartenberg (*Z. anorg. Chem.*, 1926, **151**, 313) has recently found that the heat of formation of 1 g.-mol. of hydrogen fluoride in aqueous solution is equal to 74·6 Cal., instead of 50·3 Cal., the generally adopted value of Berthelot and Moissan. Latimer (*J. Amer. Chem. Soc.*, 1926, **48**, 2868) estimates the potential of gaseous fluorine to be as high as + 2·85 volts, direct measurements being impossible, since fluorine reacts instantaneously with water.

In spite of the well-known and powerful chemical affinity of

fluorine, its effect upon aqueous solutions of mineral salts does not appear to have been examined by Moissan, and even Ruff, who used gaseous fluorine in the preparation of the highest fluorides of the platinum metals, does not mention its use in this way.

Our assumption that fluorine, owing to its position in the potential table, would act as the most powerful oxidising agent proved to be correct, for we have prepared crystalline potassium and ammonium persulphates by its action upon the corresponding bisulphates, and perphosphates, percarbonates, and perborates in a similar way (*Helv. Chim. Acta*, 1923, **6**, 640; 1926, **9**, 467; 1927, **10**, 549). The oxidising power of fluorine is, therefore, at least equal to that of a platinum anode. The formation of persulphates from bisulphates might be written as $2KHSO_4 + F_2 = K_2S_2O_8 + 2HF + 42{\cdot}6$ Cal., or as $2SO_4'' + F_2 = S_2O_8'' + 2F'$. If we adopt the first equation, we should write the electrochemical formation of persulphates in a similar way: $2KHSO_4 + O = K_2S_2O_8 + H_2O$, whereas the usual explanation emphasises the ionic reaction $2SO_4'' = S_2O_8'' + 2\ominus$. The difference between the two conceptions is purely formal.

The oxidising power of fluorine, however, surpasses that of a platinum anode, for by introducing it into sulphuric acid of medium concentration we obtain sulphur tetroxide ($H_2SO_4 + F_2 = SO_4 + 2HF$), a very labile compound which exists only a few hours and decomposes with evolution of ozone. Berthelot had previously obtained this tetroxide by treating a mixture of sulphur dioxide with excess of oxygen in an ozoniser. Our method gives better yields, but the tetroxide cannot be isolated from its solution. The production of ozone in the electrolysis of concentrated sulphuric acid with platinum anodes must, apparently, be explained by the intermediate formation of the same labile sulphur tetroxide.

These reactions of fluorine upon acids or anions are capable of wide extension, for we have recently found that nitric and perchloric acids furnish extremely labile peroxides or peracids. We now describe the action of fluorine upon kations of a lower valency.

Marshall discovered that a well-cooled solution of cobaltous sulphate in sulphuric acid gives, by electrolysis, the sulphate of tervalent cobalt (J., 1891, **59**, 760), and Fichter and Wolfmann (*Helv. Chim. Acta*, 1926, **9**, 1093) prepared the same salt by passing fluorine into a solution of cobaltous sulphate in sulphuric acid. The latter noted that in such cases the anion of the salt is of importance, for only the sulphate can be thus oxidised and the concentration of free sulphuric acid has to be kept between certain limits. Although this preparation of cobaltic sulphate requires a relatively high concentration of sulphuric acid, no mechanism other than the

orthodox ionic explanation ($2Co'' + F_2 = 2Co''' + 2F'$) has hitherto been suggested, but we prefer the hypothesis that the labile sulphur tetroxide, formed by interaction of fluorine and sulphuric acid, is the true oxidising agent: $2CoSO_4 + SO_4 = Co_2(SO_4)_3$.

Our experiments with chromium salts corroborate this conception. A solution of chromium alum, acidified with very dilute sulphuric acid, is not altered by the passage of fluorine for several hours, but if the concentration of free acid is as high as $1{\cdot}5N$, a regular oxidation to chromic acid sets in, and is easily recognised by the change of colour from violet to orange-yellow. Higher concentrations of sulphuric acid up to $7{\cdot}5N$ have the same effect. The oxidation is certainly indirect, for if the amount of chromic acid is determined by titration, the fresh solution, which evolves ozone, has about 1·5 times the possible oxidising power. After standing over-night or heating on a water-bath, the excess of oxidising substances is destroyed, and the solution has an oxidising value corresponding exactly to the theoretical amount of chromic acid. The oxidising substance must be sulphur tetroxide, for it is effective at 0°, whereas persulphate oxidises chromic salts only at higher temperatures.

We may conclude from these experiments that the electrochemical oxidation of chromium alum to chromic acid is also an indirect one. Since it is essential that the sulphuric acid be concentrated (Höchster Farbwerke, D.R.-P. 103,360, 1898), we suggest that this is because the acid must be strong enough to furnish sulphur tetroxide.

If a dilute solution of potassium dichromate is treated with fluorine, it becomes green and is reduced to a chromic salt, most probably the fluoride. Our crude fluorine always contains free hydrogen fluoride; the action of fluorine upon an aqueous solution furnishes hydrofluoric acid, and its concentration would be sufficient for the formation of chromic fluoride. In this case, fluorine acts as a reducing agent. This contradictory behaviour must be explained by the intermediate formation of hydrogen peroxide, thus: $2H_2O + F_2 = H_2O_2 + 2HF$. The formation of hydrogen peroxide can be detected by working with a small quantity of chromic acid and in the presence of dilute sulphuric acid; under these conditions and by proper cooling we obtain the blue perchromic acid, soluble in ether. Perchromic acid is very unstable, losing oxygen and yielding chromic salts; in this manner the reduction of dichromate can be carried out quantitatively by prolonged treatment with fluorine.

The concentrated sulphuric acid used in the oxidation of chromium alum to chromic acid fulfils two functions: first, it furnishes the sulphur tetroxide, the true oxidising agent, and, secondly, it prevents

the formation of hydrogen peroxide, and hence of perchromic acid which would lead to reduction.

Both reactions which chromium compounds undergo under the influence of gaseous fluorine must be explained by intermediate products formed by the action upon water or sulphuric acid. Consequently, in oxidations with fluorine, an excess of this gas is often detrimental, for it destroys, by secondary reactions, the substances which it formed first.

The electrochemical oxidation of manganese salts has been investigated by several authors (see a review by Sem, *Z. Elektrochem.*, 1915, **21**, 425). As the action of fluorine is in most cases a true counterpart of electrochemical oxidation, we directed our attention to the similarity as well as to the difference of the two methods.

When a suspension of manganous fluoride in water is treated with a stream of fluorine, it dissolves slowly, furnishing a red liquid, from which a saturated solution of potassium fluoride precipitates the complex potassium manganifluoride, K_2MnF_5,H_2O (discovered by Christensen, *J. pr. Chem.*, 1887, **35**, 57), a pink crystalline powder. In this case, we admit the possibility of a direct oxidation without formation of an intermediate product; but the reaction is far from being complete: the formation of hydrogen peroxide can be detected from the beginning, and, moreover, we have a complicated equilibrium between manganous and manganic fluorides, hydrofluoric acid, and hydrogen peroxide, where the temperature, concentration, and duration of the treatment with fluorine are of influence. Sometimes the pink colour diminishes even during the experiment.

The formation of manganese tetrafluoride proved to be impossible by this method.

In most cases we used platinum vessels for our experiments, but the metal appeared to have a catalytic effect in decomposing salts of high valency (compare hydrogen peroxide), especially when it had lost its smoothness. To avoid this danger, we employed graphite beakers, but even with this precaution it was impossible to obtain manganese tetrafluoride. Further, a solution of the yellow complex salt, K_2MnF_6 (Weinland and Lauenstein, *Z. anorg. Chem.*, 1899, **20**, 40), was immediately reduced to the red salt by fluorine. This inability of fluorine to oxidise manganous fluoride to manganese tetrafluoride is completely parallel to the failure to effect this reaction by anodic oxidation (Mueller and Koppe, *ibid.*, 1910, **68**, 160).

Manganous sulphate, in the presence of sulphuric acid, was more readily oxidised, probably owing to the intervention of sulphur tetroxide. The formation of manganic sulphate, the first stage of

easy to recognise, by the red colour. On continued passage of fluorine, this colour changes to a brownish-red and finally to a dark brown, and the oxidising power corresponds to a nearly complete transformation into the labile sulphate of quadrivalent manganese, $Mn(SO_4)_2$. If the concentration of the sulphuric acid is not high, hydrolysis sets in, and manganese dioxide is formed; but, although it is easy to obtain a yield exceeding 90%, the formation of manganese dioxide is not a certain proof of the primary formation of a salt of quadrivalent manganese, for it may be formed by hydrolysis of manganic sulphate, one-half of which is reduced to manganous sulphate and subsequently re-oxidised.

In order to bring the oxidation to the highest stage, permanganic acid, it is useful to have a low concentration of manganous ions and a high concentration of sulphuric acid, the latter being necessary to avoid the formation of hydrogen peroxide. In these circumstances, the characteristic colour of permanganate ions becomes visible the more quickly the smaller the concentration of manganous sulphate.

Manganic phosphate is very stable; a strong solution of manganous carbonate in an excess of phosphoric acid turns a deep amethyst-red on treatment with fluorine, but the oxidation is not complete. This is easy to understand, for the solution contains traces of hydrogen peroxide. We assume that fluorine acts first upon the phosphoric acid, forming monoperphosphoric acid, which readily oxidises manganous sulphate in acid solution to manganic phosphate. Schmidlin and Massini, who first prepared monoperphosphoric acid, considered the amethyst colour to be due to permanganic acid (*Ber.*, 1910, **43**, 1166), but spectrographic examination shows at once that the dark lines are lacking.

All the experiments with manganese salts and fluorine correspond exactly with the results of electrochemical oxidations. In all cases fluorine has proved to be at least as powerful an oxidising agent as a platinum anode, and our observations throw a new light on the mechanism of such oxidations, which are by no means simple. They depend largely on the anions, and also on intermediate products formed by primary oxidation of the acids, which are ignored in the theory of augmentation of positive charges (see p. 1864).

EXPERIMENTAL.

For the sake of brevity, we give for each reaction only one out of the great number of experiments carried out. (Fuller details will be published in E. Brunner's thesis.)

A. Chromic Alum and Fluorine.—(1) 0·9734 G. of chrome alum, 50 c.c. of water, and 2 c.c. of concentrated sulphuric acid were placed in a platinum crucible, cooled with ice, and treated with a current

of fluorine during 75 minutes. The solution became orange and evolved ozone. After addition of potassium iodide and starch solution, 84·17 c.c. of 0·1*N*-thiosulphate solution were needed; this corresponds to 0·2808 g. of CrO_3, whereas the possible maximum is only 0·1949 g.

(2) 1·1365 G. of the alum and the above amounts of water and acid were treated as before. After standing over-night and being heated on the water-bath, the solution was mixed with potassium iodide and titrated with 0·1*N*-thiosulphate solution (Found: 0·2281 g. CrO_3. Calc.: 0·2276 g.).

B. *Potassium Dichromate and Fluorine.*—(1) *Formation of perchromic acid.* One drop of 0·5*N*-potassium dichromate, 40 c.c. of water, and 5 c.c. of 2*N*-sulphuric acid were placed in a platinum crucible, carefully cooled with ice and salt, and a few bubbles of fluorine introduced. By shaking with ether, previously freed from organic peroxides, the dark blue colour of perchromic acid was extracted.

(2) *Reduction to chromic fluoride.* 0·5216 G. of dichromate was dissolved in 50 c.c. of water, and, after cooling in ice, treated during 3 hours with fluorine. The green solution was partly evaporated in a platinum dish on the water-bath and then precipitated by ammonia; it furnished 0·2664 g. of chromium oxide (Calc.: 0·2695 g. Yield 98·9%).

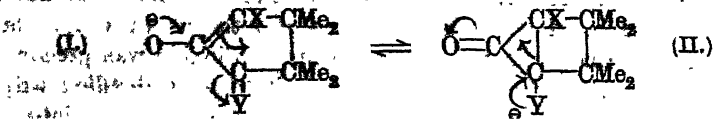
C. *Manganous Fluoride and Fluorine.*—(1) Manganese fluoride was suspended in water, by a stirrer, in a platinum crucible, and treated with fluorine until nearly all was dissolved; the unattacked fluoride was removed by filtration through a hardened filter in a paraffined funnel, and the clear solution mixed with a saturated solution of potassium fluoride, whereupon a pale red crystalline powder separated, which was washed with very dilute hydrofluoric acid and dried at room temperature (Found: Mn, by conversion into Mn_3O_4, 22·37; active F, 7·67. Calc. for K_2MnF_5,H_2O: Mn, 22·32; active F, 7·72%).

(2) 0·6384 G. of manganous fluoride, suspended in water, cooled in ice, and treated during 1½ hours with fluorine, dissolved and became red. After addition of potassium iodide and hydrochloric acid, it required 48·02 c.c. of 0·1*N*-thiosulphate solution, *i.e.*, yield = 69·9%.

D. *Manganous Sulphate and Fluorine.*—(1) *Formation of manganese dioxide.* 10 C.c. of a 1·11*N*-solution of manganous sulphate, with 0·3039 g. of $Mn^{"}$, were treated exactly as in C(2); the solution remained colourless, but manganese dioxide was precipitated. Both the solution and the precipitate were distilled with hydrochloric acid, and the evolved chlorine was passed into a

solution of potassium iodide. The liberated iodine consumed 101·2 c.c. of 0·1*N*-thiosulphate solution. If the manganous salt had been transformed completely into dioxide, 110·6 c.c. would have been needed; the yield was therefore 91·5%.

(2) *Formation of the sulphate of quadrivalent manganese.* A mixture of 2 c.c. of a 1·11*N*-solution of manganous sulphate, with 0·0608 g. of $Mn^{\cdot\cdot}$, and 4·0820 g. of concentrated sulphuric acid (95·64%) was cooled in ice and treated with fluorine during 5 hours; it became red, then browner, and finally dark brown. Concentrated hydrochloric acid and potassium iodide were added and the iodine was titrated [Found: 19·2 c.c. Calc.: 22·1 c.c. Hence yield of $Mn(SO_4)_2$ = 86·9%]. This result is probably too high, for the solution may have contained sulphur tetroxide in addition to quadrivalent manganese.



(3) *Formation of permanganic acid.* Three drops of a 1·11*N*-solution of manganous sulphate, 10 c.c. of water, and 3·3902 g. of concentrated sulphuric acid (95·64%) were treated with fluorine. After 15 minutes, the violet colour of permanganic acid appeared and became more and more distinct; the spectroscope revealed clearly the five absorption bands. With two drops of the manganous sulphate solution the violet colour appears after a few minutes; with four drops a treatment of one hour is needed, but the colour becomes very rich.

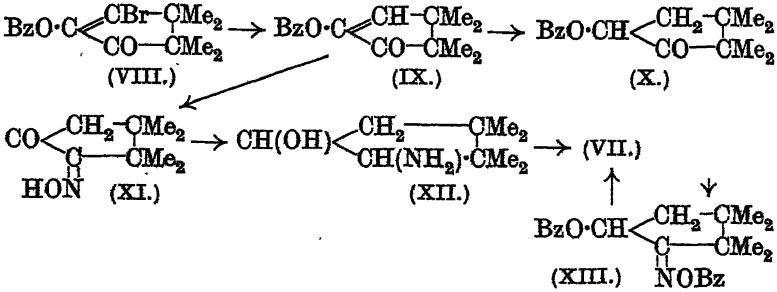
CCXLII.—*On the Possibility of Ring-chain Valency Tautomerism, and of a Type of Mobile-hydrogen Tautomerism analogous to the Wagner–Meerwein Re-arrangement. Part III. Orientation of some Cyclic Derivatives of Phorone.*

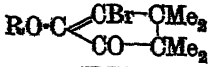
By CHRISTOPHER KELK INGOLD and CHARLES WILLIAM SHOPPEE.

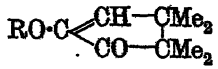


FRANCIS and WILSON (J., 1913, **103**, 2238), who first examined the cyclic derivatives of phorone, ascribed formulæ of type II, but in Part I (this vol., p. 365) it was shown that formulæ of type I are also necessary in order fully to account for the reactions of the substances.

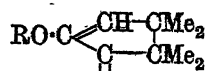
Amongst the derivatives studied in Part I was a series of acyl and alkyl derivatives of "bromohydroxyphorone" and hydroxyphorone (X = H, Br; Y = O). The acetoxy- and methoxy-compounds were definitely shown to have structure I, and this has now been confirmed as regards the acetoxy-derivatives (III) and (IV) by the preparation of the crystalline *oxime* (VI) of the dihydro-compound (V): the oxime, on complete reduction, yields 2 : 2 : 3 : 3-tetramethyl*cyclo*pentylamine (VII).

The benzoyloxy-derivatives (VIII) and (IX) were not definitely oriented in the previous communication, but a number of reactions were studied, and of these the most significant is the formation of an oxime, to which formula (XI) was assigned, from the benzoyloxy-compound (IX) with extrusion of the benzoyl group.



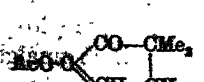


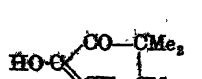
The reaction was illustrated by means of Francis and Willson's formula, but it was pointed out that definite structural conclusions could not be reached without knowledge as to whether the oximino-group enters the same position as, or another position than, that from which the extruded benzoyl group had been removed. This point has now been elucidated. In the first place, the constitution assigned to the oxime has been confirmed by reduction *via* the hydroxy-amine (XII) to 2 : 2 : 3 : 3-tetramethyl*cyclo*pentylamine (VII). Secondly, the benzoyloxy-compound, although unaffected both by zinc and by sodium amalgam in acetic acid, was successfully reduced to a dihydro-derivative (X) by means of hydrogen in the presence of palladised barium sulphate. This compound is identical with the more fusible benzoyl derivative of tetramethyl*cyclo*-pentanolone, described in Part II (this vol., p. 1662), in which the constitution of the derivative was definitely established by the

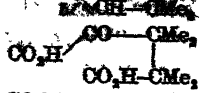


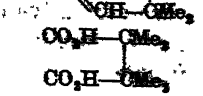
conversion of its benzoyloxime (XIII) into 2 : 2 : 3 : 3-tetramethyl-*cyclo*pentylamine. These reactions show that the benzoyloxybromo- and benzoyloxy-compounds possess the structures (VIII) and (IX) and that in the oximination of the latter the benzoyl group is extruded from another position than that into which the oximino-group is introduced.

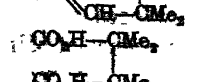
The action of hydroxylamine in causing the fission of an ester grouping in this and in some other parallel cases which are recorded in the experimental portion appears to be analogous to the process of hydrolysis, and we have confirmed the fact that hydroxylamine may exhibit this action on simple substances by showing that phenyl benzoate is broken down into phenol and benzoic acid by boiling with hydroxylamine in alcohol.

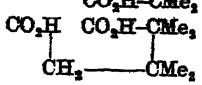


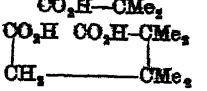












Investigation of the *p*-bromobenzyloxybromo- and *p*-bromobenzyloxy-compounds (XIV) and (XV) has shown that these possess structures similar to those of the benzoyl derivatives. The *p*-bromobenzyloxy-compound (XV) is extremely resistant to reduction and it had been found (this vol., p. 376) to yield an oxime (XVI) which, when reduced, gave a hydroxy-amine isomeric with that obtained by reduction of the oxime (XI). The former hydroxy-amine has now been reduced to 2 : 2 : 3 : 3-tetramethyl*cyclo*pentyl-amine and must therefore be a geometrical and not a position isomeride.

(XIV.)

(XV.)
(R = C_7H_6Br.)

(XVI.)

Part I recorded a study of the oxidation of hydroxybromo- and hydroxy-phorone and certain derivatives, and it was suggested that the observations could best be interpreted on the assumption that the monocyclic unsaturated forms of these substances could undergo oxidative fission in two directions (*a*) and (*b*) (formulæ below). These studies have now been extended with results which are shown in the table below and appear to suggest that the normal mode of fission produced by oxidation with potassium ferricyanide is at (*b*) whilst fission with hydrogen peroxide occurs preferentially at (*a*).

Substance oxidised.			
Product with ferricyanide.			
Product with hydrogen peroxide.		—	

EXPERIMENTAL.

5-Acetoxy-2 : 2 : 3 : 3-tetramethylcyclopentanoneoxime (VI).—The pure dihydroacetoxy-derivative, b. p. 120—121°/10 mm. (3·0 g.), hydroxylamine hydrochloride (1·2 g.), and anhydrous sodium acetate (1·4 g.) were heated together in absolute alcoholic solution on the steam-bath for 3 hours. On pouring the product into water, an oil was precipitated, the ethereal extract of which was washed with sodium hydrogen carbonate solution, dried, and evaporated. The pale yellow oil obtained did not crystallise after being kept for 2 months; the ethereal solution was therefore treated with dry hydrogen chloride at 0°, and the *oxime hydrochloride* was obtained as a colourless crystalline solid, m. p. 136—137° (with evolution of hydrogen chloride).

Solution in 2*N*-sodium carbonate and extraction with ether yielded the *oxime* as a rapidly solidifying oil. It separated from ligroin (b. p. 40—60°) in well-formed prisms, m. p. 93° (Found: C, 61·9; H, 9·2. $C_{11}H_{19}O_3N$ requires C, 62·0; H, 9·0%).

Reduction of the oxime (VI). The oxime (1·0 g.) was reduced with 2½% sodium amalgam (50 g.) by the method given in Part I (this vol., p. 393), and the product identified as 2 : 2 : 3 : 3-tetramethyl*cyclo*pentylamine.

Reduction of the oxime (XI). The oxime was first reduced in the usual manner with sodium amalgam and glacial acetic acid; the basic portion of the product was then boiled with hydriodic acid (*d* 1·7) and red phosphorus under reflux for 2 hours. The product was distilled in steam, the distillate being disregarded; the contents of the flask were then made strongly alkaline and again steam-distilled. The ethereal extract of the distillate, dried with anhydrous potassium carbonate, was evaporated to small bulk under a column, and treated with ethereal picric acid. The resulting picrate was identified as that of 2 : 2 : 3 : 3-tetramethyl*cyclo*pentylamine.

Reduction of 5-Benzoyloxy-2 : 2 : 3 : 3-tetramethyl-Δ⁴-cyclopentenone with Palladium and Hydrogen (IX).—When an acetic acid solution of the pure derivative, m. p. 68° (1·9 g.), was shaken with palladised barium sulphate (equivalent to 0·5 g. palladium) in an atmosphere of hydrogen at ordinary pressure, absorption ceased after 1 hour, 150 c.c. being taken up (calc. for 1 mol. of hydrogen, 160 c.c.). The mixture was poured into water, and an ethereal extract of the product was washed twice with ice-cold 5% sodium hydroxide solution and dried with calcium chloride. Evaporation yielded the reduction product as a rapidly crystallising oil. It separated from ligroin (b. p. 40—60°) in pearly plates, m. p. 60°. Identity was established by mixed melting points and by analysis (Found: C, 73·6; H, 8·0. Calc. for $C_{10}H_{16}O_2$: C, 72·3; [illegible]).

Reduction of 5-p-*Bromobenzyloxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenone* (XV).—The pure derivative (1·5 g.) in glacial acetic acid solution was shaken with palladised barium sulphate and hydrogen (pressure, 30 lb./sq. in.). Little absorption took place, and the bulk of the product was recovered unchanged. A substance, m. p. 26—27°, was isolated, but the quantity was insufficient for analysis.

Reduction of the Acetyl Derivative of 5-p-*Bromobenzyloxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenoneoxime* (XVI).—The acetoxime (1·0 g.) was reduced with 2½% sodium amalgam (100 g.) in acetic acid in the usual manner, and the basic portion of the product isolated and converted into the picrate of 5-hydroxy-2 : 2 : 3 : 3-tetramethyl-*cyclo*pentylamine, m. p. 210—215° (decomp.) (compare this vol., p. 403). The picrate was boiled for 2 hours under reflux with hydriodic acid (*d* 1·7) and red phosphorus, and the liquid was made alkaline and steam-distilled. The reduction product was isolated by extraction with ether and identified as 2 : 2 : 3 : 3-tetramethyl-*cyclo*pentylamine by conversion into the picrate.

Fission of Esters in Presence of Hydroxylamine.—Phenyl benzoate. The ester (2·0 g.), dissolved in absolute alcohol (20 c.c.), was treated with hydroxylamine hydrochloride (0·7 g.) and anhydrous sodium acetate (0·85 g.) on the steam-bath for 1 hour. The product was worked up into neutral, acid, and quasi-acid fractions: the latter two yielded benzoic acid and phenol respectively. The benzoic acid weighed 0·23 g., which is equivalent to 20% hydrolysis. A blank experiment in which the hydroxylamine hydrochloride was omitted yielded no trace of benzoic acid or phenol.

5-*Benzoyloxy*-2 : 2 : 3 : 3-*tetramethyl*cyclo*pentanone* (X). The derivative (1·0 g.), hydroxylamine hydrochloride (1·0 g.), and anhydrous sodium acetate (1·2 g.), when similarly treated for 3 hours, gave an oily oxime (compare this vol., p. 1669) and practically pure benzoic acid (yield, 0·25 g.).

5-*Methoxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenone*. When the methoxy-compound was similarly treated with hydroxylamine hydrochloride (several mols.) and anhydrous sodium acetate for 3 hours, the product consisted mainly of a solid, together with a trace of oil. The solid was washed with ligroin and crystallised twice from boiling alcohol; it then had m. p. 210—211° (decomp.) (Found: C, 58·6, 58·7; H, 8·8, 8·7; N, 14·6, 14·6. Calc. for $C_9H_{16}O_2N_2$: C, 58·7; H, 8·7; N, 15·0%) and was identified as the dioxime of 3 : 3 : 4 : 4-tetramethyl*cyclo*pentan-1 : 2-dione by direct comparison and by mixed melting point.

Oxidation of 5-*Benzoyloxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenone* (IX).—(A) *With potassium ferricyanide.* The benzoyloxy-compound (1·0 g.) and anhydrous potassium carbonate (2·0 g.),

dissolved in dilute alcohol, were treated at 60° with potassium ferricyanide (9·3 g.) in alcoholic solution during 5 days, and the mixture was left for 5 days at the same temperature. The solution was acidified and the acid products were removed with ether; on evaporation a mixture of solid acids was obtained. After successive removals of benzoic acid, by solution in water, cooling to 0° and filtration, an acid was obtained which, after crystallisation from ethyl acetate–ligroin, had m. p. 140° and was identified as the lactonic acid of γγ-dihydroxy-ααββ-tetramethylglutaric acid by mixed melting point and by hydrolysis (Found: C, 53·2; H, 6·9. Calc. for $C_9H_{14}O_5$: C, 53·4; H, 6·9%).

(B) *With hydrogen peroxide.* The derivative (0·5 g.), dissolved in an aqueous acetone solution of sodium carbonate containing a trace of ferrous sulphate, was treated with 2·4 c.c. of 3% hydrogen peroxide at 0°. Benzoic acid was precipitated on acidification and removed by filtration. From the filtrate, an acid was obtained which, after two crystallisations from ethyl acetate–ligroin, had the characteristic form and m. p. (144°) of ααββ-tetramethylglutaric acid. The melting point of a mixture with a genuine specimen was 143—144°, but that of a mixture with the above lactonic acid was depressed to 115—120°.

Oxidation of 5-*Acetoxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenone* (IV).—The pure acetoxy-compound was prepared from the hydroxy-ketone by treatment with acetyl chloride in pyridine solution. The pale yellow oil (0·5 g.) and anhydrous potassium carbonate (1·0 g.), dissolved in dilute alcohol, were treated with alcoholic potassium ferricyanide (5·0 g.), added during 3 days, and the mixture was left for 3 days at 45°. After extraction with ether, the liquid was acidified and again extracted with ether. This extract yielded a solid acid which, after crystallisation from ethyl acetate–ligroin, had m. p. 190° and was identified as tetramethylsuccinic acid. The yield was poor and the neutral ethereal extract gave some unchanged acetoxy-compound on evaporation.

Oxidation of 2 : 2 : 3 : 3-*Tetramethyl*-Δ^5-cyclo*penten*-5-*ol*-4-*one* (2 : 2 : 3 : 3-*Tetramethyl*-[0,1,2]-dicyclo*pentan*-4-*ol*-5-*one*).—This was carried out with the quantities and by the procedure given above for the acetoxy-compound. A good yield of tetramethylsuccinic acid, m. p. 190° after crystallisation from ethyl acetate–ligroin, was obtained.

One of us (C. W. S.) wishes to record his indebtedness to the Royal Commission of 1851 for a Senior Studentship.

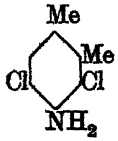
THE UNIVERSITY, LEEDS. [*Received, May 25th*, 1928.]

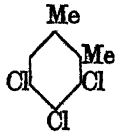
CCXLIII.—*Dichloro-o-xylenes.*

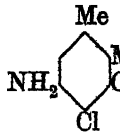
By LEONARD ERIC HINKEL, ERNEST EDWARD AYLING, and LILIAN COLLIER BEVAN.

WITH the exception of 3 : 5-dichloro-*o*-xylene (Crossley, J., 1902, **81**, 1536) there appears to be no trustworthy information concerning the dichloro-*o*-xylenes. The direct chlorination of *o*-xylene was considered by Claus and Kautz (*Ber.*, 1885, **18**, 1367) to yield only a liquid dichloro-derivative, b. p. 227° and solidifying at 3°, which Claus and Groneweg (*J. pr. Chem.*, 1891, **43**, 352) believed to be 4 : 5-dichloro-*o*-xylene. Koch, however, showed (*Ber.*, 1890, **23**, 2321) that the liquid was a mixture, which slowly deposited a dichloro-*o*-xylene, m. p. 73°. Villiger (*Ber.*, 1909, **42**, 3529), moreover, considered the dichlorophthalic anhydride obtained by Claus and Groneweg from the liquid derivative to be a mixture.

Ferrand (*Compt. rend.*, 1901, **133**, 169) claims to have identified three dichloro-derivatives from the chlorination. He regards the solid, m. p. 73°, as the 3 : 4-dichloro-*o*-xylene and the two liquids, b. p. 226—228° and 229·5—231·5°, as mixtures of the 4 : 5- and 3 : 5-dichloro-derivatives; little reliance, however, can be placed on his work, since he employed *o*-xylene containing as much as 10% of *m*-xylene. From the solid, he obtained a dichlorophthalic anhydride, m. p. 186°, corresponding to the 4 : 5- and not the 3 : 4-dichloro-anhydride as he supposed (compare Villiger, *loc. cit.*).







The chlorination of pure *o*-xylene under conditions designed to produce dichloro-derivatives has been studied with the result that all the dichloro-*o*-xylenes can now be described. The only one about which any doubt exists is 3 : 6-dichloro-*o*-xylene. It is produced in such small amount that it has not been possible thoroughly to investigate its properties, but it will be described more fully when experiments now in progress for its synthesis are completed.

The first action of chlorine on *o*-xylene results in the formation of 3- and 4-monochloro-derivatives in the proportion of 1 to 2 (Kruger, *Ber.*, 1885, **18**, 1755; Claus and Baeyer, *Annalen*, 1893, **274**, 304), and on further chlorination the former should yield the 3 : 4- and the 3 : 6- and the latter the 3 : 4- and the 4 : 5-dichloro-derivatives. Dichlorination, therefore, should yield principally 3 : 4- and 4 : 5-dichloro-*o*-xylenes together with a small quantity of 3 : 6-dichloro-*o*-xylene. This has been proved to be the case.

The dichloroxylene of m. p. 76° yields on oxidation a dichlorophthalic anhydride, m. p. 187°, and is therefore 4 : 5-*dichloro*-o-*xylene* (compare Villiger, *loc. cit.*). On nitration it yields 4 : 5-*dichloro*-3-*nitro*-o-*xylene*, reduction of which gives 4 : 5-*dichloro*-o-3-*xylidine*.

Diazotisation of the xylidine by the Gattermann process gave an altogether unforeseen result, tetrachloro-*o*-xylene being formed with the expected 3 : 4 : 5-trichloro-*o*-xylene. The former probably results from further chlorination occurring in the presence of the cuprous chloride and concentrated hydrochloric acid.

The liquid dichloro-*o*-xylene, b. p. 234°, on nitration gave as the main product a *mononitro*-derivative. Substitution of chlorine for the amino-group in the corresponding amine (m. p. 63°) gave 3 : 4 : 5-trichloro-*o*-xylene, m. p. 96° (I) (compare Hinkel, J., 1920, **117**, 1296). This trichloro-compound could theoretically be obtained from all the dichloro-*o*-xylenes except the 3 : 6-isomeride; consequently, since the constitution of the 4 : 5-isomeride has been established, the liquid compound must have the chlorine atoms either in the 3 : 4- or the 3 : 5-positions and the dichloro-*o*-xylidine, m. p. 63°, must therefore be represented by (II) or (III).

(II.)  (I.)  (III.) 

3 : 5-Dichloro-*o*-4-xylidine (II) has been synthesised by Crossley from *o*-4-acetoxylidide (J., 1904, **85**, 264) and has now been obtained more conveniently from 3 : 5-dichloro-*o*-xylene. The melting points of the amine so prepared and of its acetyl derivative have been raised to 47·5° and 126°, respectively. The amine of m. p. 63° must consequently be 5 : 6-*dichloro*-o-4-*xylidine* (III), and the liquid of b. p. 234° 3 : 4-*dichloro*-o-*xylene*. This orientation has been substantiated by the conversion of 3 : 4-dichloro-*o*-xylene into the corresponding *dichloro*-o-*diamine*, which gave the characteristic test for *o*-diamines with phenanthraquinone.

The constitutions of three out of the four possible dichloro-*o*-xylenes are thus definitely established and the fourth isomeride, m. p. 68°, must therefore be 3 : 6-*dichloro*-o-*xylene*. Reduction of its mononitro-derivative gave the corresponding xylidine. Replacement of the amino-group by chlorine in the usual manner gave, instead of 3 : 4 : 6-trichloro-*o*-xylene (compare Hinkel, *loc. cit.*), a mixture of chloro-compounds which, owing to the small quantity available, could not be further investigated.

The three dichloro-*o*-xylenes yield the same tetrachloro-*o*-xylene on further chlorination.

EXPERIMENTAL.

Chlorine was passed into pure *o*-xylene (b. p. 143·5°) at —10° in presence of iron filings until the gain in weight corresponded to

2 atoms of chlorine. After being washed with water and with sodium hydroxide solution, the liquid was dried and distilled; on boiling, a vigorous evolution of hydrogen chloride occurred due to the decomposition of intermediate additive compounds. Three main fractions were ultimately collected: (i) 225—230°; (ii) 230—236°; (iii) 236—246°.

Fraction (i), when cooled in ice, deposited 3 : 6-*dichloro*-o-*xylene*, which crystallised from methyl alcohol in white, iridescent flakes, m. p. 68°, b. p. 227° (corr.) (Found: Cl, 40·9. $C_8H_8Cl_2$ requires Cl, 40·6%).

Fraction (ii) gave 3 : 4-*dichloro*-o-*xylene*, b. p. 234° (corr.). This solidified when cooled in a mixture of ice and salt and melted at 9° (Found: Cl, 40·7%).

Fraction (iii), when cooled in ice, gave 4 : 5-*dichloro*-o-*xylene*, which crystallised from methyl alcohol in long, transparent needles, m. p. 76°, b. p. 240° (corr.) (Found: Cl, 40·6%).

Conversion of the Dichloro-o-*xylenes into Tetrachloro*-o-*xylene.*—Each of the dichloro-*o*-xylenes was chlorinated as described by Hinkel (J., 1920, **117**, 1300). Repeated crystallisation from alcohol or ethyl acetate of the tetrachloro-*o*-xylene so prepared does not entirely remove the last trace of any trichloro-*o*-xylene formed during the chlorination, but this can be readily achieved by crystallisation from carbon tetrachloride containing a small quantity of chloroform. The pure compound so obtained melts at 227°.

Oxidation of 4 : 5-*Dichloro*-o-*xylene.*—2 G. of 4 : 5-dichloro-*o*-xylene were heated with 15 c.c. of nitric acid (*d* 1·15) in a sealed tube for 7 hours at 180°. The resulting liquid was evaporated to dryness over solid caustic soda in a vacuum. The acid obtained melted at 199—200° after crystallisation from water. The anhydride, prepared by heating the acid with acetyl chloride, separated from carbon tetrachloride in small crystals, m. p. 187° (compare Villiger, *loc. cit.*).

4 : 5-*Dichloro*-3-*nitro*-o-*xylene.*—2 G. of 4 : 5-dichloro-*o*-xylene were added to 20 c.c. of a mixture of fuming nitric acid (3 vols.) and glacial acetic acid (1 vol.) and heated on a steam-bath for 7 minutes. The solution was poured into water; the solid which separated crystallised from alcohol in fine white needles, m. p. 117° (Found: Cl, 32·5. $C_8H_7O_2NCl_2$ requires Cl, 32·3%).

4 : 5-*Dichloro*-3 : 6-*dinitro*-o-*xylene.*—1 G. of 4 : 5-dichloro-*o*-xylene was heated for 10 minutes with 5 c.c. of sulphuric acid and 3 c.c. of nitric acid. The white solid that separated crystallised from alcohol in colourless prisms, m. p. 210° (Found: Cl, 26·65. $C_8H_6O_4N_2Cl_2$ requires Cl, 26·8 %).

4 : 5-*Dichloro*-o-3-*xylidine.*—A mixture of 3 g. of 4 : 5-dichloro-

3-nitro-*o*-xylene, 9 g. of iron filings, and 30 c.c. of glacial acetic acid was heated with frequent stirring for several hours on a steam-bath. The resulting solid was made alkaline and distilled with steam. The solid product crystallised from aqueous alcohol in long, silky needles, m. p. 88° (Found: Cl, 37·2. $C_8H_9NCl_2$ requires Cl, 37·3%). The *acetyl* derivative, prepared in the usual manner, crystallised from aqueous alcohol in small rosettes, m. p. 197° (Found: Cl, 30·8. $C_{10}H_{11}ONCl_2$ requires Cl, 30·6%).

Conversion of 4 : 5-*Dichloro*-o-3-*xylidine into* 3 : 4 : 5-*Trichloro*-o-*xylene.*—The amine, 0·5 g. at a time, was dissolved by heating in 10 c.c. of concentrated hydrochloric acid and 25 c.c. of water. The finely divided hydrochloride obtained on cooling was diazotised, and the whole was poured into a solution of cuprous chloride and distilled in steam. The solid obtained, after crystallising from methyl alcohol, softened at 95° and melted completely at 105°. It was obviously a mixture, although not consisting of 3 : 5 : 6- and 3 : 4 : 5-trichloro-*o*-xylenes, which melt at 47·5° and 96° respectively. Repeated fractional crystallisation from carbon tetrachloride containing varying amounts of chloroform resolved the mixture into 3 : 4 : 5-trichloro-*o*-xylene, m. p. 96°, and tetrachloro-*o*-xylene, m. p. 227°.

4 : 5-*Dichloro*-3 : 6-*diamino*-o-*xylene.*—4 : 5-Dichloro-3 : 6-dinitro-*o*-xylene was reduced in alcoholic solution by means of sodium hydrosulphite. After removal of the alcohol under reduced pressure, the solid was crystallised from alcohol, the *diamine* separating in small, white needles, m. p. 186°, decomp. 187° (Found: Cl, 34·4. $C_8H_{10}N_2Cl_2$ requires Cl, 34·6%).

3 : 4-*Dichloro*-5-*nitro*-o-*xylene.*—3 : 4-Dichloro-*o*-xylene was nitrated as described on p. 1876. The solid obtained was crystallised from alcohol, and separated from a small quantity of the 6-nitro-isomeride by washing with light petroleum (b. p. 40—60°) at 0°. It finally crystallised from light petroleum in clumps of hard, prismatic needles, m. p. 78° (Found: Cl, 32·0. $C_8H_7O_2NCl_2$ requires Cl, 32·3%).

3 : 4-*Dichloro*-5 : 6-*dinitro*-o-*xylene.*—3 : 4-Dichloro-*o*-xylene was nitrated as described on p. 1876. The resulting solid crystallised from ethyl acetate in prismatic needles, m. p. 172° (Found: Cl, 27·1. $C_8H_6O_4N_2Cl_2$ requires Cl, 26·8%).

5 : 6-*Dichloro*-o-4-*xylidine.*—3 : 4-Dichloro-5-nitro-*o*-xylene was reduced as described on p. 1876. The solid product crystallised from aqueous alcohol in a felt-like mass of white needles, m. p. 63° (Found: Cl, 37·1. $C_8H_9NCl_2$ requires Cl, 37·3%). The *acetyl* derivative crystallised from aqueous alcohol in fine needles, m. p. 147° (Found: Cl, 30·6. $C_{10}H_{11}ONCl_2$ requires Cl, 30·6%).

3 : 4-*Dichloro*-5 : 6-*diamino*-o-*xylene*.—3 : 4-Dichloro-5 : 6-dinitro-*o*-xylene was reduced with sodium hydrosulphite as described on p. 1877. The *diamine* obtained crystallised from aqueous alcohol in hair-like crystals, m. p. 176° (Found: Cl, 34·8. $C_8H_{10}N_2Cl_2$ requires Cl, 34·6%). The diamine and phenanthraquinone in acetic acid gave a yellow precipitate.

3 : 6-*Dichloro*-4-*nitro*-o-*xylene*.—3 : 6-Dichloro-*o*-xylene was nitrated under the conditions described on p. 1876. The solid obtained crystallised from methyl alcohol in small, white needles, m. p. 95° (Found: Cl, 32·2. $C_8H_7O_2NCl_2$ requires Cl, 32·3%).

3 : 6-*Dichloro*-4 : 5-*dinitro*-o-*xylene*, prepared from 3 : 6-dichloro-*o*-xylene by the method described on p. 1876, crystallised from alcohol in small, transparent, colourless prisms, m. p. 220° (Found: Cl, 26·4. $C_8H_5O_4N_2Cl_2$ requires Cl, 26·8%).

3 : 6-*Dichloro*-o-4-*xylidine*, obtained by reduction of 3 : 6-dichloro-4-nitro-*o*-xylene as described on p. 1876, crystallised from aqueous alcohol in white, silky needles, m. p. 82° (Found: Cl, 37·2. $C_8H_9NCl_2$ requires Cl, 37·3%). It could not be acetylated by the ordinary methods, but when it was heated for 1 hour on the water-bath with acetic anhydride–acetyl chloride the *diacetyl* derivative was obtained. This crystallised from alcohol in transparent prisms, m. p. 141° (Found: Cl, 25·8. $C_{12}H_{13}O_2NCl_2$ requires Cl, 25·9%).

3 : 5-*Dichloro*-4-*nitro*-o-*xylene*.—5 G. of 3 : 5-dichloro-*o*-xylene prepared according to Crossley (J., 1902, **81**, 1533) were heated for 30 minutes on a water-bath with 125 c.c. of a mixture of fuming nitric acid (3 vols.) and glacial acetic acid (1 vol.). The solid obtained by pouring the mixture into water crystallised from alcohol in a felt-like mass, m. p. 92°, which became waxy when pressed. It could not be freed from the small quantity of the 6-nitro-isomeride also formed during the nitration (Found: Cl, 32·1. $C_8H_7O_2NCl_2$ requires Cl, 32·3%).

3 : 5-*Dichloro*-o-4-*xylidine*.—The crude 3 : 5-dichloro-4-nitro-*o*-xylene (m. p. 92°) (5 g.) was reduced with iron filings and acetic acid as described on p. 1876. The solid produced was dissolved in alcohol; a few yellowish-white needles, m. p. 171°, then separated. The filtrate from these crystals (which were probably 3 : 5-dichloro-6-amino-*o*-xylene and were not further examined) was diluted slightly with water; the fine needles that separated crystallised from aqueous alcohol in small rosettes, m. p. 47·5°. The acetyl derivative, prepared in the usual manner, crystallised from boiling water in fine needles, m. p. 196° (Crossley gives m. p. 44·5° and 186°, respectively).

UNIVERSITY COLLEGE, SWANSEA. [*Received, April 14th*, 1928.]

CCXLIV.—*The Nitration of* m-*Fluorophenol.*

By HERBERT HENRY HODGSON and JOSEPH NIXON.

ALTHOUGH *m*-fluorophenol has been prepared (Swarts, *Bull. Acad. roy. Belg.*, 1913, 241), no mention of the nitro-derivatives appears in the literature. The present investigation proceeds on similar lines to those of the *m*-chloro- and *m*-bromo-analogues (J., 1925, **127**, 1599; 1926, 155). A trustworthy method for the preparation of *m*-fluoronitrobenzene from *m*-nitroaniline is described.

Monosulphonation of 3-fluoro-2-nitrophenol in the cold or at 100—120° appears to give exclusively 3-fluoro-2-nitrophenol-4-sulphonic acid, since only 3-fluoro-2 : 6-dinitrophenol could be obtained from it by further mononitration.

The orientations proposed for the dinitro-compounds follow from the modes of preparation and by analogy with the corresponding chloro- and bromo-compounds (*loc. cit.*). In addition is the following evidence: (1) All three dinitro-compounds are convertible into 3-fluoro-2 : 4 : 6-trinitrophenol, indicating that the two nitro-groups in each compound are in meta-positions to each other. (2) The 4 : 6-dinitro-compound gives 4 : 6-dinitro-*m*-phenylenediamine, and the 2 : 6- and 2 : 4-isomerides give the same 2 : 4-dinitro-*m*-phenylenediamine, when heated in a sealed tube with aqueous ammonia. (3) 3-Fluoro-2 : 4- and -2 : 6-dinitrophenols both give 2 : 4-dinitroresorcinol when boiled with aqueous sodium hydroxide.

Certain marked differences in behaviour of the fluoro- and the other halogeno-analogues have been observed: (*a*) 3-Fluoro-4 : 6-dinitrophenol forms a stable, yellow, crystalline silver derivative which does not exhibit transformations similar to those of the chloro-, bromo-, and iodo-compounds. The silver derivative of 3-fluoro-2 : 6-dinitrophenol, however, is produced initially as a yellow gel which rapidly passes through an orange-red gel stage into a permanent orange-red crystalline form. (*b*) The silver derivative of 3-fluoro-2 : 4-dinitrophenol has a deeper red colour than its 2 : 6-isomeride—the chloro- and bromo-analogues are yellow, crystalline substances. (*c*) All the silver derivatives are readily soluble in aqueous ammonia (compare the insolubility of the silver derivatives of the 3-halogeno-2 : 4 : 6-trinitrophenols and the varying solubility of the lower nitrated products). (*d*) The 3-fluoro-2-, -4-, and -6-nitrophenols resist acetylation. (*e*) Anomalies are exhibited in the m. p.'s: *e.g.*, 3-fluoro-4-nitrophenol has m. p. 56·5°, its analogues have m. p.'s 122°, 131°, and 124°; 3-fluoro-2 : 4 : 6-trinitrophenol has m. p. 173°, whereas the chloro-, bromo-, and iodo-compounds melt at 114°, 149°, and 197°, respectively.

EXPERIMENTAL.

Initial Materials.—A solution of *m*-nitroaniline (140 g.) in 60% hydrofluoric acid (450 c.c.) in a copper beaker was diazotised at 0° with a rapid stream of nitrous fumes (30 minutes) and added gradually to 60% hydrofluoric acid (75 c.c.), in a lead pot with a copper reflux condenser, heated on a boiling water-bath. The mixture was kept hot for 1 hour and the *m*-fluoronitrobenzene then isolated, in 25% yield, by steam-distillation. It was reduced to *m*-fluoroaniline, which was converted in almost quantitative yield into *m*-fluorophenol (Hodgson, E.P. 200,714).

Nitration.—The methods of preparation of the 3-fluoronitrophenols are those described for the corresponding chloro- and bromo-analogues with appropriate modifications.

3-*Fluoro*-6-*nitrophenol* (yield, 6 g. from 29 g. of *m*-fluorophenol) is volatile in steam and crystallises from light petroleum in yellow needles, m. p. 32°, having a characteristic sweet nitrophenolic odour (Found: N, 9·1. $C_6H_4O_3NF$ requires N, 8·9%). The *sodium* salt crystallises from water in red needles. The orange-brown *silver* salt, which deepens in colour on keeping, is readily soluble in aqueous ammonia and gradually decomposes in boiling aqueous solution. The *methyl ether* crystallises from light petroleum in colourless micro-parallelepipeds, m. p. 52° (Found: N, 8·3. $C_7H_6O_3NF$ requires N, 8·2%), and the *benzoate* in colourless micro-scales, m. p. 110—111° (Found: N, 5·6. $C_{13}H_8O_4NF$ requires N, 5·4%). The acetates of this substance and of its isomerides could not be prepared by any of the usual methods.

3-*Fluoro*-4-*nitrophenol* (yield, 9 g.) is non-volatile in steam and crystallises from water or light petroleum in long, colourless needles, m. p. 42° (Found: N, 9·2%). The *sodium* salt crystallises from water in long, pale yellow needles. The bright yellow *silver* salt, although more soluble in water and aqueous ammonia than its isomerides, also decomposes on boiling (Found: Ag, 40·6. $C_6H_3O_3NFAg$ requires Ag, 40·9%). The *methyl ether* crystallises from light petroleum in colourless needles, m. p. 56·5° (Found: N, 8·3%), and the *benzoate* in colourless, rectangular micro-plates, m. p. 118° (Found: N, 5·6%).

3-*Fluoro*-2-*nitrophenol*, prepared by the nitration of disulphonated *m*-fluorophenol (J., 1925, 127, 1600), passes over on hydrolysis in a current of steam as a reddish oil which, after being frozen and pressed, crystallises from light petroleum in short red needles, m. p. 39° (Found: N, 9·0%). The formation of a hydrate could not be detected (compare J., 1926, 156, 631). The reddish-brown *sodium* salt is exceedingly soluble in water, and the very deep reddish-brown *silver* salt is readily soluble in hot water, but gradually decomposes,

and in aqueous ammonia. The *methyl ether* crystallises from light petroleum in long, colourless needles, m. p. 43·5° (Found: N, 8·4%), and the *benzoate* in clusters of white needles, m. p. 114° (Found: N, 5·5%).

3-*Fluoro*-4 : 6-*dinitrophenol* was prepared from *m*-fluorophenol and from 3-fluoro-6- and -4-nitrophenols in the same way as the corresponding bromo-compound (*loc. cit.*, p. 158). It is readily volatile in steam and crystallises from water or light petroleum in colourless needles, m. p. 80° (Found: N, 14·1. $C_6H_3O_5N_2F$ requires N, 13·9%).

In each preparation a non-volatile product was 3-fluoro-2 : 4 : 6 trinitrophenol. The silver salt, prepared like its analogues (*locc. cit.*, pp. 1603, 159, 634), separates very gradually in long, fine yellow needles and does not exhibit the phenomena recorded for the other three analogues. It is soluble in aqueous ammonia and stable in hot water (Found: Ag, 34·6. $C_6H_2O_5N_2FAg$ requires Ag, 34·9%).

3-*Fluoro*-2 : 6-*dinitrophenol* was prepared by recorded methods (*locc. cit.*, pp. 1602, 159) from 3-fluoro-2- and -6-nitrophenols. It crystallises from light petroleum in colourless needles, m. p. 68·5° (Found: N, 14·05%). The *silver* salt is readily soluble in aqueous ammonia and hot water, giving deep yellow solutions; from the aqueous solution, on cooling, it separates in orange-red microneedles (Found: Ag, 34·7%).

3-*Fluoro*-2 : 4-*dinitrophenol* was obtained together with 3-fluoro-2 : 6-dinitrophenol when *m*-fluorophenol was disulphonated and then dinitrated as in the procedure for the chloro-analogue (*loc. cit.*, p. 1602). The product was hydrolysed in a current of steam, the long, colourless needles of 3-fluoro-2 : 6-dinitrophenol which separated from the distillate on cooling were removed, and the filtrate was rendered alkaline and concentrated to a small bulk; on acidification, 3-*fluoro*-2 : 4-*dinitrophenol* was precipitated. It crystallised from light petroleum in pale yellow micro-parallelepipeds, m. p. 138—139° (Found: N, 13·9%), and was much more soluble in water than the other two isomerides. The deep red *silver* salt (Found: Ag, 34·6%) is readily soluble in hot water and aqueous ammonia, giving deep yellow solutions.

Action of Ammonia on 3-*Fluoro*-4 : 6-, -2 : 6-, *and* -2 : 4-*dinitrophenols*.—These (0·5 g.) were separately heated in sealed tubes with concentrated ammonia (5 c.c.) at 150° during 2 hours. On cooling, the products were obtained as brownish-yellow needles. The 4 : 6-dinitro-*m*-phenylenediamine obtained from the first-named compound melted at about 300° (compare Nietzki and Schedler, *Ber.*, 1897, **30**, 1667) (Found: N, 28·5. Calc.: N, 28·3%). 3-Fluoro-2 : 6- and -2 : 4-dinitrophenols each gave 2 : 4-dinitro-*m*-phenylenediamine, m. p. and mixed m. p. 264° (Barr, *Ber.*, 1888,

21, 5545, gives m. p. 250°; Hodgson and Moore, *loc. cit.*, give m. p. 258°) (Found: N, 28·4% and 28·2%, respectively).

The two specimens of 2:4-dinitroresorcinol obtained from 3-fluoro-2:6- and -2:4-dinitrophenols by the action of boiling aqueous sodium hydroxide melted, alone or mixed with each other, at 146° (compare *loc. cit.*, p. 160).

3-*Fluoro*-2:4:6-*trinitrophenol* crystallises from water in characteristic, almost colourless, hexagonal plates, m. p. 173° (Found: N, 17·1. $C_6H_2O_7N_3F$ requires N, 17·0%), which are not volatile in steam but sublime slowly from boiling concentrated sulphuric acid. This property is exhibited also by the other halogeno-analogues. The substance does not possess the violent sternutatory properties of the iodo-analogue, forms deep yellow solutions in water and alcohol, and is not brominated when its aqueous solution is treated with bromine. The bright yellow crystalline *silver* salt is readily soluble in aqueous ammonia and hot water.

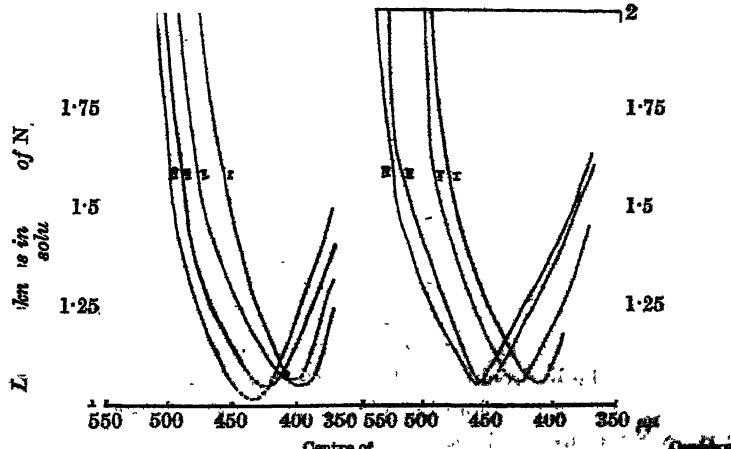
The authors' thanks are due to the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, April 27th*, 1928.]

CCXLV.—*Studies in Colour and Constitution. Part III. The Influence of the Methylthiol, Methoxy-, and Chlorine Groups on the Colours of the Nitrobenzaldehydephenylhydrazones.*

By HERBERT HENRY HODGSON and FREDERICK WILLIAM HANDLEY.

THE study of the influence of the methylthiol, methoxy-, and chlorine groups on the colours of simple azo-dyes (this vol., p. 162) has been extended to certain nitrobenzaldehydephenylhydrazones containing these substituents in ortho- and para-positions in the benzaldehyde and phenylhydrazine residues, respectively. In addition to the visual observations, absorption spectra data are included; work in the latter field has been recorded by Baly and Tuck (J., 1906, 89, 982), Hewitt, Johnson, and Pope (J., 1914, 105, 364), and Ciusa and Rastelli (*Atti R. Accad. Lincei*, 1919, 28, ii, 366; 1920, 29, ii, 146; *Gazzetta*, 1922, 52, ii, 121, 126).



Trustworthy conclusions could not be deduced from the colours of the solid hydrazones because of their wide variation with the mode of crystallisation, but equimolecular alcoholic solutions exhibited a well-defined order. The absorption spectra curves of the *p*-nitrobenzaldehydephenylhydrazones confirm the results of the visual observations, and the relative order of the effects of the substituents

is the same whether these are present in the aldehyde or the hydrazine residue and is independent of the position of the nitro-group, *viz.*,

o-Cl, (Lemon-yellow) → *o*-SMe, *p*-Cl, H, *o*-OMe, *p*-SMe, → *p*-OMe. (Deep reddish-orange)

Increasing depth

The influence of the substituents is, in general, less marked than in the case of the azo-dyes; *e.g.*, (1) *o*-methoxyl is much less bathochromic; (2) *p*-methoxyl, which is only slightly bathochromic in the dyes, has a strong effect in the hydrazones, equalling or even exceeding that of *p*-methylthiol; (3) the feeble hypsochromic effect of *o*-chlorine in the dyes becomes most pronouncedly so in the hydrazones.

	Centre of band.		Centre of band.
I	p-*Nitrobenzaldehyde*-o-*chlorophenylhydrazone* . . .	395	I p-*Nitrobenzaldehyde*-p-*chlorophenylhydrazone* . . .	413
II	p-*Nitrobenzaldehyde*-o-*methylthiolphenylhydrazone* . .	405	II p-*Nitrobenzaldehydephenylhydrazone*	425
III	p-*Nitrobenzaldehydephenylhydrazone*	425	III p-*Nitrobenzaldehyde*-p-*methylthiolphenylhydrazone* . .	455
IV	p-*Nitrobenzaldehyde*-o-*methoxyphenylhydrazone* . . .	433	IV p-*Nitrobenzaldehyde*-p-*methoxyphenylhydrazone* . . .	465

The colours of the solutions in alcoholic potash of all the hydrazones studied were in accord with the generalisations of Chattaway and Clemo (J., 1923, 123, 3041); as, however, the same marked differences in colour did not occur, no further conclusions have been drawn therefrom.

The Chromoisomerism of p-*Nitrobenzaldehydephenylhydrazone.*—Ciusa and Vécciotti (*Atti R. Accad. Lincei*, 1911, 20, i, 803) recorded the existence of two polymorphic forms of *p*-nitrobenzaldehydephenylhydrazone, and the following related phenomena have now been observed: (1) The hydrazone crystallises from glacial acetic

acid in yellow needles, m. p. 194°, which slowly become pale orange without alteration of m. p. (2) Exposure to ultra-violet light for some hours or to sunlight for some weeks failed to bring about any such change as that noted by Chattaway (J., 1906, **89**, 462) for benzaldehydephenylhydrazone. (3) Addition of water to a solution of *p*-nitrobenzaldehydephenylhydrazone in glacial acetic acid precipitated a yellow variety which changed in a few seconds into the red form of Ciusa and Vecciotti, a transformation which occurs in the absence of sunlight.

Attempts to prepare *o*-methylthiolbenzaldehyde were unsuccessful.

EXPERIMENTAL.

4-Methylthiolphenylhydrazine, which could not be prepared satisfactorily by the methods of Hodgson and Beard (*J. Soc. Chem. Ind.*, 1926, **45**, 56T) and Thompson (*J. Soc. Dyers and Col.*, 1921, **31**, 7), was obtained as follows: The diazonium compound obtained from 4-thioanisidine hydrochloride (8 g.), concentrated hydrochloric acid (40 c.c.), and 20% aqueous sodium nitrite (18 c.c.) at 0° was reduced at 0° with stannous chloride (24 g.) and hydrochloric acid (24 c.c.), and the *hydrochloride* produced was collected after 1 hour, washed with a little concentrated hydrochloric acid, and recrystallised from hot water, separating in colourless, glistening plates (Found: N, 15·0; Cl, 18·45. $C_7H_{10}N_2S,HCl$ requires N, 14·8; Cl, 18·6%).

4-Methylthiolphenylhydrazine, liberated from a hot aqueous solution of the hydrochloride by alkali or sodium acetate, crystallised from water in colourless plates, m. p. 60° (Found: S, 20·8. $C_7H_{10}N_2S$ requires S, 20·65%).

2-Methylthiolphenylhydrazine.—The reaction product obtained by the above method from 2-thioanisidine hydrochloride consisted of a mixture of a pale brown, amorphous substance A (1·1 g.) and a colourless, crystalline substance B (7 g.). A melted below 100°, was insoluble in cold and decomposed by boiling water, and was probably analogous to certain compounds described by Thompson (*loc. cit.*), who suggested a diazo-hydrazide structure for them (compare Bamberger, *Ber.*, 1895, **28**, 840); it has not been studied further. B contained tin, which was removed from an aqueous solution of the substance by hydrogen sulphide; addition of alkali or sodium acetate then gave *2-methylthiolhydrazine*, which crystallised from water in colourless needles, m. p. 40° (Found: S, 20·6. $C_7H_{10}N_2S$ requires S, 20·65%). Both 2- and 4-methylthiolphenylhydrazine reduce Fehling's solution and ammoniacal silver nitrate in the cold, and decompose on keeping.

4-Methylthiolbenzaldehyde (phenylhydrazone, m. p. 138°) was obtained by Friedländer and Lenk's method (*Ber.*, 1912, **45**, 2084).

Preparation of the Hydrazones.—A mixture of the aldehyde in glacial acetic acid and of a slight excess of the hydrazine hydrochloride in aqueous solution was warmed gently for 5 minutes. The hydrazone separated on cooling and was recrystallised from dilute acetic acid.

Absorption Spectra.—These were obtained by means of a glass spectrograph, the source of light being an iron arc, and are shown in the figure.

The authors desire to thank Dr. H. Lowery for advice with respect to the absorption spectra, and the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, May 9th*, 1928.]

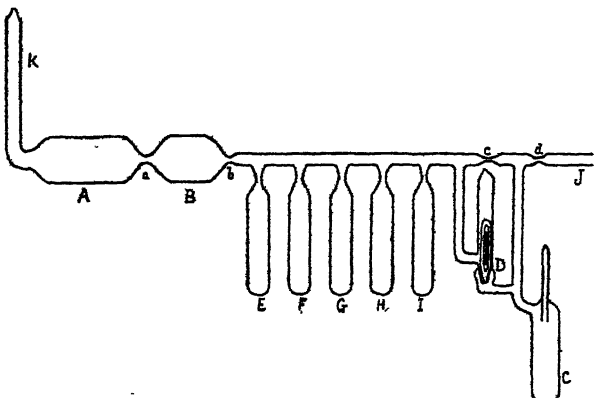
CCXLVI.—*The Influence of Intensive Drying on the System Nitrogen Peroxide–Nitric Oxide–Oxygen.*

By JOHN WILLIAM SMITH.

IT was observed by Baker (J., 1894, 65, 611) that when carefully purified gaseous nitric oxide and oxygen, which had been dried separately over phosphoric oxide for 10 days, were mixed, no

combination occurred, and on opening the container under dry mercury no contraction in volume was noted. When a trace of moisture was introduced, however, combination immediately took place. Hasche (*J. Amer. Chem. Soc.*, 1926, **48**, 2253) found that the velocity of reaction between carefully dried nitric oxide and oxygen was reduced by 20% if the walls of the reaction vessel were coated with paraffin wax. This he ascribed to a protective action, preventing the gases from coming into contact with the walls of the vessel, which would hold adsorbed water vapour. Briner (*J. Chim. physique*, 1926, **23**, 848) unsuccessfully attempted to repeat Baker's observations: although the duration of the drying in each case ranged from 3 months to a year, in no case did the gases remain colourless on mixing.

The thermal dissociation of nitrogen peroxide into nitric oxide and oxygen has been fairly fully worked out, notably by Richardson (J., 1887, **51**, 397), Bodenstein and Katayama (*Z. physikal. Chem.*, 1909, **69**, 44), and Bodenstein, Boes, Lindner, and Ramstetter (*ibid.*, 1922, **100**, 68). At pressures of the order of 1 atmosphere, considerable dissociation occurs at 500—600°. Hence it was thought that, if nitrogen peroxide were heated in the intensively dried state, interesting phenomena might be observed. Three possibilities presented themselves: (*a*) The nitrogen peroxide might not dissociate, *i.e.*, the colour of the gas would not diminish on strong heating. (*b*) Complete dissociation might occur into nitric oxide and oxygen, which might not recombine on cooling. (*c*) Some intermediate stage might be attained, and a definite shift in the chemical equilibrium might be observed, corresponding to a shift in the inner equilibrium in the case of dried liquids.



Experimental.

Apparatus No. 1.—The first apparatus employed was an adapted form of that used by Lewis and Rideal in their work on the synthesis of hydrogen bromide and the dissociation of hydrogen iodide (*J. Amer. Chem. Soc.*, 1926, **48**, 2554). The whole was constructed of "Durosil" glass which had been freed from capillaries by the method recommended by Smits and his co-workers (J., 1926, 2657). The apparatus (Fig. 1) consisted essentially of a horizontal tube carrying a series of reaction bulbs, *E*, *F*, *G*, *H*, *I*, each of which was connected to the horizontal tube through a capillary neck suitable for vacuum sealing. This tube connected at one end to two bulbs, *B* and *A*, for use when charging with phosphoric oxide, as described below, and at the other end to the vacuum pump system and to a bulb to serve as a nitrogen peroxide reservoir, connected as shown in the diagram.

After being cleaned with chromic acid, washed thoroughly, and dried roughly by heating to 300° in an electric oven, the apparatus was assembled and connected to a high-vacuum pump system through the tube *J*. After being tested for leakage, the whole apparatus was heated at 300° for 2 days, a high vacuum (10^{-6} mm.) being maintained in it during this period.

Dry air was then admitted, and pure resublimed phosphoric oxide introduced into *A* through *K*, which was immediately sealed off. The apparatus was again evacuated, all the tubes except bulb *A* being heated to 300°. It was then allowed to cool and bulb *A* was heated. In this way the pentoxide was sublimed in a vacuum from bulb *A* to bulb *B*. Bulb *A* was then removed by sealing off at

FIG. 1.

the constriction *a*. The reaction bulbs were heated strongly again, and, after cooling, the pentoxide was sublimed into them by heating the bulb *B*. The bulb *I* was kept free from the pentoxide, so as to serve as a standard of comparison, and a free space was left in each of the other bulbs to admit of colour observation being made through the tube. Each had been drawn from a tube of uniform diameter, so that rough quantitative colour comparison could be carried out. The bulb *B* was then drawn off at the constriction *b*, and constriction *c* was also sealed. This disconnected the bulbs from the vacuum pump system and from the reservoir bulb *D*. Dry air was then admitted to *C*, followed by a little phosphoric oxide and a few c.c. of dry nitrogen tetroxide. The tetroxide was frozen in liquid air and the bulb was evacuated again. Occluded air was removed by allowing the tetroxide to re-melt in a vacuum, after which it was frozen again and the bulb re-evacuated. When a high vacuum was reached, the whole apparatus was sealed off at the constriction *d*.

After being left for a few days to allow the nitrogen peroxide to dry, the bulb *C* was cooled in ice, and the septum *D* broken. The gas was allowed to reach equilibrium with the liquid at 0°, and the separate bulbs were sealed off. Thus these bulbs were all sealed off at the same known pressure, *viz.*, the vapour pressure of nitrogen peroxide at 0°—264 mm. The bulbs were matched on a tintometer to a Lovibond scale.

After the gas had been allowed to dry in the bulbs for a further 3 days, one of the bulbs was heated at 250—300° for 1½ hours. On cooling, the colour of the gas had diminished to about one-half of its original intensity, and after a further 5 hours' heating it became practically colourless. At the same time the phosphoric oxide changed completely in appearance, passing from a finely crystalline, snow-like mass into colourless transparent plates of a type that had not been observed previously under any conditions. None of the other bulbs became so nearly colourless, but in each case a very marked diminution in the intensity was observed.

The fact that the gas became so nearly colourless was at first thought to be due to an almost complete shift of the equilibrium towards the dissociated side. At this stage, however, I was privileged to see a private communication from Dr. Hartung to Professor Donnan, in which it was noted that nitrogen tetroxide reacted with phosphoric oxide at temperatures above 200°, yielding an addition compound. The formation of this compound appeared to account for the great diminution in the colour of the bulbs, so, as other lines of attacking the problem were being commenced, this investigation was abandoned.

Some months later, however, a rough analysis of the residual gas was carried out by breaking the tip of a bulb under pure, dry, recently boiled mercury. In tube 1 the colour intensity was about one-quarter of the initial intensity. On opening, the volume of residual gas was 4·43 c.c. The mercury, however, rose steadily, and after 24 hours the volume was 2·26 c.c. An attempt was then made to introduce a small drop of water into the tube, but the mercury only was moistened. An immediate further contraction in volume was observed. This was complete in 5 minutes, a further 24 hours' standing causing no further change. The residual gas was then mainly nitric oxide, for on introduction of a drop of ferrous sulphate solution a brown colour was produced. A small bubble of other gas of unknown composition remained, however. The total volume of the tube was 13·04 c.c., so the pressure of the gas remaining after heating was 238 mm. The bulb had been filled at a pressure of 264 mm., so it was concluded that some combination must have taken place with the phosphoric oxide, but that the pressure change was

small compared with the colour change. Hence it was concluded that the colour change was not due entirely to a simple absorption of the gas by the pentoxide.

This was confirmed by tube 2, in which the colour was too faint to match on the tintometer. The tip of this bulb was opened under mercury which had been carefully purified and dried over phosphoric oxide for a year. On the introduction of moisture, the residual gas immediately turned dark brown and contracted in volume from 3·02 c.c. to 1·30 c.c. The peroxide formed gradually acted on the mercury, leaving a bubble of nitric oxide at the top of the tube. The residual gas pressure (130 mm.) was here again large compared with that to be expected from the colour change.

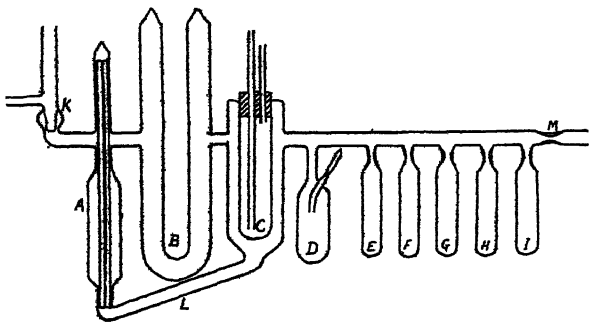
Hence it seems quite clear that the tubes contained nitric oxide and oxygen, and that the moisture introduced caused recombination. The actual temperature of drying is here unknown—it may have been carried out before the tube was heated, or at the higher temperature when the gas was somewhat dissociated. At first sight, this result seems to be in conflict with that obtained later with apparatus No. 3, but it may be accounted for if the drying were effected while the gas was slightly dissociated. However, the residual gas appears to have been much more dissociated than normal nitrogen peroxide would be on heating to the same temperature under the same pressure, so a definite shift in the equilibrium seems to be indicated. These experiments seem to confirm Baker's observation of the co-existence of nitric oxide and oxygen gases in the intensively dried state.

Apparatus No. 2.—It was thought desirable to be able to test the residual gas in the absence of the nitrogen peroxide–phosphoric oxide compound, since it might be alleged that admission of moisture to the tubes liberated the peroxide from this compound, thereby causing the dark brown coloration. Such an explanation was regarded as very improbable, for the moisture was introduced only on the surface of the mercury and no gas was seen to rise from the compound, which was covered with mercury. This explanation, also, did not account for the rapid volume change. In this apparatus the bulbs were prepared with a constriction in the middle. Phosphoric oxide was sublimed into one section of this only, so that the compound could be removed before testing. The bulbs were sealed off at the same pressure as before.

Tube No. 6 was heated at 300° for 18 hours, the gas being then quite colourless. After cooling, the tube was divided, and the section free from the phosphoric oxide was opened under dry mercury. A considerable volume of gas remained. On the introduction of moisture, very little effect was noticed, however, and the

residual gas proved to be 2·81 c.c. of oxygen and 1·41 c.c. of nitrogen. No nitrous oxide could be found. The ratio of oxygen to nitrogen (2 : 1) is here so exact that it must be supposed that the peroxide had completely dissociated into its elements, although it does not normally do so at any appreciable rate at this temperature. The volume of the bulb was 22·17 c.c. The loss was presumably due to the compound formation. The bulb containing the compound was treated in exactly the same way, but no coloration was observed on introducing a little moisture, and no volume contraction occurred. Hence the results obtained with tubes 1 and 2 were shown not to be due to the decomposition of this compound. The introduction of excess of moisture caused only comparatively slow decomposition.

Tube 7 was heated at 300° for 6 hours. It was then cooled, divided, and opened under mercury as in the previous case. The mercury was not so dry as that used before, and the residual gas gradually contracted in volume and became deeper reddish-brown in colour. Rather more moisture than was desired was then added, and a definite aqueous film was produced. This caused a sharp contraction in volume which was complete in a very short time, further standing producing only a minute further contraction. The residual gas was again nitrogen and oxygen, but in about equal parts. The fact that the proportion of oxygen to nitrogen was lower in this case may be attributed to the interaction of some of the nitrogen peroxide with mercury, yielding nitric oxide, which absorbed more oxygen, and so on. This appears to confirm the observations made with tubes 1, 2, and 6.



The decomposition of the nitric oxide into its elements may be catalysed by the large surface of the phosphoric oxide, which was very finely divided indeed. It has been found that the elements are not formed to any great extent on heating the nitrogen peroxide–phosphoric oxide addition compound, and also that they are not formed to any extent if the tubes are heated in the initial stages to temperatures of about 350°, at which the phosphoric oxide passes into the glass-like form. The evidence of these experiments shows that a temperature of about 300° and prolonged heating favour the decomposition of the nitrogen oxides into their elements, a reaction which is almost entirely absent at slightly lower temperatures.

The Effect of Intensive Drying at the Ordinary Temperature on the Thermal Dissociation of Nitrogen Peroxide into Nitric Oxide and Oxygen.—The apparatus employed (Fig. 2) embodied the circulation principle used by Smits, de Liefde, Swart, and Claassen (J., 1926, 2659). The liquid evaporated from the bulb *A*, passed through the phosphoric oxide in the wide U-tube *B*, and was condensed in *C*, which was cooled by a stream of water passing through the inner

tube, as shown. From here it ran back along the tube L into A. The apparatus was connected to a bulb, D, in which the liquid could be frozen out, and to a series of bulbs, E, F, G, etc., in which small amounts of the gas could be sealed off for testing purposes. The apparatus at this side ended in a connexion to a high-vacuum pump system through the constriction M. The constrictions joining the bulbs to the horizontal tube were not made very narrow, but the walls at these points were made very thick so that the bulbs could still be readily sealed off in a vacuum. This avoided the usual restriction on the diffusion of gases, and hence also of moisture from the bulbs—a very serious drawback to capillaries in drying apparatus.

The whole apparatus was constructed of capillary-freed "Pyrex" glass. It was heated under a high vacuum for a week, after which phosphoric oxide was sublimed into the U-tube B. The nitrogen

FIG. 2.

peroxide was introduced into D, where it was frozen out, the apparatus was evacuated, and the constriction M sealed off. The apparatus was kept in an air thermostat at about 30° while a stream of cold water was passed through the inner vessel, C. In this way a steady circulation was maintained, the average amount condensing being about 10 drops a minute.

After 3 months, the liquid was all condensed in bulb D. This was then placed in a bath at 0°, and when equilibrium was reached a bulb of the gas was sealed off. The colour of the gas in this bulb, when matched on a tintometer, was not appreciably different from that of a blank undried specimen. The bulbs were slowly heated together in an electric furnace. The colours deepened similarly up to about 400°; on raising the temperature further, however, the colour of the undried gas appreciably lightened owing to dissociation into nitric oxide and oxygen, but that of the dried gas remained constant, so far as could be judged visually. The colour difference was quite

perceptible at 500°, and at 600° it was very marked. It being thought possible that the rate of dissociation was very much retarded by the intensive drying, the bulbs were maintained at 550° for 24 hours. Even after this period, the nitrogen peroxide did not appear to have dissociated to any appreciable extent. On slow cooling, the colour of the moist bulb became about the same as that of the dry bulb at about 400°. On further rather rapid cooling to room temperature, the dry bulb remained somewhat darker than the undried one. About 3 hours were required before the colour of the former returned to that of the moist bulb. This was evidently due to the slow rate of polymerisation of the NO_2 molecules.

From this simple experiment the following deductions may be drawn. (*a*) Intensively dried gaseous nitrogen peroxide does not dissociate very considerably into nitric oxide and oxygen, even on heating at 550° for 24 hours. (*b*) The rate of polymerisation of the coloured NO_2 molecules to form the colourless N_2O_4 molecules is retarded by the intensive drying.

After drying for 6 months, another bulb was sealed off from the same apparatus. The complication had now arisen that the vapour pressure at 0° had so far increased that the colour of the gas in equilibrium with the liquid at 0° was much darker than in the specimen "wet" tube. Accordingly, the liquid was cooled in a freezing mixture until the colours were as nearly matched as possible. The bulb was then sealed off. It was observed later that this bulb was a little lighter in colour than the standard tube. On heating to 600°, however, it was appreciably darker. The tubes were maintained at about 620° for 24 hours, this temperature being as near to the softening point of the glass as it was thought safe to heat the bulb. The bulbs were then of equal colour intensity, and on cooling and re-heating all abnormality seemed to have disappeared from the bulb. This was probably due to the fact that at such high temperatures the "Pyrex" glass tends to decompose superficially, evolving a small quantity of water.

Summary.

When nitrogen peroxide is heated with phosphoric oxide, at least three reactions take place: (*a*) The pentoxide combines with the nitrogen peroxide, yielding the compound described by Hartung (private communication). (*b*) The nitrogen peroxide is dissociated into nitric oxide and oxygen to a greater extent than in the moist gas, and these products do not recombine on cooling. (*c*) The nitric oxide decomposes into its elements at a greater rate than normally. This reaction may be catalysed by the large surface of the phosphoric oxide.

A temperature of about 300° and prolonged heating favour reaction (*c*).

Nitrogen peroxide which had been intensively dried at the ordinary temperature did not dissociate very considerably into nitric oxide and oxygen, even on heating at 550° for 24 hours, but on heating at about 620° for the same period, it seemed to revert completely to the normal form, probably owing to a superficial decomposition of the glass.

In the dried gas the rate of polymerisation of the coloured NO_2 molecules to form the colourless N_2O_4 molecules is retarded.

In conclusion, the author desires to express his thanks to the Department of Scientific and Industrial Research for a grant, and especially to Professor F. G. Donnan, F.R.S., for his helpful advice and criticism throughout the progress of this research.

UNIVERSITY COLLEGE, LONDON. [*Received, May 4th*, 1928.]

CCXLVII.—*The Thermal Decomposition of Thiobenzanilide.*

By ARTHUR WILLIAM CHAPMAN.

IT is on record (Jacobson, *Ber.*, 1886, **19**, 1067) that thiobenzanilide decomposes when distilled, yielding hydrogen sulphide and 1-phenylbenzthiazole (I). As the thermal decomposition of the *S*-phenyl ether of thiobenzanilide (*N*-phenylbenziminophenyl thioether) had recently been investigated (J., 1926, 2296), it appeared desirable to study the decomposition of the parent thiobenzanilide in greater detail, and, after a preliminary trial had confirmed the original statement that hydrogen sulphide and 1-phenylbenzthiazole were produced, experiments were carried out to determine if possible the precise mechanism of the change.

The simplest reaction by which 1-phenylbenzthiazole might be produced is the following :

$$C_{13}H_{11}NS = C_{13}H_9NS + H_2.$$

Experiment showed that hydrogen is not evolved in the decomposition, so if this reaction does take place, all the hydrogen is absorbed by some reducible material.

Under certain conditions, thioanilides are readily oxidised to thiazoles (compare Jacobson, *loc. cit.*) and the formation of thiazole in this case might be attributed to atmospheric oxidation. The

reaction, however, proceeds equally well in an atmosphere of an inert gas, so the oxygen of the air plays no part in the decomposition.

The hydrogen sulphide is not produced by direct reduction of the thioanilide thus,

$$PhC(SH):NPh \xrightarrow{2H} PhCH:NPh + H_2S,$$

since neither benzalaniline nor benzaldehyde was detected among the products of the reaction.

Separation of all the products of decomposition was attempted and *s*-diphenylbenzenylamidine (II) (yield, 11—19%), stilbene, and tetraphenylthiophen (III) were isolated in addition to hydrogen sulphide (37—40%) and 1-phenylbenzthiazole (38—58%). The quantities of stilbene and tetraphenylthiophen formed could not be determined.

The presence of the amidine indicated that aniline was present at some stage of the process. The yield was not affected by careful drying of the material before heating, and the formation of the amidine could therefore not be attributed to hydrolysis of the anilide. Aniline could, however, be formed by reduction of the thioanilide thus,

$$Ph{\cdot}CS{\cdot}NHPh \xrightarrow{2H} Ph{\cdot}CHS + H_2N{\cdot}Ph,$$

the necessary hydrogen being furnished from the production of the thiazole. The thiobenzaldehyde would then decompose (compare Baumann and Klett, *Ber.*, 1891, **24**, 3307), yielding hydrogen sulphide, stilbene, and tetraphenylthiophen, all of which were actually isolated.

It appears very probable that this view of the decomposition is the correct one, as it is also in agreement with the yields of products isolated in the separations. The complete series of reactions can be represented by the scheme :

$$Ph{\cdot}CS{\cdot}NHPh \longrightarrow (I)\ PhC\begin{matrix}N\\S\end{matrix}C_6H_4 + 2H.$$

$$2H + Ph{\cdot}CS{\cdot}NHPh \longrightarrow Ph{\cdot}NH_2 + Ph{\cdot}CHS.$$

$$Ph{\cdot}NH_2 + Ph{\cdot}CS{\cdot}NHPh \longrightarrow (II)\ PhC\begin{matrix}NPh\\NHPh\end{matrix} + H_2S.$$

$$Ph{\cdot}CHS \xrightarrow{heat} CHPh:CHPh + (III)\ \begin{matrix}PhC{:}CPh\\PhC{:}CPh\end{matrix}\!\!>S + H_2S.$$

EXPERIMENTAL.

Numerous experiments were performed the results of which were all in agreement. Thiobenzanilide (5 g.) was placed in a large test-tube heated in an oil-bath and fitted with inlet and outlet tubes to enable the air to be replaced by carbon dioxide or nitrogen. The

exit tube was connected in series to a cooled U-tube, so that any volatile liquid product might be condensed and observed, and, in the experiments for the detection of hydrogen, to a nitrometer, or, in the other quantitative experiments, to a series of wash-bottles containing standard iodine solution to absorb hydrogen sulphide.

Decomposition occurred at 250° and brisk evolution of gas took place at 270° and above, the gaseous product being swept out by the current of nitrogen or carbon dioxide. The bath was maintained in different experiments at various temperatures between 250° and 310°. Above 270°, the decomposition was practically complete in an hour, but at 250° about half the material could be recovered unchanged at the end of that time.

The hydrogen sulphide formed was estimated by titration of the iodine solution in the absorption vessels. A trace of non-aqueous liquid, insufficient for examination, condensed in the connecting tube. It was probably aniline, as Jacobson detected a trace of aniline among the products obtained under his conditions. The residue in the tube was a very dark brown oil which crystallised on cooling. It was dissolved in ether, and the solution extracted repeatedly with dilute aqueous sodium hydroxide. The alkaline extract yielded unchanged thiobenzanilide on acidification. The ethereal solution was then evaporated, the residue extracted several times with hot concentrated hydrochloric acid, and the extract poured into five times its volume of water. A voluminous precipitate of 1-phenylbenzthiazole was produced which on crystallisation from alcohol gave colourless needles, m. p. 113—114°. When the aqueous acid filtrate was made alkaline with sodium hydroxide, *s*-diphenylbenzenylamidine was precipitated (long prisms, m. p. 145° after crystallisation from alcohol). The identity of every substance isolated in this investigation was confirmed by direct comparison and mixed melting-point determinations with an authentic specimen prepared by a known method.

The residue insoluble in hydrochloric acid was dark brown, oily above 100°, and hard and crystalline at room temperature. It represented about 20% of the weight of the original thiobenzanilide. After a number of attempted separations had indicated the nature of the material, the following method of purification was adopted, the residue from several batches of heated thiobenzanilide being used. Part of the material was submitted to steam-distillation; a small quantity of white solid distilled over, which on crystallisation from alcohol gave colourless scales, m. p. 114—121° (120° when mixed with stilbene). Further purification of this small specimen was not attempted. The remainder of the residue was distilled (b. p. 300° to above 400°), and the distillate crystallised from

alcohol. Slender needles of tetraphenylthiophen (m. p. 184—185°; very sparingly soluble in alcohol) were obtained. The mother-liquors were evaporated to dryness and the residue was taken up in carbon disulphide and treated with a slight excess of bromine. A precipitate of α-stilbene dibromide was immediately produced, which was purified by washing with absolute alcohol, in which it was very sparingly soluble (m. p. 237° decomp.).

The author wishes to express his indebtedness to the Chemical Society for a grant which has defrayed part of the cost of this investigation.

CCXLVIII.—*The Action of Nitrous Acid on Amino-compounds. Part II. Aliphatic Amino-acids.*

By THOMAS WESTON JOHNS TAYLOR.

THE action of nitrous acid on aliphatic amino-acids is largely used for their estimation by the method of van Slyke (*J. Biol. Chem.*, 1911, **9**, 275; 1912, **12**, 275); a large excess of nitrous acid is employed, and the progress of the reaction followed by measuring the volume of nitrogen evolved. Apart from qualitative estimates of the relative speeds of reaction of various acids, however, no measurements of reaction velocity have been made, with the exception of the work of Dunn and Schmidt (*ibid.*, 1922, **53**, 401), who, using van Slyke's method, investigated a series of acids and showed that the reaction was more rapid the nearer the amino- and the carboxyl group were in the carbon chain. They also state that the amino-acid disappears at a rate in accordance with the unimolecular law, although their experimental results are far from consistent.

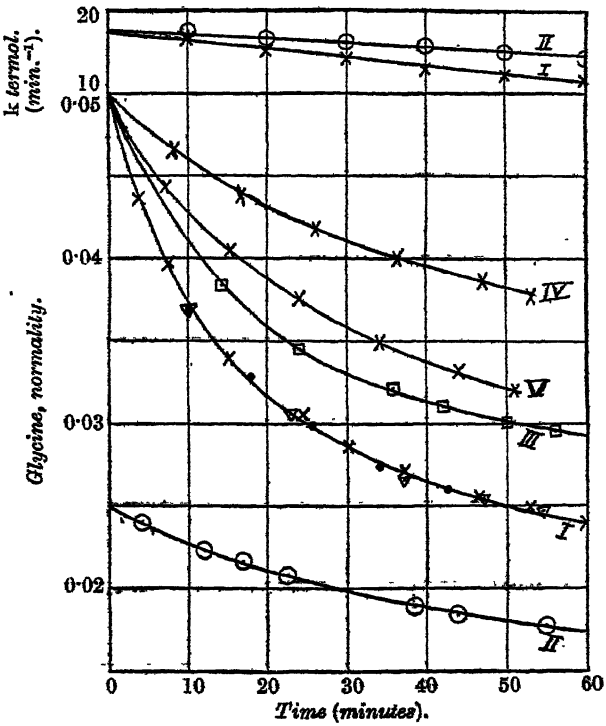
The amino-acids react with nitrous acid much more rapidly than do methylamine and ammonia, and in order to throw light on this difference, measurements of the reaction velocity in the cases of glycine, α-alanine, and β-alanine have been made. For reasons pointed out in Part I (this vol., p. 1099) any method similar to that of van Slyke is unsuitable, and the reaction has been followed by estimation of the amino-acid. It is shown that the difference referred to arises from the fact that, with an amino-acid $NH_2 \cdot R \cdot CO \cdot OH$, the form $NH_3^+ \cdot R \cdot CO \cdot O^-$ is able to react rapidly.

Method and Materials.—The reactions were investigated at $25° \pm 0{\cdot}1°$. The solutions were made up from standard solutions of the amino-acid, of sulphuric acid and of pure barium nitrite; the mixture was protected by a layer of medicinal paraffin (see Part I),

through which passed a small stirrer and a tube; through the latter, samples were withdrawn from time to time by pipette.

The sample was immediately run into excess of aqueous baryta and the amino-acid content estimated by a modification of Sörensen's formaldehyde titration method (*Biochem. Z.*, 1908, 7, 45). Phenolphthalein was added and dilute sulphuric acid run in from a burette until the pink colour just disappeared; excess of 20% formaldehyde solution, which had been previously neutralised to phenolphthalein by baryta, was then added and the amino-acid was titrated with 0·05*N*-baryta. The method was found by blank experiments to give results accurate to 1% in the case of glycine, if the final concentration of the glycine was not less than about 0·01*N*; with more dilute solutions the end-point is not very definite. In the case of the two aminopropionic acids the end-point is not so good and the accuracy consequently suffers; no other method giving a greater accuracy is, however, available.

The glycine was a commercial A.R. sample which had been recrystallised three times from aqueous alcohol. α-Alanine was prepared by the method of Zelinsky and Stadnikoff (*Ber.*, 1908, **41**, 2061) and β-alanine from succinimide (Holm, *Arch. Pharm.*, 1904, **242**, 597); after three recrystallisations from aqueous alcohol the α-compound melted at 295° (corr.) and the β at 206° (corr.); the latter melting point is 10° higher than that usually accepted, but agrees with the observation of Lengfeld and Stieglitz (*Amer. Chem. J.*, 1893, **15**, 508).



Results.

The three acids show qualitatively the same behaviour towards nitrous acid. At a dilution of 0·05*N* with an equivalent of barium nitrite no reaction could be detected over a period of 6 hours. With an equivalent of nitrous acid there is a rapid reaction unlike the cases of methylamine and ammonia; the rate of this reaction is lowered by the addition of mineral acids or of neutral salts.

Glycine.—Curves I and II of Fig. 1 show the rate of reaction with an equivalent of nitrous acid in 0·05*N*- and 0·025*N*-solution respectively. The reaction is so fast that nitrogen bubbles freely from the solution and thus the spontaneous decomposition of the nitrous acid is pronounced; consequently the interpretation of the results is not so simple as in the case of methylamine (Part I, *loc. cit.*). Since the velocity is lowered by the presence of sulphuric acid (Curves III and IV, Fig. 1) and since a product of the reaction is glycollic acid, experiments were carried out with solutions to which glycollic acid had been added (Curve I, Fig. 1). Even if [illegible] large excess (0·25*N*), however, the velocity of reaction is [illegible], and thus there is no negative autocatalysis.

The reaction with one equivalent of nitrous acid is approximately of the third order. From the smooth curves shown in Fig. 1 values of the glycine concentration at intervals of 10 minutes were read and from these termolecular velocity coefficients were calculated; these are shown in Table I for both 0·05*N*- and 0·025*N*-solutions; *k* cannot be expected to remain constant because of the marked

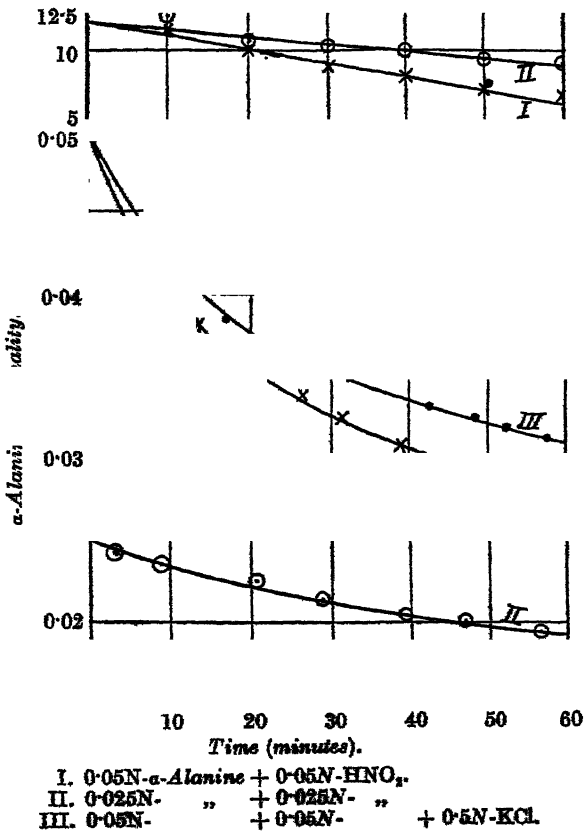
spontaneous decomposition of one of the reactants. If, however, these values are plotted against time, as in the upper part of Fig. 1, and straight lines are drawn through them, the lines for the two dilutions converge to the same value at time 0.



The values of *k* fall more rapidly for the stronger solution, as would be expected, since the rate of spontaneous decomposition of the nitrous acid is greater in that solution because of the higher ratio

of passage of gas bubbles through the liquid. If any other simple order is assumed for the reaction, there is no kind of convergence of the *k* values; assuming a quadrimolecular reaction, which gives more constant values for *k* at any one dilution, the extrapolated

value for k at 0·05N is 390 min.$^{-1}$, and at 0·025N 720 min.$^{-1}$; and for a bimolecular reaction 0·78 at 0·05N and 0·43 at 0·025N.

Experiment showed that doubling the concentration of nitrous acid increased the rate of reaction much more than doubling the concentration of glycine. Hence of the three reacting molecular species, one must be glycine in some form and the other two nitrous acid; there is an immediate analogy with the case of methylamine, where the reaction velocity is proportional to the product $[RNH_3^+][NO_2']$[HNO_2].

α-Alanine and β-Alanine.—Precisely the same holds for these two acids, except that β-alanine reacts much less readily, so that in 0·025N-solution the velocity is too slow for accurate measurement. Measurements were therefore made in 0·05N- and 0·04N-solution. The results are shown in Figs. 2 and 3 and in Tables II and III.

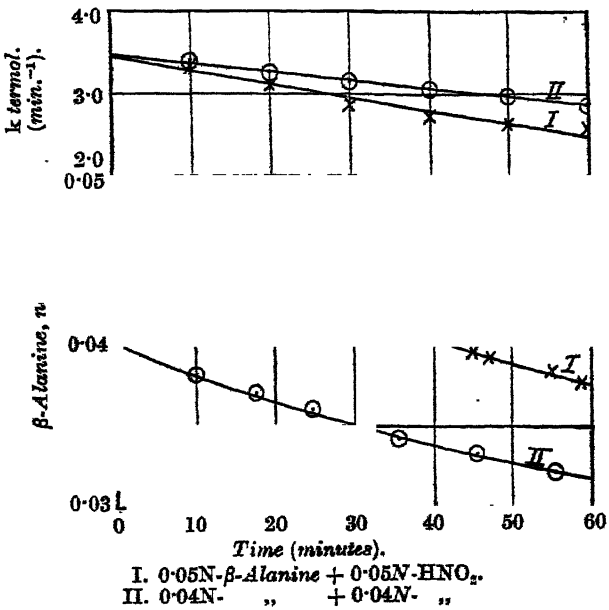
Now an aliphatic amino-acid, NH_2·R·CO·OH, in solution together with the weak acid nitrous acid exists almost entirely in the two forms NH_3^+·R·CO·O$^-$ (A^{+-}) and NH_3^+·R·CO·OH (A^+) (Bjerrum, *Z. physikal. Chem.*, 1923, **104**, 147). If the total concentration of the amino-acid is equal to that of the nitrous acid and is x, and if a fraction f of the acid is present as the ion A^+, we have

$$(1-f)x[H^+]/fx = K_s \quad . \quad . \quad . \quad . \quad (1)$$

where K_s is the acid dissociation constant of the amino-acid and

$[H^{\cdot}]$ is the hydrogen-ion concentration. Further, since the whole solution is electrically neutral, $[NO_2'] = [H^{\cdot}] + [A^+]$, which gives



$$[NO_2'] = fx + [H^{\cdot}] \text{ and } [HNO_2] = (1-f)x - [H^{\cdot}] \quad . \quad . \quad (2)$$

Therefore, if K_N is the dissociation constant of nitrous acid,

$$(fx + [H^{\cdot}])[H^{\cdot}]/\{(1-f)x - [H^{\cdot}]\} = K_N \quad . \quad . \quad (3)$$

Elimination of $[H^{\cdot}]$ between equations (1) and (3) leads to a cubic equation connecting x and f. Numerical values were substituted for K_a, K_N and x, giving to the last the values 0·05N and 0·025N

FIG. 3.

* Bjerrum, *loc. cit.*
† Calculated from Ley's results (*Ber.*, 1909, **42**, 374).

It can be seen that the fraction of the amino-acid present in either form hardly changes in value on alteration in hydrogen-ion concentration, and the assumption is made here that it is independent of concentration.

The form of the amino-acid which reacts with nitrous acid may be

A^+ or A^{+-} or both. Now addition of sulphuric acid lowers the reaction velocity; if A^+ is the reacting form, the concentration of this form will be increased by addition of mineral acid, and hence the nitrite ion must be involved in the reaction, since there is no other derivative of nitrous acid whose concentration is decreased by mineral acid.

If, however, A^{+-} is the reacting form, the concentration of this is decreased by increasing the hydrogen-ion concentration (compare equation 1), and thus the velocity may be proportional to the product $[A^{+-}][HNO_2]^2$. The measurement of reaction velocity in the presence of sulphuric acid shows that of all possible hypotheses the latter is correct.

The results of measurements with 0·05*N*-glycine and 0·05*N*-nitrous acid in the presence of 0·05*N*-sulphuric acid and of 0·1*N*-sulphuric acid are shown in curves III and IV of Fig. 1. Assuming that the reaction velocity is proportional to the product $[A^{+-}][HNO_2]^2$, let the concentration of glycine and of nitrous acid be a initially and x at time t. For the results shown in curve IV the amount of sulphuric acid present is $2a$; the hydrogen-ion concentration at time t may be taken as $2a-x$, since the glycine will be almost completely in the form A^+. Hence, if f is the fraction of glycine present as A^+, we have analogously with equation 1,

$$(1-f)x(2a-x)/fx = K_s,$$

whence $f = (2a-x)/(K_s+2a-x)$. It can be further assumed that the nitrous acid is completely undissociated in the presence of the sulphuric acid, and thus on the above assumption we get for the reaction velocity

$$-dx/dt = kx^3K_s/(K_s+2a-x),$$

which on integration between times t and 0 gives

$$k = \frac{1}{t}\left(\frac{a^2-x^2}{2a^2x^2} + \frac{a-x}{K_sx^2}\right).$$

Values of k calculated from this equation for every 10 minutes are shown in Table V.

For the reaction in the presence of one equivalent of sulphuric acid, after a certain time an appreciable amount of free sulphuric acid is present in the solution, since some glycine has disappeared. The hydrogen-ion concentration can be taken as equal to that of this free acid; thus at time t, $[H^+] = (a-x)$. In a fashion similar to that above, it can be shown that

$$-dx/dt = kx^3K_s/(K_s+a-x).$$

This expression cannot be integrated back to the beginning, since

the assumptions made do not hold at the start of the reaction. Integration between times t_2 and t_1 gives

$$k = \frac{1}{t_2 - t_1}\left[\frac{K_3 + a}{2K_3x^2} - \frac{1}{K_3x}\right]_{x_1}^{x_2}.$$

Values of k calculated from this with $t_1 = 20$ mins. are shown in Table V.

Now for the reaction between glycine and nitrous acid alone, the fraction of glycine present in the form A^{+-} is given in Table IV; the concentration of undissociated nitrous acid is given by equation (2), since the term $[H^+]$ can be obtained from equation (1). Thus on the present assumption the reaction velocity should be given by

$$\frac{dx}{dt} = k(1-f)x\left(\sqrt{1-f}x - \frac{K_3 f}{1-f}\right)^2$$

whence, assuming f is independent of concentration and writing $(1-f) = b$ and $K_3 f/(1-f) = c$,

$$k = \frac{1}{bc^2}\left(\frac{1}{bx-c} \quad \frac{1}{ab-c} - \log_e \frac{bx-c}{a}\right) \qquad (4)$$

Values of k calculated both for 0·05N- and 0·025N-solutions are shown in Table V.

It will be seen that the values of k from the four sets of experiments agree as well as could be expected. In the reactions which proceed more slowly, and thus where the spontaneous decomposition of the nitrous acid is less marked, the values of k are higher and fall off less rapidly.

	(Curve IV.)		(Curve III.)		(Curve I.)	(Curve II.)

If any other assumption is made as to the [illegible] involved in the reaction, similar calculations [illegible] it is found that there is no kind of agreement between the values derived from the four sets of experiments.

Taking it as proved that the reaction velocity is proportional to the product $[A^{+-}][HNO_2]^2$, values for the true velocity coefficients for the three acids can be obtained from (4), plotted against time

and extrapolated to zero time. The results are in Table VI; they are not very accurate for the alanines because equation (4) is very sensitive to small changes in x, and the analytical method is not capable of the accuracy it demands.

TABLE VI.

	k (min.$^{-1}$).	K_B.
Glycine	46	$4{\cdot}7 \times 10^{-4}$
α-Alanine	32	$2{\cdot}45 \times 10^{-4}$
β-Alanine	45	$2{\cdot}49 \times 10^{-4}$

The apparent difference in the speeds of reaction in the three cases arises mainly from the difference in the acid dissociation constants K_B. A small value of K_B causes a small concentration of the form A^{+-} and therefore a small reaction velocity. The results of Dunn and Schmidt (*loc. cit.*) are thus in agreement with the general conclusions of Bjerrum (*loc. cit.*), that the more closely the amino- and the carboxyl group are situated in the carbon chain, the greater the value of K_B.

The possibility remains that the reaction may also proceed by an alternative mechanism, at a rate proportional to the product $[A^+][NO_2'][HNO_2]$ as in the case of methylamine and ammonia. If the velocity coefficient for this mechanism is of the same order as in those two cases, 1 min.$^{-1}$, the effect of this mechanism will be small compared with the "Zwitterion" mechanism, and the experimental accuracy is not great enough to detect it.

The results arrived at have two possible interpretations. Either the reaction is actually of the third order, or else it is a reaction between undissociated nitrous acid and a complex formed from the "Zwitterion" and nitrous acid, since the concentration of any such complex will be proportional to the product $[A^{+-}][HNO_2]$. Taking into account the results with methylamine, the latter explanation becomes the more probable; an uncharged complex can only arise in the case of methylamine from the molecular species $CH_3{\cdot}NH_3^+$ and NO_2'; in the amino-acids it can arise from the species A^{+-} and HNO_2; and in each case the reaction velocity is proportional to the product of the concentration of the appropriate molecular species multiplied by that of undissociated nitrous acid. The velocity coefficient is forty times larger in the amino-acids than in the amine; the difference, on this view, would be a measure of the ratio of the probabilities of the formation of a complex from the species A^{+-} and HNO_2 and from the ions RNH_3^+ and NO_2'.

Effect of Neutral Salts.

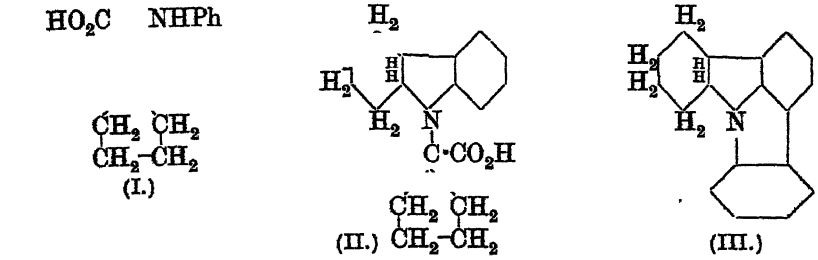
The effect of neutral salts is of interest because of the view of Pfeiffer that neutral salts and amino-acids form complexes which

exist in solution as well as in the solid state (references in Pfeiffer's "Organische Molekulverbindungen," 1927, p. 143 *et seq.*). His results indicate that calcium chloride is more able to form complexes than potassium chloride; but the reaction velocities in the presence of 0·05*N*-calcium chloride and of 0·05*N*-potassium chloride were found to be the same within the limits of error of the method. The retarding effect of neutral salts is also found in the cases of methylamine and ammonia, where it is almost certainly an ionic strength effect, and thus the present results provide no support for Pfeiffer's views.

Summary.

1. The velocity of reaction of nitrous acid with glycine, α-alanine, and β-alanine has been measured at 25° in dilute aqueous solution.
2. The reaction is approximately of the third order, and is retarded by the presence of neutral salts or of mineral acid.
3. It is shown that the principal reacting species are undissociated nitrous acid and the amino-acid in its "Zwitterion" form $NH_3^+ \cdot R \cdot CO \cdot O^-$. The implications of this result are discussed.

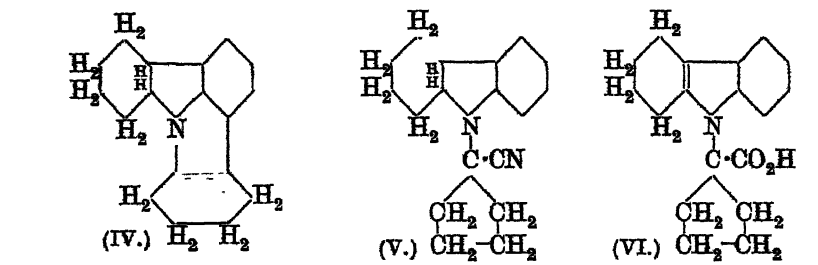
My thanks are due to Mr. J. F. Cowley for his help during the preliminary experiments.



THE DYSON PERRINS LABORATORY,
OXFORD. [*Received, May 31st*, 1928.]

CCXLIX.—*The Condensation of Hexahydrocarbazole and of Tetrahydropentindole with* cyclo*Pentanone Cyanohydrin.*

By SYDNEY GLENN PRESTON PLANT and DOROTHY MAY LYDDON RIPPON.



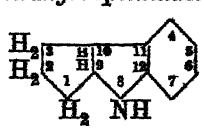
IT has been observed by Plant and Facer (J., 1925, 127, 2037) that the fusion of 1-anilino*cyclo*pentane-1-carboxylic acid (I) with potassium hydroxide yields carbazole, a reaction which involves the enlargement of the *cyclo*pentane ring, since 1-*p*-toluidino- and 1-*o*-toluidino-*cyclo*pentane-1-carboxylic acid yield 3-methyl- and 1-methyl-carbazole, respectively, under similar conditions (Oakeshott and Plant, J., 1926, 1210; 1927, 484). A similar process, starting with certain heterocyclic bases in the place of aniline, might be expected to give polynuclear carbazole derivatives, *e.g.*, from 1-(9′-hexahydrocarbazyl)cyclopentane-1-carboxylic acid (II) a substance of the structure (III) might arise. Manjunath (*J. Indian*

Chem. Soc., 1927, **4**, 271) has prepared substances * which clearly contain the ring system present in (III). By reducing 9-nitrosohexahydrocarbazole with zinc dust and acetic acid in the presence of *cyclo*hexanone he obtained 8 : 9-(1′ : 2′-*cyclo*hexyl)tetrahydro-

carbazole, which, on electrolytic reduction, gave the corresponding 8 : 9-(1′ : 2′-*cyclo*hexyl)hexahydrocarbazole (IV).

Although, for reasons given below, it was not found possible during the course of the present work to synthesise a polynuclear carbazole of the type described, several interesting reactions have been brought to light. When hexahydrocarbazole (the ordinary *cis*-modification, m. p. 99°; see Gurney, Perkin, and Plant, J., 1927, 2676) was treated with *cyclo*pentanone and potassium cyanide in glacial acetic acid solution, 1-(9′-*hexahydrocarbazyl*)-1-*cyano*cyclo*pentane* (V) resulted. This nitrile, on boiling with concentrated hydrochloric

acid or with alcoholic hydrochloric acid, was hydrolysed with the formation of hexahydrocarbazole and *cyclo*pentanone, so this route to the corresponding acid could not be adopted. When a solution of the nitrile in concentrated sulphuric acid was left for two days, the corresponding *amide* was produced. Hydrolysis of this to the acid could not be carried out, the amide either remaining unchanged or breaking up with the production of hexahydrocarbazole under the conditions used. When the amide itself was heated with



* The formulæ given for these substances in Manjunath's paper do not contain the ring system under discussion here and are obviously misprints, but there can be no doubt concerning the actual structure of the compounds described.

potassium hydroxide with a view to converting it directly into the polynuclear carbazole, it again broke up with the formation of hexahydrocarbazole.

As a possible alternative method for obtaining 1-(9′-hexahydrocarbazyl)*cyclo*pentane-1-carboxylic acid, the nitrosoamine of 1-anilino*cyclo*pentane-1-carboxylic acid (Plant and Facer, *loc. cit.*) was reduced with zinc dust and hot acetic acid in the presence of *cyclo*hexanone. This led to the formation of 1-(9′-*tetrahydrocarbazyl*)-cyclo*pentane*-1-*carboxylic acid* (VI), but reduction to the corresponding derivative of hexahydrocarbazole has not been brought about. However, the acid has some interesting reactions. When warmed with 60% aqueous sulphuric acid, when distilled, or when heated with solid potassium hydroxide, it dissociates into tetrahydrocarbazole and Δ^1-*cyclo*pentene-1-carboxylic acid (VII). It has previously been observed that 1-anilino*cyclo*pentane-1-carboxylic acid, on heating, yields the lactone of 1-1′-hydroxy*cyclo*pentane-1′-carboxylylanilino*cyclo*pentane-1-carboxylic acid (Plant and Facer, *loc. cit.*); but 1-anilino*cyclo*hexane-1-carboxylic acid behaves differently on heating alone, giving aniline and Δ^1-*cyclo*hexene-1-carboxylic acid, and 4-indoxyl*spirocyclo*hexane results on fusion with potassium hydroxide (Betts, Muspratt, and Plant, J., 1927, 1310). 1-(9′-Tetrahydrocarbazyl)*cyclo*pentane-1-carboxylic acid, on heating, behaves like 1-anilino*cyclo*hexane-1-carboxylic acid, but lactone formation is here impossible in the absence of an unsubstituted >NH group.

The unexpected course of some of the above reactions suggested an investigation of similar reactions with *tetrahydropentindole* (VIII).

(VII.) 

(VIII.) 

This base, which has been obtained by the electrolytic reduction of dihydropentindole, theoretically ought to exist in *cis*- and *trans*-modifications, analogous to the two forms of hexahydrocarbazole (see Gurney, Perkin, and Plant, *loc. cit.*); the *trans*-configuration, however, is very highly strained and its formation in appreciable quantities during the reduction of dihydropentindole is not to be expected. This point has been investigated, and the reduction product has been shown to consist essentially of a single substance, undoubtedly the *cis*-modification of tetrahydropentindole. It can be acetylated and benzoylated, and it is converted by the action of methyl iodide into 8-*methyltetrahydropentindole*, which yields a characteristic *methiodide*, m. p. 189°, that has been used for recognising tetrahydropentindole. When dissolved with *cyclo*pentane

in glacial acetic acid and treated with potassium cyanide, tetrahydropentindole is converted into 1-(8′-*tetrahydropentindyl*)-1-*cyano*cyclo*pentane*. By a reaction analogous to that observed with the corresponding hexahydrocarbazole derivative, this nitrile is hydrolysed on boiling with concentrated hydrochloric acid with the formation of tetrahydropentindole and *cyclo*pentanone. In view of the ease with which these nitriles were hydrolysed it is interesting to point out that Kötz and Merkel (*J. pr. Chem.*, 1926, **113**, 75) observed that 1-piperidyl-1-cyano*cyclo*hexane was hydrolysed in a similar way, on boiling with aqueous-alcoholic potassium hydroxide. By allowing the solution of 1-(8′-tetrahydropentindyl)-1-cyano*cyclo*pentane in concentrated sulphuric acid to remain for two days, 1-(8′-*tetrahydropentindyl*)cyclo*pentane*-1-*carboxyamide* is produced. This amide decomposed with the formation of tetrahydropentindole when heated with solid potassium hydroxide. Many amides of this type seem to be hydrolysed to the corresponding acids only with difficulty, if at all (compare, *e.g.*, Kötz and Merkel, *loc. cit.*; Betts, Muspratt, and Plant, *loc. cit.*; Oakeshott and Plant, J., 1927, 492), and this fact, together with the alternative reactions outlined above, can account for the inability to prepare the acids from the amides described in the present work.

Experimental.

1-(9′-*Hexahydrocarbazyl*)-1-*cyano*cyclo*pentane* (V) soon began to separate when hexahydrocarbazole (21 g.), dissolved in a mixture of glacial acetic acid (210 c.c.) and *cyclo*pentanone (17·5 c.c.), was treated gradually with a solution of potassium cyanide (14 g.) in water (50 c.c.); after several hours, the mixture was diluted with water, and the product collected. It crystallised from dilute alcohol in colourless prisms, m. p. 76° (Found: N, 10·5. $C_{18}H_{22}N_2$ requires N, 10·5%).

A solution of this nitrile in an excess of concentrated hydrochloric acid was boiled under reflux for 3 hours and then distilled in steam for a short time. From the distillate, saturated with sodium chloride, ether extracted *cyclo*pentanone, b. p. 129—130°, which was identified by converting its phenylhydrazone into dihydropentindole (Perkin and Plant, J., 1923, **123**, 3242), m. p. and mixed m. p. 108°. The aqueous solution remaining after the steam distillation contained hexahydrocarbazole in good yield. The same reaction took place when the nitrile was boiled under reflux for 6 hours with alcohol saturated with hydrogen chloride.

1-(9′-*Hexahydrocarbazyl*)cyclo*pentane*-1-*carboxyamide*.—A solution of the nitrile (V) in concentrated sulphuric acid was kept for 2 days, poured on ice, and made alkaline with concentrated [illegible]

ammonia. The solid product was ground with dilute aqueous ammonia to decompose any sulphate which might have been present, and then crystallised from alcohol, from which 1-(9′-*hexahydrocarbazyl*)cyclo*pentane*-1-*carboxyamide* was obtained in colourless plates, m. p. 160° (Found: N, 9·9. $C_{18}H_{24}ON_2$ requires N, 9·9%). This amide was not changed by boiling its solution in aqueous-alcoholic potassium hydroxide for 4 hours, or by heating it with 40% aqueous sulphuric acid. When its solution in concentrated hydrochloric acid was boiled under reflux for several hours, a considerable amount of hexahydrocarbazole was produced, which was removed from the solution, evaporated to small bulk and made alkaline with sodium hydroxide, by distillation in steam. When the amide was heated with powdered potassium hydroxide at 180—200°, in a copper tube fitted with a reflux air condenser, for 15 minutes, a considerable quantity of hexahydrocarbazole was produced. This was isolated by treating the cooled mixture with warm water and crystallising the precipitated solid from alcohol. The action of heat alone at 180—200° had no appreciable effect on the amide.

1-(9′-*Tetrahydrocarbazyl*)cyclo*pentane*-1-*carboxylic Acid* (VI).—The nitrosoamine of 1-anilino*cyclo*pentane-1-carboxylic acid (40 g., prepared as described by Plant and Facer, *loc. cit.*) was dissolved in a mixture of glacial acetic acid (560 c.c.) and water (240 c.c.), to which *cyclo*hexanone (56 c.c.) was added. With vigorous stirring, the mixture was warmed to 50°, and zinc dust (96 g.) was then gradually introduced, the temperature being raised slowly to 85°. The filtered solution was poured into *N*-sulphuric acid. When the solid product (yield, 25%) was crystallised from toluene, 1-(9′-*tetrahydrocarbazyl*)cyclo*pentane*-1-*carboxylic acid* separated in colourless prisms, m. p. 184° (Found: N, 5·0. $C_{18}H_{21}O_2N$ requires N, 4·9%).

When a solution of this acid (3 g.) in 60% aqueous sulphuric acid (180 c.c.) was left on the water-bath, crystals of Δ^1-*cyclo*pentene-1-carboxylic acid (m. p. and mixed m. p. 118°) gradually sublimed into the neck of the flask; dilution of the residual solution with water precipitated tetrahydrocarbazole. When a solution of 1-(9′-tetrahydrocarbazyl)*cyclo*pentane-1-carboxylic acid in cold concentrated sulphuric acid was left for several hours and then poured on ice, the acid was recovered unchanged. The acid resisted attempts to reduce it to the corresponding hexahydrocarbazole derivative by electrolytic reduction in alkaline solution, by sodium amalgam in alkaline solution, and by tin and alcoholic hydrochloric acid.

1-(9′-Tetrahydrocarbazyl)*cyclo*pentane-1-carboxylic acid was mixed with an excess of powdered potassium hydroxide and heated,

in a copper tube fitted with a reflux air condenser, at 320—340° for ½ hour. After cooling, the mixture was warmed with an excess of water. The insoluble portion, after crystallisation from aqueous alcohol, melted at 112° and was shown to be tetrahydrocarbazole by a mixed m. p. determination. The alkaline aqueous liquid, after filtering, was evaporated to a small volume, and acidified with concentrated hydrochloric acid, the mixture being kept cold. The solid which separated was crystallised from aqueous alcohol, Δ^1-*cyclo*pentene-1-carboxylic acid being obtained in colourless plates, m. p. 119° (Found: C, 64·1; H, 7·3. Calc.: C, 64·3; H, 7·1%). There is no doubt that this is identical with the Δ^1-*cyclo*pentene-1-carboxylic acid described by Haworth and Perkin (J., 1894, **65**, 101). A similar decomposition occurred on distilling 1-(9′ tetrahydrocarbazyl)*cyclo*pentane-1-carboxylic acid alone from a small distillation flask. The solid which collected in the side-tube yielded tetrahydrocarbazole (m. p. and mixed m. p. 114°) on treatment with dilute aqueous sodium hydroxide and filtration, and the alkaline filtrate, on evaporation to small bulk and acidification with concentrated hydrochloric acid, yielded Δ^1-*cyclo*pentene-1-carboxylic acid (m. p. and mixed m. p. 120°).

Tetrahydropentindole (VIII).—Dihydropentindole (5 g.) (Perkin and Plant, *loc. cit.*) was dissolved in sulphuric acid (140 c.c. of 60%) and submitted to electrolytic reduction at room temperature during 16 hours in the cathode compartment of an electrolytic cell, lead electrodes and a current of 5 amps. (0·03 amp. per sq. cm. of cathode) being used. From the solution, made alkaline with concentrated aqueous ammonia, ether extracted *tetrahydropentindole*, b. p. 152°/16 mm. (Found: C, 82·9; H, 8·3. $C_{11}H_{13}N$ requires C, 83·0; H, 8·2%). The tetrahydropentindole used in the present work was liquid, but a specimen was made to solidify and was found to melt at 21°.

A solution of tetrahydropentindole (3 g.) in hot acetic anhydride (30 c.c.) was boiled for 20 minutes, cooled, and shaken with water; the 8-*acetyltetrahydropentindole* obtained crystallised from alcohol in colourless prisms, m. p. 78° (Found: N, 6·9. $C_{13}H_{15}ON$ requires N, 7·0%). On shaking tetrahydropentindole (5 g.) with benzoyl chloride (5·5 g.) and an excess of dilute aqueous sodium hydroxide, 8-*benzoyltetrahydropentindole* separated as an oil, which gradually solidified; it crystallised from alcohol in colourless prisms, m. p. 86° (Found: N, 5·2. $C_{18}H_{17}ON$ requires N, 5·3%). When tetrahydropentindole (1·8 g.) and picric acid (2·5 g.) were mixed in hot toluene, the *picrate* separated; it crystallised from alcohol in yellow prisms, m. p. 159°.

8-*Methyltetrahydropentindole*.—An alcoholic solution of tetrahydropentindole (40 g.) and methyl iodide (45 g.) was boiled under reflux;

for 24 hours, as much alcohol as possible was distilled off, and the residue was treated with an excess of dilute aqueous sodium carbonate and extracted with ether. After the extract had been dried over potassium carbonate and the solvent removed, the residual oil was boiled with an excess of acetic anhydride under reflux for an hour in order to acetylate any unchanged tetrahydropentindole. The cooled solution was shaken with an excess of water, concentrated hydrochloric acid (50 c.c.) added after 12 hours, the 8-acetyltetrahydropentindole removed by shaking twice with ether, and the aqueous solution made alkaline with sodium hydroxide and extracted with ether, which removed 8-*methyltetrahydropentindole*, b. p. 136—137°/15 mm. (Found: N, 7·8. $C_{12}H_{15}N$ requires N, 8·1%). From a solution of this (2 g.) and picric acid (2·6 g.) in hot alcohol, the *picrate* separated in yellowish-green plates, m. p. 116°, on cooling. When 8-methyltetrahydropentindole or tetrahydropentindole was warmed in alcohol with an excess of methyl iodide the *methiodide* of 8-methyltetrahydropentindole slowly separated in colourless prisms, m. p. 189° (Found: I, 40·2. $C_{13}H_{18}NI$ requires I, 40·3%).

1-(8′-*Tetrahydropentindyl*)-1-*cyano*cyclo*pentane*.—A solution of tetrahydropentindole (37 g.) and *cyclo*pentanone (25 c.c.) in glacial acetic acid was treated with a concentrated aqueous solution of potassium cyanide (27 g.). After several hours, the solution was poured into an excess of water and the oily product, which solidified when rubbed, was recrystallised from alcohol, 1-(8′-*tetrahydropentindyl*)-1-*cyano*cyclo*pentane* being obtained in colourless prisms, m. p. 51° (Found: N, 11·4. $C_{17}H_{20}N_2$ requires N, 11·1%). When this nitrile (1 g.) was mixed with picric acid (1·1 g.) in hot alcohol, and the solution was left, the *picrate* separated gradually in yellow prisms, m. p. 126°.

A solution of 1-(8′-tetrahydropentindyl)-1-cyano*cyclo*pentane in concentrated hydrochloric acid was boiled under reflux for 3 hours, and then submitted to steam distillation. From the distillate, ether extracted *cyclo*pentanone (identified by conversion into dihydropentindole as before). The acid solution, after being made alkaline with sodium hydroxide, was again submitted to steam distillation; the tetrahydropentindole isolated from the distillate by means of ether was identified by conversion into 8-methyltetrahydropentindole methiodide.

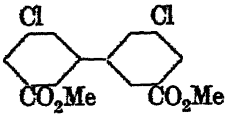
1-(8′-*Tetrahydropentindyl*)cyclo*pentane*-1-*carboxyamide*.—A solution of 1-(8′-tetrahydropentindyl)-1-cyano*cyclo*pentane in concentrated sulphuric acid was after 2 days poured on ice, and made alkaline with concentrated aqueous ammonia while being kept cool. The product, after being ground with dilute aqueous ammonia, was crystallised from alcohol, 1-(8′-*tetrahydropentindyl*)cyclo*pentane*-1-

carboxyamide separating in colourless prisms, m. p. 130° (Found : N, 10·3. $C_{17}H_{22}ON_2$ requires N, 10·4%).

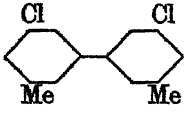
A mixture of this amide with powdered potassium hydroxide was heated at 280—315° for ½ hour, and, after cooling, was treated with water and submitted to steam distillation. From the distillate, ether extracted tetrahydropentindole (identified by converting it into 8-methyltetrahydropentindole methiodide). No tetrahydropentindole could be detected when this amide was heated alone at 280—315° for ½ hour. Attempts to hydrolyse the amide to the corresponding acid by boiling its solution in concentrated hydrochloric acid or in aqueous sulphuric acid were not successful.

THE DYSON PERRINS LABORATORY,
OXFORD.

[*Received, April 28th*, 1928.]



CCL.—*The Molecular Configurations of Polynuclear Aromatic Compounds. Part VII. 5 : 5′-Dichlorodiphenyl-3 : 3′-dicarboxylic Acid.*



By FRED BRIDGES MCALISTER and JAMES KENNER.

FOR reasons which have been fully set out elsewhere (Kenner, *Chem. and Ind.*, 1927, **46**, 218), it was of importance to synthesise and examine a diphenyldicarboxylic acid isomeric with one of the 6 : 6′-diphenic acids, of which the asymmetry has been demonstrated (J., 1922, **121**, 614; 1923, **123**, 779, 1948; 1926, 470, 671), and carrying its substituents in the 3-, 3′-, 5-, and 5′-positions. 5 : 5′-Dinitrodiphenyl-3 : 3′-dicarboxylic acid having been found to be inaccessible by the usual method of synthesis, attention was directed to the corresponding dihalogenated acids. In this direction the facility with which 3-bromo-5-nitro-*p*-toluidine is available (Neville and Winther, *Ber.*, 1880, **13**, 968) suggested 5 : 5′-dibromodiphenyl-3 : 3′-dicarboxylic acid as the most suitable objective. However, bromine as well as iodine was eliminated when either *-bromo-5-iodotoluene* or *methyl 3-bromo-5-iodobenzoate* was heated with copper powder, so that no definite diphenyl derivative could be synthesised from either of them.

Finally, therefore, the more laborious preparation of *3-chloro-5-iodotoluene* and of *methyl 3-chloro-5-iodobenzoate* was undertaken, and from each of these compounds the desired diphenyl derivative was obtained. Even in the latter case, however, the *methyl 5 : 5′-dichlorodiphenyl-3 : 3′-dicarboxylate* (I) underwent decomposition, so that the compound could only be obtained in poor yields under carefully regulated conditions, and, although, on the other hand, 5 : 5′-*dichloro*-3 : 3′-*ditolyl* (II) was readily isolated, it proved to be

of no value for the present purpose since it could not be readily oxidised to the corresponding dicarboxylic acid.

(I.) 

(II.)

The *brucine*, *quinine*, and *acid morphine* salts of 5 : 5′-*dichlorodiphenyl*-3 : 3′-*dicarboxylic acid* were each found to be uniform, and the solutions of ammonium 5 : 5′-dichlorodiphenyl-3 : 3′-dicarboxylate prepared from them were in each case optically inactive. It would therefore appear that the acid has not the asymmetry of its 2 : 2′-6 : 6′-structural isomeride.

EXPERIMENTAL.

5-*Iodo*-3-*nitrobenzoic Acid*. (Experiments carried out by F. Allsop in the University of Sheffield.)—The usual procedure for the replacement of the amino-group by iodine yielded unsatisfactory results in this instance, but excellent yields were obtained in the following way. An intimate mixture of 5-nitro-3-aminobenzoic acid (5 g.) with potassium metabisulphite (3 g.) was slowly added to fuming nitric acid (12 c.c.) below −2°. After 2 hours, the solution was diluted with ice (60 g.) and then gradually treated with a solution of potassium iodide (8 g.) and iodine (4 g.) in water (8 c.c.). After 12 hours, the mixture was heated on the steam-bath, and the excess of iodine destroyed by addition of sodium bisulphite. By crystallisation from light petroleum, the *acid* was obtained in long prisms, m. p. 166—167° (Found: N, 4·8. $C_7H_4O_4NI$ requires N, 4·8%). The *ethyl* ester consisted of long prisms, m. p. 59—60° (Found: N, 4·4. $C_9H_8O_4NI$ requires N, 4·4%). Repeated attempts to prepare a diphenyl derivative from the ester in the usual manner were unsuccessful.

3-*Bromo*-5-*iodotoluene*.—When a solution of potassium iodide (24 g.) in water (40 c.c.) was gradually added to a diazonium salt solution prepared from 5-bromo-*m*-toluidine (18 g.), sulphuric acid (12 c.c.), water (120 c.c.), and sodium nitrite (8 g.), the violence of decomposition of the resultant diazonium iodide was such as to project the material from the containing vessel. In subsequent preparations, this difficulty was overcome by carrying out the mixing of the respective solutions, and the subsequent decomposition, in small aliquot proportions. 3-*Bromo*-5-*iodotoluene* boiled at 150°/29 mm. and melted at 23° (Found: X,* 141·6. C_7H_6BrI requires X, 142·4).

* X denotes weight of mixed silver halides expressed as a percentage of the weight of material analysed.

3-*Bromo*-5-*acetamidobenzoic acid*, prepared by the oxidation of 5-*bromoaceto*-m-*toluidide*, m. p. 171—172° (33·5 g.), with a solution of potassium permanganate (72 g.) and hydrated magnesium sulphate (48 g.) in water (6000 c.c.), melted at 279—281° (Found: N, 5·5. $C_9H_8O_3NBr$ requires N, 5·4%).

5-*Bromo*-3-*aminobenzoic acid* was obtained in the form of its hydrochloride by boiling a solution of the acetyl derivative (5 g.) in concentrated hydrochloric acid (50 c.c.) for one hour and then evaporating it. The acid, liberated by means of sodium acetate, separated from dilute alcohol in colourless needles, m. p. 220—222° after softening at 194° (Found: N, 6·5. $C_7H_6O_2NBr$ requires N, 6·5%).

3-*Bromo*-5-*iodobenzoic acid* was prepared from the hydrochloride of 5-bromo-3-aminobenzoic acid in the usual manner and melted at 209—211° (Found: X, 128·6. $C_7H_4O_2BrI$ requires X, 129·3). The *methyl* ester separated from benzene in small orange prisms, m. p. 59—61° (Found: X, 123·1. $C_8H_6O_2BrI$ requires X, 124·0).

3-*Chloro*-5-*iodotoluene*, prepared with the precautions explained in the case of the corresponding bromo-derivative, boiled at 138—140°/26 mm. and melted at 0° (Found: X, 149·4. C_7H_6ClI requires X, 149·5).

5 : 5′-*Dichloro*-3 : 3′-*ditolyl* was readily prepared by gradually adding copper powder during ½ hour to an equal weight of 3-chloro-5-iodotoluene at 250—260°, finally raising the temperature to 290°, and then allowing the product to cool. After crystallisation from alcohol, it melted at 101—102° (Found: Cl, 27·8. $C_{14}H_{12}Cl_2$ requires Cl, 28·4%). Experiments on its oxidation with dilute nitric acid (Cohen and Dakin, J., 1901, **79**, 1124) or neutral or alkaline permanganate led to no satisfactory result.

3-*Chloro*-5-*acetamidobenzoic acid*, m. p. 265—267° (Found: N, 6·55; *M*, 213·9. $C_9H_8O_3NCl$ requires N, 6·6%; *M*, 214·5), and 3-*chloro*-5-*aminobenzoic acid hydrochloride*, m. p. 118—121° (Found: N, 6·65. $C_7H_7O_2NCl_2$ requires N, 6·7%), were prepared in the manner adopted for the bromo-derivatives. In place, however, of the ordinary procedure, the following was a much more satisfactory method of preparing 3-*chloro*-5-*iodobenzoic acid*: A finely ground mixture of 3-chloro-5-aminobenzoic acid hydrochloride (30 g.) with potassium metabisulphite (16·2 g.) was gradually added below 0° to nitric acid (78 c.c.; *d* 1·5). After 4 hours, the mixture was poured on ice (240 g.) and gradually treated with a solution of iodine (22·2 g.) and potassium iodide (43·2 g.) in water (40 c.c.). The acid crystallised from dilute alcohol in reddish-yellow needles, m. p. 190—191° (Found: X, 133·5; *M*, 281. $C_7H_4O_2ClI$ requires X, 134·2; *M*, 282·4). Its *methyl* ester crystallised from methyl

alcohol in orange needles, m. p. 43—44° (Found: X, 127·0. $C_8H_6O_2ClI$ requires X, 127·9).

Methyl 5 : 5′-*dichlorodiphenyl*-3 : 3′-*dicarboxylate* was obtained when copper powder was gradually added to an equal weight of methyl 3-chloro-5-iodobenzoate at 265—270°, and the mixture was then heated for 10 minutes at 270°. For the success of the preparation the copper powder must be added as quickly as possible consistent with the maintenance of the temperature within the limits indicated, since prolonged or over-heating causes decomposition. Even in the most favourable circumstances the yield could not be raised above 25%. The ester separated from benzene in small cubical crystals, m. p. 156° (Found: Cl, 21·5. $C_{16}H_{12}O_4Cl_2$ requires Cl, 21·2%).

5 : 5′-*Dichlorodiphenyl*-3 : 3′-*dicarboxylic acid*, prepared from its ester by means of aqueous sodium hydroxide, was practically insoluble in the ordinary solvents and was sparingly soluble in glacial acetic acid. From this it crystallised in nodules, m. p. 358—360° (Found: Cl, 23·2. $C_{14}H_8O_4Cl_2$ requires Cl, 23·1%).

The *brucine* salt crystallised from methyl alcohol in radiate clusters of small prisms, m. p. 178—179°, decomp. 191—193° (Found: N, 5·1. $C_{60}H_{60}O_{12}N_4Cl_2$ requires N, 5·1%). For a 0·78% solution in chloroform, $[\alpha]_D = -5·2°$.

The *quinine* salt separated from methyl alcohol in small prisms, m. p. 170—172°, decomp. 174° (Found: N, 5·8. $C_{60}H_{60}O_4N_4Cl_2$ requires N, 5·85%). They were insoluble in acetone, chloroform, and ether, and only sparingly soluble in methyl or ethyl alcohol. For a 0·18% solution in absolute alcohol, $[\alpha]_D = -132°$.

The *acid morphine* salt crystallised from methyl alcohol in small nodules, m. p. 218—219°, decomp. 223—225° (Found: N, 2·4. $C_{31}H_{27}O_7NCl_2$ requires N, 2·4%). The salt was almost insoluble in benzene, chloroform, acetone, and ether, and sparingly soluble in methyl or ethyl alcohol. For a 0·20% solution in ethyl alcohol, $[\alpha]_D = -30°$.

Solutions of the ammonium salt were prepared from both the brucine and the quinine salt by shaking them with chloroform and dilute ammonia solution, but in the case of the acid morphine salt dilute ammonia alone was employed, the bulk of the morphine being then removed by filtration, and the last traces by means of chloroform. In each case the solutions obtained were optically inactive. The quinidine salt was an oil, easily soluble in methyl alcohol and acetone, sparingly in ether or benzene. The cinchonine salt was a gum, readily soluble in chloroform, water, and methyl alcohol, but very sparingly soluble in benzene or ether, and could not be obtained in the solid condition.

THE UNIVERSITY, SYDNEY.

[*Received, May 17th*, 1928.]

CCLI.—*The Apparent Hydration of Ions. Part I. The Densities and Viscosities of Saturated Solutions of Sodium and Potassium Chlorides in Hydrochloric Acid.*

By JOHN WILLIAM INGHAM.

A REVIEW of the determined values of the hydration numbers of strong electrolytes in aqueous solutions shows that, whilst there is a certain unanimity with respect to the alkali chlorides and their ions, there is considerable doubt as to the relative position of the hydrogen ion.

Recent work by Sugden (J., 1926, 174), who studied the distribution of acetic acid between aqueous solutions of salts and amyl alcohol, and of Glasstone and his collaborators (J., 1925, 127, 2660; 1926, 2935, 2939; 1927, 635), using the salting-out effect upon ethyl acetate and aniline, confirms much earlier work, to which these authors refer, in establishing the series $Li^{\cdot} > Na^{\cdot} > K^{\cdot}$, although the two methods give numerically different results for the hydration numbers:

	LiCl.	NaCl.	KCl.
Sugden	10·5	7·9	3·4
Glasstone	27	24	22

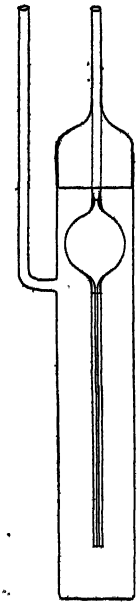
Sugden finds the chlorine ion to be non-hydrated, so his values for the salts are also those of the kations; on the other hand, Glasstone finds 10 for Cl', the corresponding kation values being $Li^{\cdot}$ 17, $Na^{\cdot}$ 14, $K^{\cdot}$ 12. These "hydration numbers" of Glasstone are for ions at infinite dilution, smaller values being found for higher concentrations. Sugden obtained reasonably constant values over a range of concentration N—$N/10$.

Neither of these methods is suitable for comparative determination with hydrochloric acid, the relative position of which has been found by other methods (for references, see General Discussion upon the Theory of Strong Electrolytes, *Trans. Faraday Soc.*, 1927, 23). Remy (*ibid.*, p. 381) deduces from mobilities the values $H^{\cdot}$ 0·9, $K^{\cdot}$ 4·1, $Na^{\cdot}$ 7·4, $Li^{\cdot}$ 12·6 for the "water-sheaths" of these ions, Cl' having the value 3 dependent upon the assumption that large organic ions have no sheaths. Scatchard (*ibid.*, p. 454; *J. Amer. Chem. Soc.*, 1925, 47, 2098; 1927, 49, 217), from calculations of activities in water–alcohol solutions, concludes that lithium, sodium, potassium, and chlorine ions are not "chemically hydrated," but that the hydrogen ion may be present in the form $H_9O_4^{\cdot}$. This conception of the hydrogen ion has been used also by Fajans (*Trans. Faraday Soc.*, 1927, 23, 357) in dealing with refractometric measure-

ments upon hydrochloric acid solutions. It is necessary to distinguish between "chemical hydration" and the more general attraction between ions and solvent ("solvation"), such as is assumed to lead to the presence of aggregates of water molecules with ions as centres (compare Scatchard, *loc. cit.*).

Bjerrum (*Z. anorg. Chem.*, 1920, **109**, 275) calculated from heats of dilution that hydrochloric acid is associated with 8 molecules of water and that sodium and potassium chlorides are relatively non-solvated. It appears that some methods detect only chemical hydration and that others which indicate solvation as well have not yet been satisfactorily correlated.

The extension to concentrated solutions by Hückel (*Physikal. Z.*, 1925, **26**, 93) of the original theory of complete dissociation of strong electrolytes (Debye and Hückel, *ibid.*, 1923, **24**, 185), and the work of Harned (*J. Amer. Chem. Soc.*, 1926, **48**, 326) upon the activity of hydrochloric acid in concentrated solutions of lithium, sodium, and potassium chlorides, supporting the extended theory, have prepared the way for the examination of other properties of such solutions. The work now described is a contribution in this direction.



The solubilities of potassium and sodium chlorides in hydrochloric acid solutions of concentrations varying between the widest limits have been determined, together with the densities and viscosities of the solutions, all at 25°. Previous measurements of the solubilities of alkali chlorides in hydrochloric acid have been made at 0° by Engel (*Compt. rend.*, 1886, **102**, 113, 619) and at 30° by Masson (J., 1911, **99**, 1132). Others, including Armstrong and Eyre (*Proc. Roy. Soc.*, 1907, *A*, **79**, 564 *et seq.*) and Gibson and Denison (*Proc. Roy. Soc. Edin.*, 1911, **30**, 562), have studied in a more general way the precipitating action of the acid. A full review is given in the Reports of the British Association of 1910 and 1911 in the sections on Solubility. The viscosities do not appear to have been measured for such mixtures.

Determination of Viscosities.

The method adopted was that due to Scarpa (*Gazzetta*, 1910, **40**, 271) with a viscometer (Fig. 1) similar to that used by Farrow (J., 1912, **101**, 347). The dimensions of the apparatus were: bulb 5 c.c., capillary length 10 cm., bore 0·4 mm.; the lower end of the capillary stood 2 cm. above the bottom of the outer cylindrical vessel, which was 3 cm. in diameter. The rest of the apparatus (negative pressure device and manometer) was like that of Farrow, except that a three-way stopcock was added in order to facilitate the operations.

The viscometer was standardised with conductivity water at 25° ± 0·02°, with a negative pressure of 300 mm. on the gauge, absolute alcohol being used as the gauge indicator liquid. The constant of the apparatus was thus determined, using the expression $k = \eta_w/[t_1t_2/(t_1 + t_2)]_w$, η_w, the coefficient of viscosity of water, being taken as 0·0891 (Thorpe and Rodger), and t_1 and t_2 being the times of flow upwards under the applied negative pressure and downwards by gravity. Rigorous precautions of cleanliness were taken throughout the whole of the experiments, and corrections were applied for variations in temperature of the gauge liquid which stood outside the thermostat. The constant of the viscometer was independent of the amount of water used in the outer vessel to within 0·1%, and was reproducible with this accuracy at intervals during the subsequent measurements with the solutions. It was also shown that a layer of well-washed garnets placed below the end of the capillary tube, even to a depth of 1 cm., had no influence on the constant; so that, in the case of solutions, any small layer of undissolved solid would have no effect in this way.

FIG. 1.

The apparatus was tested by determinations upon a sample of absolute alcohol ($d_4^{25°}$ 0·78711) and comparisons were made with values found for the same liquid in (i) an ordinary Ostwald viscometer and (ii) an Ostwald constant-pressure viscometer, in the same thermostat. The results were:

η (Scarpa) 0·01107; η (Ostwald, i) 0·01108; η (Ostwald, ii) 0·01106.

With a higher negative pressure of 400 mm. the Scarpa method gave a lower value, *viz.*, 0·01098. It appeared that the Scarpa method, with a gauge pressure of 300 mm., would be accurate to 0·1% compared with the Ostwald ordinary method. (The adjustments required in the Ostwald constant-pressure method are tedious, and it seems likely that the Scarpa method could conveniently replace it when a method not requiring density measurements is required.)

Recently, King and Partington (*Trans. Faraday Soc.*, 1927, **23**, 528), using the Scarpa method with a different design of tube, found difficulty in obtaining satisfactory agreement with the Ostwald method carried out in the same tube. For some of their salt solutions values as much as 6% higher were calculated from the former, and for a sample of alcohol ($d_4^{25°}$ 0·78507) they gave

η (Scarpa) 0·01065; η (Ostwald) 0·01071.

Whilst no explanation of these discrepancies can be offered, they should not be taken as reflecting on the accuracy of the present work, the results of which afford a testimony to the usefulness of the method.

For the determinations upon the salt and acid mixtures, the acid solution of approximately known strength, prepared from a stock of specially distilled acid, was heated in a flask on a water-bath at 50—60° with a moderate excess of the pure salt, and the saturated solution was subsequently brought to equilibrium by shaking in the thermostat at 25° ± 0·02°. A quantity of 35—40 c.c. of solution, together with a little of the salt, was then quickly poured into the viscometer vessel, which was stoppered and had a glass stirrer. The final equilibrium was thus attained in the viscometer, and before the introduction of the capillary tube, slightly warmed, any suspended salt crystals were allowed to settle. Even with the strongest and densest solutions a perfectly clear solution was readily obtainable. The times of flow, measured to 0·2 sec., were usually constant after the first run, and only infrequently was any trouble experienced due to crystals finding their way into the capillary. The viscosity was calculated from $\eta_s = k \times [t_1 t_2/(t_1 + t_2)]_s$, the appropriate value of k for the observed gauge temperature being used.

Density determinations were made by pipetting with a warmed pipette sufficient liquid to fill a 25 c.c. density bottle which was suspended in the thermostat. The bottle had a cap over the stopper and was calibrated with pure water. The contents of the bottle were suitably diluted, and the acid was estimated by titration and the total chloride by weighing as silver chloride.

Redeterminations of the viscosities were frequently made upon the liquid remaining after the first withdrawal, with or without fresh additions, and the value was found to be unaltered and independent of the amount of liquid in the outer vessel. The usual order of agreement was to 0·1%, and the variation never exceeded 0·3%.

All apparatus used in the analyses was carefully calibrated and duplicate determinations were made, the total chloride estimations agreeing at least to 0·05%. The salts were tested and proved to be very pure. Acid solutions of high concentration were obtained by generating pure dry hydrogen chloride from the stock acid by a method which was shown to give no contamination with sulphuric acid.

In Table I are the results for solutions containing potassium chloride. In col. 1 are the absolute densities, $d_4^{25°} = 0{\cdot}99707\frac{w'}{w} - \left[\frac{0{\cdot}0012(w' - w)}{w}\right]$; in col. 2 is η, the coefficient of viscosity (in c.g.s.

units); cols. 3, 4, and 5 respectively give molar concentrations of acid, salt and total solute; col. 6 the molar concentration of water ($H_2O = 18{\cdot}016$); col. 7 is the sum of cols. 5 and 6.

Table II gives the data for solutions saturated with sodium chloride; and at the end are given the comparative values for pure water and for one solution of pure acid with no salt.

Discussion of Results.

Density and Volume Relations.—The changes which take place when acid replaces salt in the solutions can be expressed in terms of the molecular and ionic solution volumes of the constituents. In view of the order of ionic sizes as deduced from crystal lattice measurements by Wasastjerna (*Soc. Sci. Fenn. Comm. Phys. Math.*, 1923, **38**, 1), the various species to be considered would fall in the series $H^{\cdot} < Na^{\cdot} < K^{\cdot} < H_2O < HCl < NaCl < KCl$, and the hydrogen

ion may be assumed to have negligible volume, or, if combined in the form $H_3O^{\cdot}$, it may provisionally be put equal to O'' or to H_2O.

The first addition of acid to the saturated sodium chloride solution results in a slight decrease in the total chloride (Table II, col. 5), accompanied by a small increase in water concentration and in the total number of molecules per litre (cols. 6 and 7). Rather more than an equivalent of salt is precipitated and hence there is more room for water to enter.

With further additions of acid the total solute concentration rises and, as the main factor influencing the volume effects is the chlorine ion (or radical), the amount of water which can remain begins to fall. The increase in chlorine-ion concentration more than balances the effect due to the decrease in sodium-ion concentration.

The volume effects are accompanied by mass changes reflected in the densities and this value falls at first, reaches a minimum, and then rises when the mass influence of the increasing chlorine-ion concentration preponderates.

The case for the potassium chloride mixtures is slightly different, and there is no lowering of the total solute content on the first addition of acid to the saturated solution of the pure salt. The removal of the larger potassium ions (compared with sodium ions), more nearly equal in size to water molecules, allows more room for chlorine accompanying hydrogen. The total solute concentration and the total number of molecules per litre both increase, and this continues until most of the potassium has been removed. Then, first the water concentration, and subsequently the total number of molecules, diminish as with the sodium chloride solutions. The mass effects again show in the densities, but the minimum occurs at a lower salt concentration. It can be seen that potassium chloride is not completely precipitated, and at the end of the series in solutions of high acid concentration it is still appreciably soluble, there being actually a slight increase in solubility.

The solubility effects thus appear to be dependent to a large degree upon the volumes in these series of mixed solutions of high concentration.

The above considerations can be extended in a quantitative way. Masson (*loc. cit.*) used an expression of the form $d = K + k_1a + k_2b$ to connect the densities with the molar concentrations of acid (a) and salt (b), K, k_1, and k_2 being constants. The constants k_1 and k_2 represent terms such as $(M - \alpha d_w)/1000$, where M is the molecular weight of the acid or salt, α the molar solution volume, and

d_w the density of the solvent in solution. The equation may be rewritten:

$$1000(d_4^{25°} - d_w) = a(M_a - \alpha d_w) + b(M_b - \beta d_w).$$

This gives the difference in mass of one litre of solution and the same volume of water of the same apparent density as that in the solution. Thence also:

$$d_4^{25°} = d_w + (a/1000)(M_a - \alpha d_w) + (b/1000)(M_b - \beta d_w).$$

Masson's conclusion, that the molecular solution volumes of water, salt, and acid remain constant over considerable ranges, is borne out.

Instead of the above formula, there may be substituted for it a similar expression in which the ionic solution volumes are used instead of the molecular values of the acid and salt. This reads

$$d_4^{25°} = K + 0{\cdot}001a + k_2'b + k_3c.$$

K is the same as before, and since the ionic volume of the hydrogen ion is very small and its mass is approximately unity, k_1' has become 0·001, a, b, and c being the concentrations of hydrogen (ion), sodium (ion), and chlorine (ion) respectively. The data have been tested and constants deduced for this formula. The constants were first determined for the sodium chloride series, and it was then found that only k_2' had to be changed in order to obtain agreement with the data for potassium chloride. Having determined k_2' for each salt, the constants for the simpler formula of Masson could be obtained by direct summation, since for this equation

$$k_1 = 0{\cdot}001 + k_3 \text{ for the acid } (H^{\cdot} + Cl'),$$
$$k_2 = \quad k_2' + k_3 \text{ for the salt } (Na^{\cdot} + Cl').$$

The two formulæ give, of course, practically identical results when tested on the same data, and hold good for each series as far as the point of minimum density. Tables III and IV give the results of these calculations, the appropriate values of the constants being included.

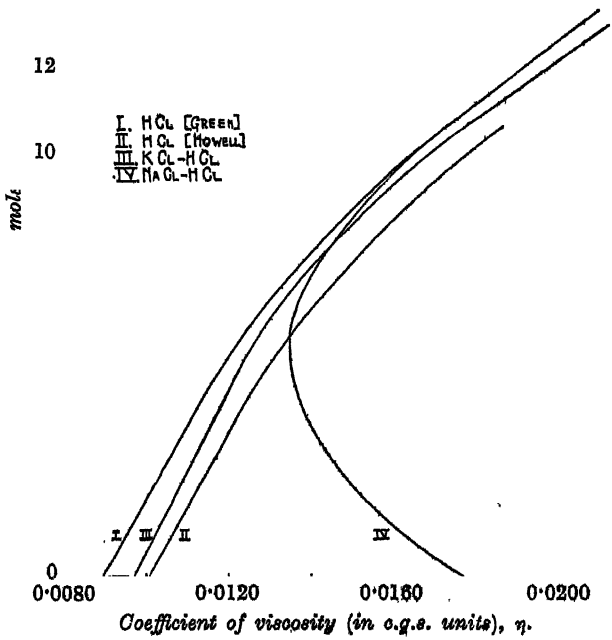
It appears that if the ionic solution volumes of the constituents remain constant in the mixtures for which the calculations hold good, then the molecular volume of the water also is constant and the apparent density of the water is $d_w = 1{\cdot}01275$. From this value, the ionic and molecular solution volumes can be obtained, these being presented in the following table, together with values calculated from the ionic lattice radii of Wasastjerna (*loc. cit.*) on the assumption that the ionic volumes bear the same relation to the solution volumes as does the volume of the bivalent oxygen atom O″ (ion) to the water molecule H_2O, taken as 18. The molecular volumes of the acid and salts are taken as the sums of the ionic volumes, the hydrogen ion being assumed to have negligible volume.

	$Na^{\cdot}$.	$K^{\cdot}$.	Cl'.	H_2O.	HCl.	NaCl.	KCl.
From data	1·58	12·25	22·43	17·795	22·43	24·00	34·66
From lattice radii ...	8·06	17·60	39·83	18·000	39·83	47·89	57·43



The further removed in size the ion is from the water molecule, the smaller is its apparent solution volume compared with that calculated from lattice radii (compare Hartley and Raikes, *Trans. Faraday Soc.*, 1927, **23**, 393). The values for the acid and salts are roughly half those so derived.

The constancy of the apparent density of the water in the solutions over the ranges indicated is connected with the constancy of the molar concentration of water over these regions, and when the acid concentration rises further, the calculated densities become increasingly lower than the observed values. If the molar or ionic volumes of acid and salt still remain constant, an increase in the apparent density of the water must be assumed.

Thus, to account for the density of the solution for which $a = 7{\cdot}976$ and $b = 0{\cdot}158$ in Table II, the value of K would have to be about 1·0150, and k_1 and k_2 0·0137 and 0·0341, respectively, giving $d_4^{25°}$ (calc.) 1·1296. It would be possible to express the densities of all the solutions of higher acid strength in a similar way. The changes in the apparent density of water can also be followed in solutions of pure hydrochloric acid, and for this purpose

the data of Green (J., 1908, **93**, 2023) and Ellis (*J. Amer. Chem. Soc.*, 1916, **38**, 750) have been examined. Calculations based on $d_4^{25^\circ} = 1{\cdot}01275 + 0{\cdot}01375a$ give fair agreement for those regions of acid concentration comparable with the total solute concentrations in the acid–salt mixtures for which the same formula holds, thus indicating that the molecular volumes of water and acid are the same, or nearly so, as in the mixed solutions. There is, however, undoubtedly, a continuous change in the water value as the acid concentration rises from zero.

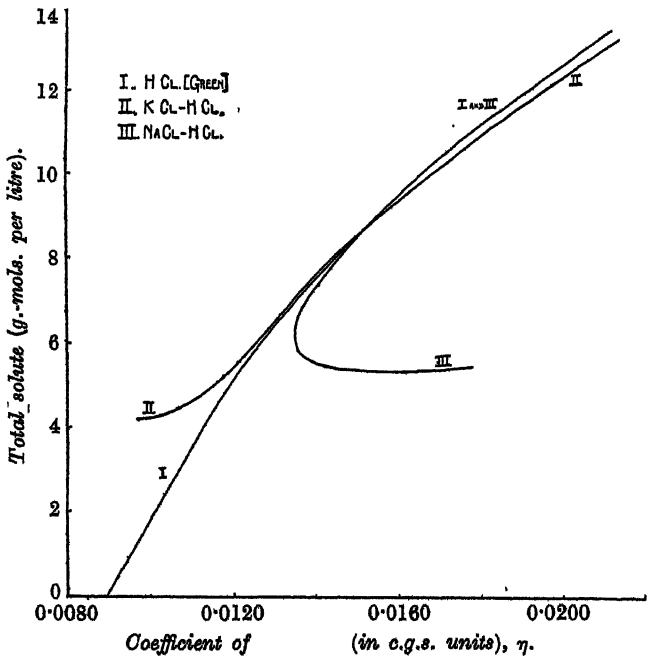


FIG. 2.

Viscosities.—From Tables I and II, it is seen that for the solutions containing potassium chloride the viscosities increase throughout with increasing acid concentration, and that the case for the solutions containing sodium chloride is essentially different, there being a pronounced minimum. In Fig. 2 are plotted the coefficients of viscosity as abscissæ against acid concentration as ordinates. For comparison the curves for the data of Green (*loc. cit.*) at 24·9° and of Howell (J., 1927, 168) at 20° for aqueous solutions of hydrochloric acid alone are also drawn. The positions of the curves in the regions of high acid concentration afford excellent evidence of the accuracy of the method used. The outstanding features of the curves in the regions of medium and low acid concentrations [illegible]

first, the parabolic form for the sodium chloride mixtures, and, secondly, the quite different form, similar to that for pure acid solutions, for the potassium chloride mixtures. As shown by Table V, the data for the sodium chloride solutions can be fairly accurately represented by the expression $6700(\eta - \eta_m) = (C - C_m)^2$, where η_m is the minimum viscosity, and C_m the acid concentration of the corresponding solution, η and C being the values for other solutions between $C = 0$ and $C = 10$. Above the latter concentration scarcely any salt is present and the curve is almost linear.

FIG. 3.

The interpretation of this relationship is not yet clear and in the meantime another method of approach has been considered.

TABLE V.

$6700\ (\eta - \eta_m) = (C - C_m)^2$; $\eta_m = 0{\cdot}01353$; $C_m = 5{\cdot}300$.

3·830	1391	1385	13·41	2111	2336

In Fig. 3, the viscosities are plotted against *total solute*, the curve for Green's data again being included. It is now seen that the curve for potassium chloride mixtures lies to the left of that for the pure acid (except at very high concentrations), whilst that for sodium chloride mixtures lies to the right, and solutions of equal chlorine (ion) concentration have in the one case lower and in the other case higher viscosities than for the pure acid solutions. The curves merge at concentrations of about $8{\cdot}7N$ and above this point those for pure acid and for sodium chloride mixtures are indistinguishable, the concentration of salt being very low; the curve for potassium chloride mixtures in this region diverges from the others, having crossed the pure acid curve at the above point.

Dealing first with the case for the sodium chloride mixtures, for which the volume relations are simpler (since the total number of molecules, water concentration, and chlorine-ion concentration do not vary so much as in the potassium chloride solutions during the replacement of the major portion of the salt by the acid), there has to be explained a large relative fall in viscosity caused by the substitution almost equivalent by equivalent of hydrogen for sodium. The changes are roughly proportional to the fractions of salt precipitated, almost as far as the point of minimum viscosity. The conclusion that the sodium ions are present in the form of particles of relatively large effective size and that they are solvated to a higher degree than the hydrogen ions seems very reasonable.

To obtain an idea of the magnitude of the solvated sodium ions ($Na',\varkappa H_2O$), which would quantitatively account for the effects found, the following procedure may be considered.

The formula $\eta_2 = \eta_1(1 + 2{\cdot}5\phi)$ can be applied to calculate the changes of viscosity for hydrochloric acid solutions of from 3·5 to $6N$, η_1 and η_2 being the viscosities for two different concentrations c_1 and c_2; ϕ is a term $0{\cdot}02243(c_2 - c_1)$, and is therefore the volume of chlorine ions added to 1 c.c. of solution and replacing a volume of water. The volume 22·43 for Cl' is that already deduced from the density data of these solutions and the mixed solutions. The formula, which is a modification of that of Einstein (*Ann. Physik*, 1906, **19**, 289), gives good agreement when tested on Green's data. Better agreement is, however, obtained by using the formula $\eta_2 - \eta_1 = \frac{1}{2}(\eta_1 + \eta_2) \times 2{\cdot}5\phi$, which expresses the variations about the mean viscosity value in terms of the volumes of ions added or removed, any specific effect of the hydrogen ions being for the present neglected. The formula may now be used to calculate approximately the volume of the sodium ions in a saturated solution of sodium chloride, by comparing this solution with a solution of hydrochloric acid of equal chlorine (ion) concentration, it being

assumed that the hydrated sodium ions have, like the chlorine ions, an effect proportional to their volume. The resulting calculation made from the figures

$$c = 5{\cdot}43;\ \eta(\mathrm{NaCl}) = 0{\cdot}01779;\ \eta(\mathrm{HCl}) = 0{\cdot}01226, \text{ from graph}$$

gives for the 5·43 g.-ions of sodium in the litre a volume of 147·2 c.c. Hence the volume of $(Na^{\cdot},xH_2O)$ is 27·1 c.c. If the value 1·58 found for the $Na^{\cdot}$ ion alone be subtracted, the volume 25·54 c.c. is obtained for the water accompanying 1 g.-ion of sodium, and the hydration number is 1·44, using $d_w = 1{\cdot}01275$.

In a somewhat similar way the series of sodium chloride–hydrochloric acid solutions may be used to obtain the volumes of the $Na^{\cdot},xH_2O$ ions and the hydration numbers, the hydrogen ions being again supposed to have no volume effect. In Table VI are the results of calculations made from values taken from the graphs of the original data, changes of concentration of sodium chloride of 0·5*N* being taken as convenient.

TABLE VI.

η.	NaCl.	HCl.	Total solute.	Vol. of $Na^{\cdot},xH_2O$.	x.
0·01779	5·43	—	5·43	32·02	1·71
0·01713	5·00	0·37	5·37	32·44	1·73

0·01580	4·00	1·36	5·36	29·26	1·56
0·01525	3·50	1·90	5·40	26·48	1·40
0·01477	3·00	2·42	5·42	29·14	1·55
0·01433	2·50	3·03	5·53	26·32	1·39
0·01396	2·00	3·65	5·65	23·52	1·23
0·01367	1·50	4·30	5·80	32·44	1·73
0·01350	1·00	5·30	6·30		

In these calculations, due allowance has been made for changes of chlorine-ion concentration. It is seen that the degree of hydration (x) of the sodium ions required in order to account for the observed viscosities is quite low, being about 2 for the saturated solution of the pure salt. As acid is added the value falls, and this may be due to the formation of $H_3O^{\cdot}$ ions; but there is at present no direct evidence on this point, although there is evidence that the hydrogen ions are not more highly hydrated. The chlorine ions are probably not appreciably hydrated in these solutions.

The potassium chloride mixtures may now be examined and the hydration numbers derived. In this case we have to deal with the replacement of smaller particles (the potassium ions) by the larger water molecules, the viscosities rising with increasing acid concentration at a greater rate than would be accounted for by the increase in chlorine-ion concentration alone. By comparison of the saturated

potassium chloride solution with the pure acid solution of equal concentration, the calculation for the volume of ions substituted gives, from $c = 4{\cdot}2$, $\eta(KCl) = 0{\cdot}00971$, and $\eta(HCl) = 0{\cdot}01143$, a value 15·5 c.c. for the potassium ion. Since, however, the exchange in this case is not that of H_2O for Cl', but of $K^{\cdot}$ for H_2O, this value really measures the size of a potassium ion compared with a water molecule, as though a water molecule had a volume equal to that of a chlorine ion, and the number requires reducing in the proportion 17·795 : 22·43. If this is done, the final value of 12·29 is obtained, which is almost exactly that previously deduced for the potassium ions from the density data. Hence these ions are not appreciably hydrated.

The series of potassium chloride–acid solutions gives, when examined in this way, as with the sodium chloride series, allowance being made for changes of chlorine-ion concentration, a series of volumes for the potassium ions falling from 15·68 to 12·20, whilst the potassium chloride concentration falls from 4·2 to 0·96, thus supporting the conclusion that the potassium ions do not show hydration to any marked extent. The calculations also further support the view that the chlorine ions are not hydrated, and that there is no hydration of the hydrogen ions beyond the stage $H_3O^{\cdot}$.

It is not suggested that these explanations give a complete account of the phenomena studied. In the regions of higher acid concentration, the viscosities rise much more rapidly than can be accounted for on the basis of the ionic and molar volumes deduced for the lower concentrations, and there are indications of the formation of other types of complex ions.

Summary and Conclusions.

The solubilities have been determined at 25° of potassium and sodium chlorides in aqueous solutions of hydrochloric acid of concentrations varying between 0 and 13·5*N*.

The densities and the viscosities of the same solutions have been measured, the method of Scarpa for the determination of relative viscosity being shown to be trustworthy with the apparatus used.

Complete dissociation of the acid and of the salts being assumed, a formula is developed connecting the densities of the solutions, on the one hand, with the ionic concentrations, ionic solution volumes, and the apparent density of the water in the solutions, on the other; this formula is used for the calculation of the solution volumes of all the constituents. For solutions of acid concentrations between 0 and 6*N*, with either salt, it is unnecessary to assume any variations in the solution volumes and the same values for the chlorine ion and the water molecule apply in both series. These values also give

satisfactory account of the densities of pure hydrochloric acid solutions of comparable total chloride strength.

Solutions of equal chlorine-ion concentration up to about 9*N* have either lower or higher viscosities than solutions of hydrochloric acid alone according as they are saturated with potassium or with sodium chloride. The solution volumes deduced from the densities are used to give an account of the viscosities of those solutions of hydrochloric acid alone and of potassium chloride–hydrochloric acid to which they refer. No hydration of the chlorine ions is indicated. The potassium ions are hydrated only to a slight extent, if at all. The hydrogen ions may be present in the form H_3O^+ but are probably not more highly hydrated. The viscosities of the solutions containing sodium chloride cannot be accounted for on a similar basis without introducing a hydration factor of about 2. This value falls as the solutions become more strongly acid.

The author desires to express his thanks to Professor Boon for providing the facilities which have enabled the work to be carried out.

HERIOT-WATT COLLEGE, EDINBURGH. [*Received, May 5th*, 1928.]

CCLII.—*The Influence of Structure on the Solubilities of Ethers. Part I. Aliphatic Ethers.*

By GEORGE MACDONALD BENNETT and WILLIAM GEORGE PHILIP.

THE mutual solubilities of ethyl ether and water have been determined with considerable accuracy by several observers, but the corresponding data for other ethers are lacking. In order to reveal the influence of variations in structure on this property, we have measured the solubilities of six isomeric ethers of the formula $C_5H_{12}O$, *viz.*, methyl *n*-butyl, methyl *iso*butyl, methyl *sec.*-butyl, methyl *tert.*-butyl, ethyl *n*-propyl, and ethyl *iso*propyl ethers, and also of the following ethers: methyl *n*- and *iso*-propyl, di-*n*-propyl, propyl *iso*propyl, di-*n*-butyl, and diallyl.

Preparation of Materials.—With the exception of methyl *tert.*-butyl ether, the ethers were most conveniently prepared by Chancel's modification (*Annalen*, 1869, **151**, 305) of the Williamson method, in which an alcohol and an alkyl halide are heated with an excess of solid potassium hydroxide. The latter may be heated first under reflux with the alcohol and the halide then added, or, in other cases, the finely powdered potassium hydroxide may be added gradually to the boiling mixture of the alcohol and the halide. For ethyl *iso*propyl ether, ethyl iodide, *iso*propyl alcohol, and

potassium hydroxide were heated in a closed bottle at 100° for several hours. It was found necessary to use only normal alkyl iodides in this reaction, methyl *iso*propyl ether being obtainable, for example, from *iso*propyl alcohol and methyl iodide, but not from methyl alcohol and *iso*propyl iodide. Methyl *tert.*-butyl ether could not be prepared by Chancel's method, and that of Henry (*Rec. trav. chim.*, 1904, **23**, 329) was adopted.

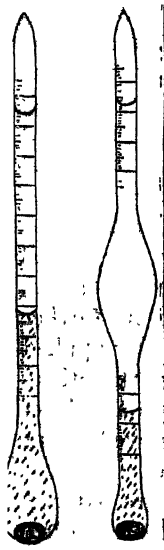
The customary methods of purification of some of these substances were incapable of removing the last traces of the halides used in their preparation. A specimen of ethyl *iso*propyl ether, for instance, after repeated fractional distillation and after boiling for 6 hours with metallic potassium, still contained some iodide, although its density, $d_4^{0°}$ (vac.) 0·7452, was in agreement with the value in the literature. (Compare the difficulty of removing iodides from hydrocarbons; Welt, *Compt. rend.*, 1894, **119**, 743.) The trace of iodide was completely removed by boiling the liquid for 5 hours with diethylamine (15—20% by wt.), and then washing it successively with water, dilute acid, and again with water. The specimen, referred to above, thus purified had, after drying and redistillation, $d_4^{0°}$ (vac.) 0·7440; it was entirely free from halogen, and a repetition of the process of purification caused no further alteration in its density. This method of purification was applied in all cases where an alkyl halide had been used, and the ethers were obtained in a state of greater purity than had previously been attained, as is shown by the fact that the densities observed are in several cases lower than those recorded in the literature.

The following constants were observed (all densities are reduced to a vacuum; the b. p.'s are corrected, but are not to be regarded as such trustworthy criteria of purity as the densities, since often only small quantities of material were available): Methyl *n*-butyl ether, b. p. 70°, $d_4^{0°}$ 0·7635, $d_4^{20°}$ 0·7441; methyl *iso*butyl ether, b. p. 58°, $d_4^{0°}$ 0·7523, $d_4^{20°}$ 0·7311; *methyl* sec.-*butyl ether*, prepared by Chancel's method and purified as described above, b. p. 59°, $d_4^{0°}$ 0·7621, $d_4^{20°}$ 0·7415 (Found: C, 68·8; H, 13·8. $C_5H_{12}O$ requires C, 68·3; H, 13·6%); methyl *tert.*-butyl ether, b. p. 54°, $d_4^{20°}$ 0·7578; ethyl *n*-propyl ether, b. p. 64°, $d_4^{0°}$ 0·7541, $d_4^{20°}$ 0·7330; ethyl *iso*propyl ether, b. p. 53°, $d_4^{0°}$ 0·7440, $d_4^{20°}$ 0·7211; methyl *n*-propyl ether, b. p. 37°, $d_4^{0°}$ 0·7494, $d_4^{13·0°}$ 0·7356; methyl *iso*propyl ether, b. p. 32°, $d_4^{0°}$ 0·7383, $d_4^{15°}$ 0·7237; di-*n*-propyl ether, b. p. 91°, $d_4^{20°}$ 0·7360; *n*-propyl *iso*propyl ether, b. p. 83°, $d_4^{0°}$ 0·7597, $d_4^{12·5°}$ 0·7474; di-*n*-butyl ether (purchased), b. p. 140°, $d_4^{0°}$ 0·7841; diallyl ether, b. p. 94°, $d_4^{0°}$ 0·8449, $d_4^{20°}$ 0·8260.

Methods of Measurement.—Of the methods available for determining the mutual solubilities of two liquids, that of Hill (*J.*

Chem. Soc., 1923, **45**, 1143) appeared to be the best, particularly as it gives information as to the composition of both phases of the system; as originally described, however, it involved large vessels and the use of at least 400 c.c. of each liquid, and we therefore reduced the scale of the apparatus in order to adapt it to small quantities of substances (*i.e.*, 4—5 c.c. of each liquid) without appreciable loss of accuracy. The two vessels (Fig. 1) were made from glass tubing of 5 mm. bore, graduated in mm., and were care-

FIG. 1.



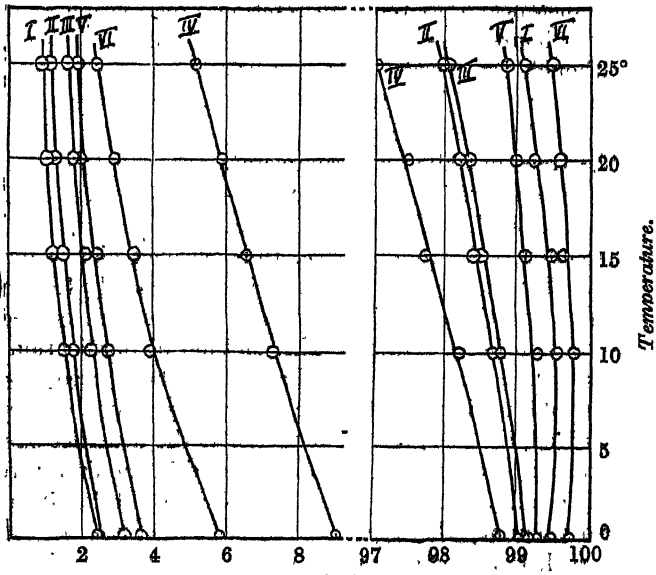


FIG. 2.

Mutual solubilities of isomeric ethers $C_5H_{12}O$ *and water.*

I. *Methyl* n-*butyl ether.*

IV. *Methyl* tert.-*butyl ether.*
V. *Ethyl* n-*propyl ether.*
VI. *Ethyl* iso*propyl ether.*

fully calibrated (in the thermostat) by measuring the volumes of observed weights of pure toluene. The pear-shaped form of the bulbs is important in order to allow the two phases to segregate completely.

It was at first found difficult to secure complete mixing of the phases in these narrow tubes in which an air bubble would not travel. An electromagnetically activated plunger did not bring about rapid mixing, but excellent results were obtained by enclosing in the tube a globule of pure mercury occupying about 1 cm. of the narrow part. When the tube was repeatedly inverted in the ther-

mostat, the mercury travelled down the tube and caused turbulent mixing, complete equilibrium being reached in less than ½ hour.

The thermostat was electrically heated and controlled, the variation being less than 0·01°. Temperatures were read on a thermometer graduated in 0·1° and recently standardised at the National Physical Laboratory. When mixing had been effected, the tubes were attached to a frame and rotated about a vertical axis for 10 minutes to promote the separation of the phases. The tubes were then fixed, preparatory to reading the volumes, in such a position that the glass points, where they had been sealed in filling, protruded 1 cm. above the water in the bath, and a current of hot air was blown on to the tips to drive down any liquid into the body of the tube. The volumes of the phases were then read through a telescope 3 feet from the glass front of the thermostat, strong illumination being supplied through a ground glass screen behind the tubes. The mixing and manipulations were repeated until the readings were constant, the values in practice being reproducible to less than 0·01 c.c. The possibility of error due to the difference in shape of the ether–water and ether–air meniscuses was examined by a trial with pure paraffin (b. p. 60—70°) and water. Any error involved is less than that of observation.

A redetermination of the solubilities of ethyl ether at several temperatures gave the following results:

Temp.	Ether in aqueous phase.	Water in ether phase.
25°	6·03% (6·03)	1·30% (1·34)
20	6·87 (6·90)	1·24 (1·26)
15	7·95 (7·91)	1·26 (1·24)
10	9·01 (9·04)	1·14 (1·16)

The agreement with Hill's values (in brackets) is close, and there is reason to believe that the reduction of scale of the experiments has not introduced an error as large as 0·05%. Apart from this, our figures are presumably subject to a small error inherent in the original method when very low solubilities are measured (compare Kablukov and Malischeva, *J. Amer. Chem. Soc.*, 1925, **47**, 1553; Hill and Malisoff, *ibid.*, 1926, **48**, 918). This error is not large, and, being systematic, will not affect the validity of any comparison made between similar values of solubility. We obtained an indication of some error of this kind by comparing the figures for *n*-propyl ether, obtained by the method described above, with those found by the "synthetic" method of Alexejew (*Wied. Ann.*, 1886, **28**, 305). In this case the latter figures are consistently 0·2% lower than the former. For a few of the ethers examined, determinations were made by the synthetic method and for the aqueous phase only. Weighed quantities of the ether and of water were sealed up together

and the temperature at which turbidity just appeared was determined in a large vessel of water.

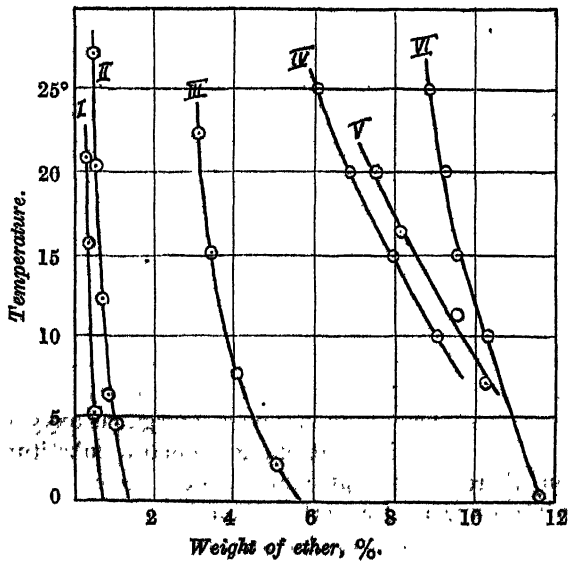
Results.—Measurements by the volumetric method were made at 25°, 20°, 15°, 10°, and 0·25° or 0·5°. Two separate sets of measurements were made in each case. The resulting data for the isomeric ethers $C_5H_{12}O$ are plotted in Fig. 2, the scale being doubled for the right-hand curves for the sake of clearness. The values recorded in Table I have been taken from the smooth curves: the corrections thus introduced are usually of the order ± 0—0·05%. The curves in Fig. 3, except those of ethyl and allyl ethers, record measurements by the synthetic method, and the smoothed values are given in Table II.



Discussion of Results.

The solubilities of water in the ethers are all small and vary only little with temperature. Those of the ethers in water vary over a wide range for the isomeric substances studied. These values, moreover, all decrease with rising temperature. Approximate

values of the (positive) molecular heats of solution (Q) of the ethers in water have been calculated in the usual way from the slopes of the solubility curves at 10—20° and are recorded in Table I.

It is noticeable that the relative order of the solubilities of the compounds remains the same at all temperatures. For the isomeric ethers $C_5H_{12}O$, this order is: Methyl *n*-butyl (1·51), methyl *iso*butyl (1·79), methyl *sec.*-butyl (2·33), ethyl *n*-propyl (2·74), ethyl *iso*propyl (3·99), methyl *tert.*-butyl (7·30), the figures in brackets being the values at 10°. The order for the isomerides $C_4H_{10}O$ is:

FIG. 3.

II. *Propyl* iso*propyl ether.*
III. *Methyl* n-*propyl ether.*
IV. *Diethyl ether.*
V. *Methyl* iso*propyl ether.*
VI. *Diallyl ether.*

Methyl *n*-propyl (3·8), diethyl (9·0), and methyl *iso*propyl (9·7). Throughout these values the solubility is seen to increase with increased branching of the carbon chains of the alkyl groups.

The various physical properties of ethers in the pure state show them to be correctly classified as "normal" liquids. Evidence of various kinds is available in the case of ethyl ether: surface tension data are given by Morgan and Stone (*J. Amer. Chem. Soc.*, 1913, 35, 1505) showing the same result with ethyl *n*-propyl ether, and measurements of the solubility of naphthalene in some of these ethers, which lead to the same conclusion, are recorded in Part II of this investigation; but the

solubility of the ethers in water indicates "abnormal" behaviour, and classifies them as "polar" in the sense suggested by G. N. Lewis (*ibid.*, p. 1448). This abnormality, absent in the pure liquid but developed in presence of water, is evidence of the presence in the latter case of a new molecular species of a polar type. Moreover, the comparative solubilities may be taken as an approximate indication of variations in the extent of the chemical action to form the complex $R_2O \longrightarrow HOH$. This point of view has recently been clearly stated by Sidgwick (Presidential Address to the British Association, Section B, 1927, and "The Electronic Theory of Valency," p. 137), who also explains the abnormally high solubilities in ether of hydroxylic substances in general as due to combination of the two to give the polar compound $R_2O \longrightarrow HOR$.

Three factors might consequently be expected to influence the solubilities in water of ethers which are of the same molecular weight.

(*a*) The chemical reactivity of the oxygen atom might be lowered by any accumulation of groups in its vicinity. Such a steric hindrance should cause a diminution in the solubility of isomerides as a normal radical is replaced by a secondary or tertiary one.

(*b*) The donating properties of the oxygen atom should, on the other hand, be increased if the attached radicals have an increased tendency to repel electrons (the "electron-source" effect). The experiments of Allan, Oxford, Robinson, and Smith (J., 1926, 401) have shown that the methyl group and particularly secondary alkyl radicals have this type of influence on a contiguous oxygen atom, as shown by its activity in controlling aromatic substitution. For this reason, therefore, the attachment of a secondary or tertiary radical to the oxygen of an ether should cause an increased solubility in water. An effect of this kind is somewhat similar to that which results in the higher strength of secondary aliphatic bases as compared with primary bases.

(*c*) Any increase in the length of a hydrocarbon chain will tend to reduce the solubility in water of the ether or of its complex with water (compare Langmuir, *Colloid Symposium Monograph*, Vol. 3, Chem. Catalog. Co., New York, 1925). It should be noticed that this effect is purely negative. The substitution of the *tert.*-butyl for the *n*-butyl radical does not, in the absence of an oxygen atom, confer an appreciable solubility on a substance, for *n*- and *iso*-butane are equally sparingly soluble in water.

The steric hindrance effect (*a*) appears to have been demonstrated for certain complexes of the alcohols by the experiments of Tschelinzeff (*Bull. Soc. chim.*, 1924, **35**, 741), but our figures do not reveal it. It is possible that this influence is present, but of a lower order of magnitude than the other effects, which oppose it. To

the latter effects, (*b*) and (*c*), may be attributed the observed variations of solubility. Although in general these two influences cannot be observed separately, the increased solubility of $MeO{\cdot}CH_2{\cdot}CHMe_2$ as compared with $MeO{\cdot}CH_2{\cdot}CH_2{\cdot}CH_2Me$ does presumably depend entirely on the length of hydrocarbon chain (*c*), whilst the increased value for $MeO{\cdot}CHMe{\cdot}CH_2Me$ as compared with $MeO{\cdot}CH_2{\cdot}CHMe_2$ reveals factor (*b*) independently of (*c*). The rapid fall in solubility with lengthened hydrocarbon chain, when molecular weight does not remain constant, is well shown by the following ethers: Ethyl (9·0), ethyl *n*-propyl (2·74), dipropyl (0·41), dibutyl (<0·01). In the molecule of diallyl ether the unsaturated groups confer a considerable freedom of movement of electrons, which should assist the donating function of the oxygen atom. The relatively high solubility of this substance was therefore to be expected.

THE UNIVERSITY, SHEFFIELD. [*Received, June 7th,* 1928.]

CCLIII.—*The Influence of Structure on the Solubilities of Ethers. Part II. Some Cyclic Ethers.*

By GEORGE MACDONALD BENNETT and WILLIAM GEORGE PHILIP.

A SERIES of cyclic ethers has been examined with respect to the solubilities in water, the compounds (*a*) being isomeric, (*b*) differing from the series of open-chain ethers (preceding paper) only by two hydrogen atoms and the closure of the ring, and (*c*) having a cyclic structure with a 6-, 5-, 4-, or 3-membered ring. The substances chosen were pentamethylene oxide, α- and β-methyltetramethylene oxides, *ββ′-dimethyltrimethylene oxide*, *αα′-dimethyltrimethylene oxide*, and αα′-methylethylethylene oxide, all of the molecular formula $C_5H_{10}O$.

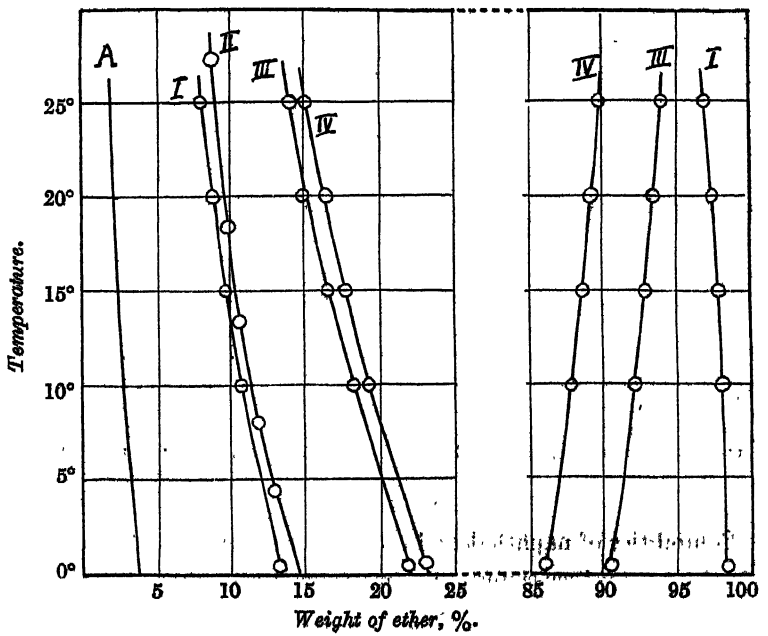
Preparation of Materials.—(i) Pentamethylene oxide was prepared as described by Clarke (J., 1912, **101**, 1788), and had b. p. 87°, $d_4^{20°}$ (vac.) 0·8814.

(ii) α-Methyltetramethylene oxide was obtained from the glycol resulting from the reduction of γ-acetylpropyl alcohol. The yields of the latter were consistently lower than those claimed by Possaner and von Ehrenthal (*Monatsh.*, 1903, **24**, 352): substitution of ethylene chlorobromide for ethylene dibromide caused no improvement, but the following method involving the use of ethylene chlorohydrin was much more satisfactory. To a solution of ethyl acetoacetate (65 g.) with sodium (12 g.) in ethyl alcohol (130 g.), ethylene chlorohydrin (45 g.) was added and the mixture boiled for 5 hours. The solution was filtered, evaporated, and the residue

boiled for 5 hours with dilute hydrochloric acid (120 c.c.; 10%). The solution was made neutral and concentrated under reduced pressure until salt had separated copiously. An excess of acetone was then added, the solution filtered from salt, evaporated, and distilled under reduced pressure (yield, 40%). The ether had b. p. 80°, $d_4^{20°}$ (vac.) 0·8732, $d_4^{20°}$ (vac.) 0·8540.

(iii) β-Methyltetramethylene oxide was prepared from ethyl methylsuccinate as described by Harries (*Annalen*, 1911, **383**, 170), and had b. p. 83°/738 mm., $d_4^{20°}$ (vac.) 0·8850, $d_4^{20°}$ (vac.) 0·8642.

(iv) ββ′-*Dimethyltrimethylene oxide* was made from the corresponding glycol (Just, *Monatsh.*, 1896, **17**, 76) through its monobromohydrin (Franke, *ibid.*, 1913, **34**, 1898). An improved yield of the latter was furnished by heating the glycol (1 mol.) with the solution made by passing sulphur dioxide into bromine (100 g.) and ice (110 g.) until the colour is yellow. The mixture was heated on the steam-bath for 5 hours, at its boiling point for 1 hour, and then diluted. The product was extracted in ether, the extract washed with sodium carbonate solution, dried over sodium sulphate, and fractionated. The bromohydrin had b. p. 100°/25 mm. (yield, 41%). It was mixed with three times its weight of dry, powdered potassium hydroxide, and heated in an oil-bath at 130—180°. The ββ′-dimethyltrimethylene oxide, after drying and redistillation, was a mobile liquid of camphoraceous odour, b. p. 78°/742 mm., $d_4^{20°}$ (vac.) 0·8550, $d_4^{20°}$ (vac.) 0·8348 (Found: C, 69·1; H, 11·5. $C_5H_{10}O$ requires C, 69·8; H, 11·6%).



(v) αα′-*Dimethyltrimethylene oxide* was prepared in a similar manner (yield, 43%) from the chlorohydrin, b. p. 72°/13 mm., obtained by the action of magnesium methyl iodide on ethyl β-chloropropionate (yield, 53%) as described by Henry (*Compt. rend.*, 1906, **142**, 133). The *oxide* had b. p. 71°/750 mm., $d_4^{20°}$ (vac.) 0·8490, $d_4^{20°}$ (vac.) 0·8279. It is a liquid of pleasant odour, and dissolves with evolution of heat in water, becoming hydrated to the corresponding glycol. Great difficulty was experienced in analysing this and the foregoing substance: apart from their volatility, the *gem*-dimethyl group may have caused low values. This substance was also hygroscopic. The specimens were always redistilled immediately before use, but no direct evidence of their freedom from impurity is available.

(vi) αα′-Methylethylethylene oxide was prepared as described by Tiffeneau (*Compt. rend.*, 1902, **134**, 775; 1907, **145**, 437). It had b. p. 80·5°/755 mm., $d_4^{20°}$ (vac.) 0·8425, $d_4^{20°}$ (vac.) 0·8220 (Found: C, 70·2; H, 11·4. Calc.: C, 69·8; H, 11·6%).

Methods of Measurement.—The experimental method was as described in the preceding paper. The solubilities of β-methyl-

tetramethylene oxide were determined by the synthetic method. With this, and with one or two other substances, a difficulty was sometimes met with in using the volumetric method described. A trace of a solid was produced in the tubes which made the separation of the phases and the reading of the meniscus difficult. The effect was slight and in some cases entirely absent. It was found by repeated experiment to be unconnected with any possible impurity in the mercury, and was finally recognised as due to the

FIG. 1.

(A, *Ethyl* n-*propyl ether.*)

oxidation of the metal to an oxide by a trace of ether peroxide (compare Richardson, J., 1891, **59**, 51). The moist ether is thus a catalyst which causes reaction between mercury and oxygen. If this explanation had been realised originally, the whole phenomenon could doubtless have been suppressed by avoiding the presence of oxygen. The measurements here recorded are free from errors due to this difficulty, but the alternative method of measurement was adopted for the one ether.

As a check on the behaviour of these substances in the pure state, the solubilities of naphthalene in them and in three open-

chain ethers at several temperatures were determined, following the method of Ward (*J. Physical Chem.*, 1926, **30**, 1316). The naphthalene was carefully purified and melted completely between 80·05° and 80·07°.

Results.—The mutual solubilities of four cyclic ethers and water are shown by the curves in Fig. 1, a curve for ethyl *n*-propyl ether being included for comparison. The data in Table I are smoothed values for these substances. The remaining two ethers, αα′-dimethyltrimethylene oxide and αα′-methylethylethylene oxide, dissolve completely in water with considerable evolution of heat. The resulting solutions were found to contain only the corresponding glycols, and these two ethers could not be recovered.

Discussion of Results.

The deviation of the solubilities of naphthalene in the ethers from the ideal value may be shown by the slope of the curve relating

log N to $1/T$ (Mortimer, *J. Amer. Chem. Soc.*, 1922, **44**, 1416; 1923, **45**, 633). The mean values of $\Delta \log N/\Delta(1/T)$ derived from the data in Table II are: Dibutyl ether 1245, ethyl *n*-propyl ether 1190, ethyl *iso*propyl ether 1200, pentamethylene oxide 920, ββ′-dimethyltrimethylene oxide 980, αα′-dimethyltrimethylene oxide 1120, αα′-methylethylethylene oxide 985. The ideal value may be taken to be 970, and the value recorded by Mortimer for ethyl ether is 1180. The figures show that these liquids are normal and differ very little in internal pressure from naphthalene, the cyclic oxides having a slightly higher internal pressure than the others. The figures for the last two ethers in the above list are possibly subject to error owing to the hygroscopic nature of the substances. The observed points for the cyclic ethers are close to the ideal curve, and the internal pressures may be taken to be approximately equal to that of naphthalene (1·00 on Mortimer's scale). This slightly greater internal pressure is also apparent from a consideration of the following boiling points: *n*-Hexane 69°, *cyclo*hexane 81°, ethyl *n*-propyl ether 64°, methyl *n*-butyl ether 70°, pentamethylene oxide 87°.

The solubilities of the cyclic ethers in water increase with falling temperature, but their relative order is independent of this change. The solubilities are in the order: Ethyl *n*-propyl ether (2·74), pentamethylene oxide (10·70), β-methyltetramethylene oxide (11·25), α-methyltetramethylene oxide (18·20), ββ′-dimethyltrimethylene oxide (19·31), the figures in brackets being the solubilities at 10·0°.

The difference between the solubilities of α- and β-methyltetramethylene oxides once more illustrates the effect of substituting a secondary for a primary radical attached to the oxygen atom, as discussed in Part I of this investigation. The extreme development of chemical reactivity due to a tertiary radical is seen in αα′-dimethyltrimethylene oxide and αα′-methylethylethylene oxide by the immediate rupture of the ring on solution in water.

The most striking feature of the results is the large increase of solubility caused by the closure of the ring, and this is also true of the solubilities of water in the ethers, the values of which are considerable.

The work of Menschutkin (J., 1906, **89**, 1532) and of Petrenko-Kritschenko (*Annalen*, 1905, **341**, 165) proved that the reactivity of an alcohol or a ketone is increased when its open chain is closed into a ring. If the open-chain substance be regarded as behaving normally, ring closure evidently confers an enhanced reactivity. This effect, which is of the nature of a negative steric hindrance, may be termed "steric activation." Menschutkin realised that this phenomenon should also arise in the closing of a heterocyclic

ring, and cited as an illustration the greater velocity of alkylation of piperidine than of *n*-amylamine. The much greater strength of piperidine as a base in comparison with diethylamine and dipropylamine may also be ascribed to steric activation. The measurements recorded in this paper are evidence of a similar effect with oxygen as the hetero-atom. To show that the solubility developed by closure of the ring is a property of the oxygen atom in particular, the solubilities of *n*-hexane and *cyclo*hexane in water were examined. Direct experiment showed that water dissolves less than 0·005% of either at 17°.

The increase of solubility due to the closure of the ring is also larger the smaller the ring, in accordance with expectation. Considering only the ethers with unsubstituted methylene groups attached to the oxygen atom, the figures to be compared are 10·70, 11·25, and 19·31% for 6-, 5-, and 4-membered rings, respectively. The fact that the difference between the first two is small is perhaps due to the strainless configuration in the 6-membered ring, which will consequently have a similar angle to that of its 5-membered isomeride. The observation of Bergmann and Kann (*Annalen*, 1924, **438**, 278), that acetoxypolymethylene oxides of the type

$R{\cdot}CH{\cdot}(CH_2)_n{\cdot}CH{\cdot}OAc$ are polymerised to a greater extent the smaller the value of n, is evidence of a similar increase of chemical reactivity in the oxygen atom with diminishing size of the ring.

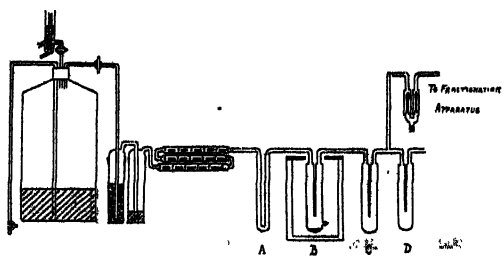
It may also be pointed out that the large majority of stable oxonium compounds arise from the chemical reactivity of an oxygen atom which is a member of a ring. This can hardly be accidental, but must be a consequence of the steric activation of such atoms.

We are indebted to the Department of Scientific and Industrial Research for a grant which enabled one of us to take part in the work recorded in this and the preceding paper.

THE UNIVERSITY, SHEFFIELD. [*Received, June 7th*, 1928.]

CCLIV. *The Phosphorescent Combustion of Sulphur.*

By HARRY JULIUS EMELÉUS.



THE temperature at which sulphur ignites in oxygen varies between 285° and 325° according to the conditions (Moissan, *Compt. rend.*, 1903, **137**, 547). Just below the ignition point the oxidation is accompanied by a bluish-white luminescence (Joubert, *ibid.*, 1874, **78**, 1853) persisting only so long as heat is supplied; at lower temperatures the reaction is non-luminous. The phosphorescent flame changes

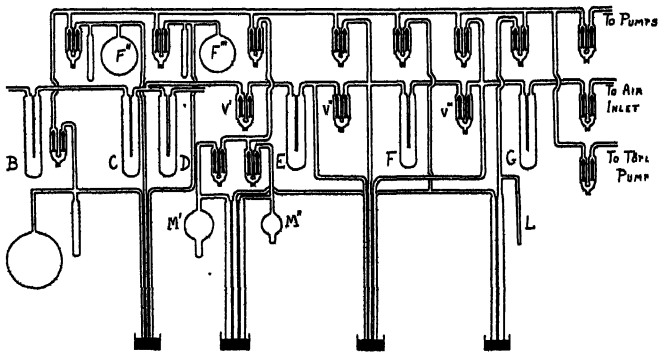
into the normal flame as the temperature is raised. Heumann showed that its products were sulphur dioxide and a little sulphur trioxide (*Ber.*, 1883, **16**, 139). Bloch found that no ionisation occurred, but stated (without giving details of his experiments) that ozone was formed (*Compt. rend.*, 1909, **148**, 782). The phosphorescent flame was also investigated by Watson (*Chem. News*, 1913, **108**, 187). The main aim of the present investigation was to search for any oxide of sulphur more volatile than sulphur dioxide (such as the still unknown sulphur monoxide might be expected to be), by methods which would enable a very small percentage of such a substance to be isolated. The alleged formation of ozone and the action of inhibiting substances on the phosphorescent flame were also examined.

The Products of the Phosphorescent Combustion of Sulphur.

The production and maintenance of the phosphorescent flame was most readily accomplished by using mixtures of oxygen and

FIG. 1.

nitrogen (obtained from cylinders) with an oxygen content varying between 5—15%, according to the temperature at which the flame was being maintained. All tendency for normal burning to occur was eliminated in this way. The apparatus used for collecting the oxidation product is shown in Fig. 1. The gas mixture from the storage bottle was passed over soda-lime and dried by sulphuric acid and phosphoric oxide, residual condensable impurities being then removed in the U-tube *A* cooled in liquid air. Recrystallised sulphur (Merck's), which had been maintained in a vacuum at its melting point for ½ hour to remove solvent, distilled in a vacuum, and broken up, was distilled in a vacuum directly into *B* from a side tube, before the apparatus was assembled. *B* was heated in an electric furnace (10 cm. internal diameter), temperatures being recorded by a mercury thermometer in contact with the outside of the bulb. The flame in a gas stream under these conditions was invisible, except in a dark room, and remained steady over long periods. Its temperature was approximately 5° above that of the



furnace. The oxidation product was frozen in *C*, which was cooled in liquid air, and it is assumed that none of the product escaped condensation under such conditions. The guard-tube *D* was similarly cooled. Connexion was made between *C* and *D* to an apparatus for the subsequent examination of the oxidation product.

Combustion was always incomplete, as shown by the following values for the oxygen content of the gas issuing at *D* for various temperatures of *B*. The ingoing gas contained 8·2% of oxygen, and was passed at the approximate rate of 1 l. per hour.

Oxygen in outgoing gas, %	7·6	5·8	5·2
Temperature	257°	326°	350°

After a number of trials, three experiments were carried out at 275°, 300°, and 325° respectively. The oxidation product

FIG. 2.

condensed in *C* was examined by a process of fractionation in the apparatus shown in Fig. 2 (compare Stock, *Ber.*, 1914, **47**, 154; 1917, **50**, 989; 1918, **51**, 983). *C* being cooled in liquid air, *B* and *D* were sealed off, the mercury valve *V'* (Stock, *Z. Elektrochem.*, 1917, **23**, 33) was opened, and the whole apparatus evacuated with a single-stage quartz diffusion pump, backed by a Cenco Hyvac pump. All the valves except *V'*, *V''*, and *V'''* were then closed, and the U-tubes *E*, *F*, and *G* were cooled in baths at −85°, −124°, and in liquid air respectively; *C* was then allowed to warm slowly to room temperature. Its contents thus underwent a process of fractional condensation in *E*, *F*, and *G* (time, 20 minutes); the valves *V''* and *V'''* were closed, and the residual solid in *C* was sublimed into *E*, which was cooled in liquid air, *V'* being then closed.

Examination of the Volatile Product.—The condensate in *G* (which was always very small) was distilled into *L* (of known volume), where its volume was determined by allowing it to vaporise and

observing the pressure produced at a known temperature; the vapour pressure at a suitable temperature was also determined. It was then distilled back into G and stored. The condensate in F was divided into three fractions in order of descreasing volatility by allowing evaporation to occur at −56° to −58°. The volume of each of these in turn was determined in the gas measuring flask M'', of known volume, and the vapour pressure–temperature curve of each was determined in L, after which the fractions were stored in M', F'', and F'''.

Results.

(All recorded gas volumes are reduced to 0° and 760 mm. of mercury.)

Experiment 1. Temperature, 275° (± 3°). Approximately 17 l. of an oxygen–nitrogen mixture containing 13·7% of oxygen were passed at the rate of 1 l. per hour.

Fraction in G: Volume = 0·1 c.c.; vapour tension at 99° = 0·7 mm.

Fraction in F:

Most volatile fraction. (Volume = 41·7 c.c.)		Middle fraction. (Volume = 58·5 c.c.)		Least volatile fraction. (Volume = 91·6 c.c.)	
Temp.	Vap. press.	Temp.	Vap. press.	Temp.	Vap. press.
−57·6°	38·0 mm.	−56·4°	41 mm.	−72·6°	10·5 mm.
−47·2	77·0 „	−48·3	70 „	−54·6	44 „
−37·1	151 „	−38·0	144 „	−40·0	123 „
−27·7	266 „	−28·2	260 „	−27·9	259 „
−17·6	470 „	−16·9	484 „	−17·5	459 „

The small fraction in G had a vapour tension consistent with its being sulphur dioxide which had escaped condensation in F. Any more volatile oxidation product would have collected in G, and its absence is a conclusive proof that no such product is formed in the phosphorescent flame. The experiment would not, however, have detected any substance not condensed in liquid air. It was shown in a separate experiment that no substance more volatile than sulphur dioxide and reacting with mercury was present.

The above vapour-tension measurements for the three fractions obtained from the condensate in F fall on one curve, indicating that a homogeneous substance was present. They agree with the values for pure sulphur dioxide obtained by use of the same pentane-filled thermometers, showing the condensate to be pure sulphur dioxide. The experiments at 300° and 325° were carried out in precisely the same manner, and led to the same conclusions. Unless special precautions were taken to avoid contamination of the sulphur by dust, a small quantity of carbon dioxide (varying from 0·6 c.c. to 0·2 c.c.) was formed during the oxidation, and was readily isolated

from the condensate in *G*, and identified by vapour-tension measurements.

The less volatile reaction product. A small quantity of solid was always found in *C* and *E*. In some experiments it was white, but in others it contained a deep blue material which disappeared after 48 hours and was not isolated. Its colour and behaviour suggested that it was sulphur sesquioxide. Its formation always occurred where solid sulphur dioxide had melted in the condensing tube, and was most pronounced at higher temperatures and with faster gas streams—two conditions favouring the sublimation of sulphur. It is concluded that this lower oxide was produced in a secondary reaction between sulphur trioxide (see below) and sulphur.

The white reaction product dissolved in water, giving a fog, and the solution contained sulphuric acid and was without reducing properties on indigo solution. It appeared to be sulphur trioxide, confirming an observation by Heumann (*loc. cit.*). Its vapour attacked mercury, giving sulphur dioxide and a sulphate. In the experiment at 275° already described, 2·2 c.c. of sulphur dioxide were formed in this way. Assuming an equal quantity of sulphur to have combined with the mercury, the quantity of sulphur trioxide formed in the phosphorescent combustion was approximately 2% of the quantity of sulphur dioxide. The value given for the formation of the trioxide in the normal combustion is approximately the same (Hempel, *Ber.*, 1890, **23**, 1455).

Formation of Ozone in the Phosphorescent Flame of Sulphur.—At the temperature at which sulphur glows, the thermal decomposition of ozone takes place rapidly. Bloch's report of its production is not accompanied by sufficient experimental detail to enable his conditions to be reproduced. Those chosen in testing for ozone were, therefore, (*a*) the oxidation of sulphur in a U-tube, as already described, and (*b*) the conditions described by Heumann (*loc. cit.*), sulphur being heated in a silica dish supported in a nickel dish (18 cm. diameter). Under these conditions the sulphur vapour oxidises near the heated surface, giving tongues of phosphorescent flame, from which gas may be withdrawn by inserting a funnel attached to a pump. In each instance the oxidation products traversed two narrow, thin-walled U-tubes, cooled to −124° to remove sulphur oxides, and the gas stream then passed over a drop of freshly distilled mercury, the tailing of which was used as a test for ozone.

With method (*a*), the glow being produced at temperatures between 200° and 300° by gas streams containing 8% of oxygen and passing at the rate of 2 l. per hour, no tailing of the mercury drop was observed (10 tests of 1—3 hours' duration each). Using method

(*b*) and the same duration of test, negative results were obtained in each of six tests. Under these conditions, therefore, no ozone is formed in the phosphorescent combustion of sulphur.

Experiments to determine whether a "Glow Pressure" exists in the Oxidation of Sulphur.—Observations on the rate of oxidation of arsenic at different pressures have shown that for each temperature there is a "glow pressure," above which the oxidation is non-luminous, and below which luminescence occurs (Emeléus, J., 1927, 783). A similar examination of the oxidation of sulphur gave negative results. The same method as for arsenic was employed, the apparatus being modified by the addition of a bulb tube immersed in liquid air to a constant depth to freeze out the sulphur dioxide. By this means the rate of oxidation could be followed manometrically. In a series of experiments at 300—340° there was no sudden increase in the oxidation rate as the pressure was reduced, corresponding to the initiation of the glow. Apparently the inhibiting action of sulphur dioxide on the phosphorescent flame is very strong (see below), and the conditions employed did not provide for its sufficiently rapid removal, even at reduced pressures.

The Inhibition of the Phosphorescent Flame of Sulphur.

The large influence of sulphur dioxide in raising the ignition point of sulphur has long been known (compare Moissan, *loc. cit.*). Recently, White (J., 1927, 793) has shown that pentane, acetylene, and methane act similarly. The influence of inhibitors on the phosphorescent stage of the combustion has not, however, been considered, and the experiments described below were directed towards this aspect of the problem. It is suggested that inhibition of the phosphorescence is the primary cause of the raising of the temperature of normal ignition.

Inhibition by Sulphur Dioxide.—In studying the influence of inhibiting substances on the phosphorescent flame, the latter was produced by heating sulphur in a U-tube in a stream of an oxygen–nitrogen mixture, as already described. The depth to which the U-tube was immersed in the furnace was made as small as possible to minimise the formation of sulphur dioxide in the non-luminous oxidation occurring in the tube above the luminous zone. With an 8% oxygen–nitrogen mixture, the influence of varied additions of sulphur dioxide on the temperature of extinction of the glow was first examined, the sulphur dioxide being introduced into the gas stream from a side tube, and the gas composition determined by counting the bubbles in previously calibrated bubblers. The glow was first obtained at a temperature at which the sulphur dioxide

concentration being examined was too small to inhibit it, and the temperature of the furnace was then allowed to fall slowly. The point could thus be found at which the glow disappeared, the observation being made in a dark room with well-rested eyes. The following readings were obtained with a gas stream of 30 c.c. per min. :

Conc. of SO_2 (% by vol. of total gas stream)	0	9·2	19	30	36	44
Temp. of extinction of glow	195°	235°	267°	295°	309°	328°

If, when the glow had disappeared, the temperature was again raised, the luminosity was first observed at a temperature 5—10° higher.

Influence of Organic Vapours.—The action of the vapours of a number of organic liquids was examined by heating the sulphur in a U-tube in a stream of an oxygen–nitrogen mixture (8% oxygen), observing the glow, and then diverting the gas stream through a bubbler containing the liquid in question. It could thus be seen whether the glow diminished in intensity or was extinguished. When inhibition took place the glow invariably reappeared on restoration of the normal gas stream, and could be put out at will, showing that no permanent change in the sulphur surface had taken place. The vapours of the substances tabulated below all inhibited the glow completely over the temperature range stated (temperature of bubblers, 14°). The effect of further increasing the temperature could not be studied, because charring took place, and also because much sulphur dioxide would have been formed in the non-luminous oxidation.

Benzene	270—350°	Ethyl alcohol	300—325°
Toluene	280—325	Ethyl acetate	290—320
Chlorobenzene	270—290	Amyl acetate	295
Pyridine	310	Chloroform	280—300
Ethylene dibromide	280—320	Acetone	220—300

The influence of the concentration of the organic vapour on its effectiveness was not investigated in detail, but the general nature of the result was shown in the case of methyl salicylate, which has a low vapour pressure at room temperature and accordingly has only a weak action on the glow. It was possible to find the temperature at which the luminosity was just inhibited at different concentrations by maintaining the bubbler containing the inhibiting substance at a series of temperatures. The method of observation was the same as that used in the experiments with sulphur dioxide. When the bubbler was maintained at 12°, 24°, and 38°, the glow was extinguished at 243°, 258°, and 268° respectively. Increase in

the concentration of the inhibitor, therefore, raises the temperature at which the glow occurs, as in the oxidation of phosphorus.

Tests were made when the luminous oxidation was inhibited by benzene to determine if any non-luminous oxidation was occurring. A small amount of sulphur dioxide could always be detected by the decoloration of potassium dichromate solution.

Discussion.

As far as can be judged from the nature of the reaction products, the chemical change in the phosphorescent combustion of sulphur is the same as in the normal flame. It is a significant fact that no evidence whatever of the formation of sulphur monoxide was obtained, though the conditions were such that, by analogy with, say, the glow of phosphorus, lower oxidation products would have been produced if they existed. The negative results of the ozone tests show that in this respect, too, the chemiluminescent oxidations of sulphur and phosphorus differ.

Consideration of these inhibition phenomena emphasises the two distinct stages in the oxidation of sulphur, *viz.*, the luminous and the non-luminous oxidation. The dynamics of the latter were investigated by Bodenstein and Caro (*Z. physikal. Chem.*, 1911, **75**, 30), who showed that the reaction rate was proportional to the sulphur surface, and hence, presumably, that the reaction was taking place at this surface. It was also found to be uninfluenced by sulphur dioxide. The slow luminous oxidation is, on the contrary, on the basis of visual observation, a gas reaction, and has been shown to be sensitive to the presence, not only of sulphur dioxide, but also of many other substances. In this, the analogy with the oxidation of phosphorus appears to be very close, and hypotheses as to the mechanism of inhibition of the latter phenomenon have been put forward which may be applied here (*e.g.*, Bäckström, *Medd. K. Vetenskapsakad. Nobel-Inst.*, 1927, **6**, No. 16). All contain in essence the idea that " active " molecules are produced in limited numbers, and are essential for the maintenance of the luminous oxidation. The molecules of the inhibiting substances are supposed to be able to deactivate such molecules, and so to hinder the reaction. In the case of the oxidation of sulphur this explanation cannot yet be put in more precise terms.

The author wishes to express his gratitude to Professor H. B. Baker, F.R.S., for his interest and advice throughout this research. It is also a pleasure to thank Professor A. Stock for the opportunity afforded to the author of studying the vacuum technique used in his laboratory in Karlsruhe. The research was carried out during the

tenure of an 1851 Senior Studentship. Apparatus and materials were purchased from a grant by Imperial Chemical Industries, Ltd., to the Chemical Department of this College, and from the Dixon Fund.

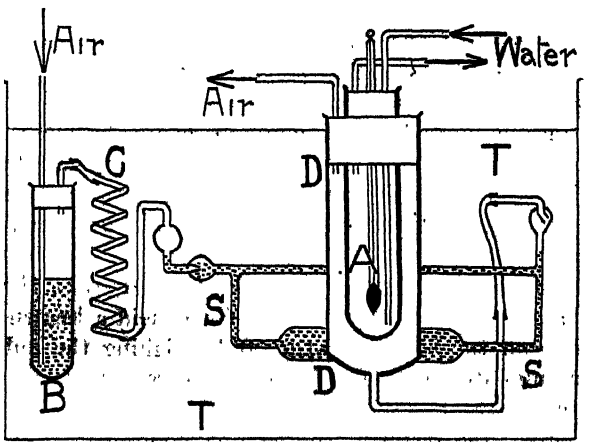
SOUTH KENSINGTON, S.W. 7. [*Received, April 23rd*, 1928.]

CCLV.—*The Constitution of Magnesium Acetate Solutions. Part II. Evidence from Vapour Pressures.*

By E. A. GOODE, NOEL STANLEY BAYLISS, and ALBERT CHERBURY DAVID RIVETT.

IN order to explain qualitatively the relations between concentrations and viscosities, freezing points, and conductivities of solutions of magnesium acetate in water, it has been suggested (J., 1926, 1063) that at high concentrations there is considerable polymerisation of the salt molecules. This association may reasonably be attributed to chelate ring formation where the magnesium atom exercises a co-ordination number of four, and chains (straight or branched) of indefinite extent are built of the unit $>Mg<\begin{matrix}O{=}C(CH_3){-}O\\O{-}C(CH_3){=}O\end{matrix}>$.

Evidence bearing on this point has now been obtained from a consideration of the lowering of the vapour pressure of water brought about by solution of the salt. For this purpose it was necessary to work at a fairly low temperature (25° was chosen), though this greatly increased the difficulty of accurate measurement. At higher temperatures the tendency to association is decreased, and magnesium acetate falls more nearly into line with most other salts.



EXPERIMENTAL.

The dew-point method of Cumming (J., 1909, **95**, 1772), as modified by McBain and Salmon (*Proc. Roy. Soc.*, 1920, *A*, **97**, 44), was adopted, its obvious advantages being the rapidity with which measurements can be made and the unimportance of dissolved or entangled air in the solution. With the more viscous solutions, other methods would have been as inapplicable as McBain found them to be for soap solutions. The silver tube A (Fig. 1), on which the dew deposited, was highly polished, the final polishing being done with chamois leather and levigated rouge. McBain's device of dipping part of the tube in boiling water was used. The dew then deposits only on the part which has not been dipped and can be

sharply detected at the boundary. It would seem that dipping removes nuclei, such as traces of dust or polishing material, which are necessary if condensation is to occur. On a very highly polished, undipped tube, it is often difficult to obtain condensation at all, but if the tube be held for an instant in hydrogen chloride fumes, the necessary nuclei are produced at once. Water was circulated through the silver tube from a reservoir heated or cooled as required. Temperatures in the tube and in the surrounding bath (T, Fig. 1) were read to 0·01°.

McBain's procedure, which is suitable for solutions at or near the boiling point and having a vapour pressure of the order of 600 mm., was not satisfactory with such low vapour pressures as those examined at 25°, the complete range of which was from 19 to 25 mm.

FIG. 1.

Thus there was an uncertainty of several tenths of a degree in the dew point as determined for pure water and for some test solutions of potassium chloride: nor was the accuracy improved by exhausting the apparatus. Probably with so little vapour round the tube the rate of diffusion was insufficient. If, however, a current of saturated air was circulated through the system, the accuracy was greatly increased, and differences in successive determinations of dew point were reduced to a few hundredths of a degree. The mean of five measurements of each solution was taken.

Fig. 1 indicates the arrangement adopted. Three saturators, of the type S, contained the solution on which the determination was required. They were separated from one another by a bubbler, B, and a metal coil, C, all immersed in the thermostat, T, and connected as shown with the deposition vessel, D, into which the silver tube, A, with its circulating system, [illegible]

to place any solution in D, as the slight splashing on to A tended to obscure the observation.

With a current of laboratory air it was impossible to get satisfactory evidence of condensation. This was no doubt due to the fact that it carried with it impurities like sulphuretted hydrogen which acted upon the dipped silver surface and formed condensation nuclei, thus destroying the contrast between dipped and undipped areas. The trouble was eliminated by passing the air first through a sulphuric acid bubbler and then through a soda–lime tower. We acknowledge our indebtedness to Professor E. J. Hartung for much help in making this apparatus effective.

The success of the method depends upon attainment of complete saturation of the air stream with respect to the solution. Great care must be taken to prevent ingress to the apparatus of traces of water or water vapour.

In making observations, the temperature of appearance of the vapour could be determined much more accurately than that of disappearance. Test measurements with pure water and potassium chloride solutions showed that if the temperature of appearance was taken as the dew point, the error in the vapour-pressure determination was of the order of 0·03 mm.: hence this, and not the mean of the temperatures of appearance and disappearance, was recorded throughout.

Concentrations of solutions were determined after dew-point measurements by evaporating with sulphuric acid a known weight of solution from the last saturator, and weighing the anhydrous magnesium sulphate obtained. They are expressed as g.-mols. per 1000 g. of water (M_w).

Table I gives the results. In the first column is M_w; in the second the temperature of the bath and solution (T_B); and in the fourth that of the dew point (T_D); whilst in the third and fifth are the vapour pressures of pure water (P_B and P_D) at these temperatures, taken from the tables of the International Bureau of Weights and Measures.

Discussion of Results.

In discussing results such as these, it is not justifiable to use the vapour-pressure lowerings as a basis for calculating molecular weights of the solute, since, apart from all question of applicability of the gas laws, to do so ignores the fact that the second component, water, is by no means a simple substance, and its behaviour, no less than that of the solute, will affect the vapour pressures. It is best to look at the figures from the point of view of Raoult's law. If this holds, $1 - P_D/P_B$ gives the mean molar fraction of the solute at each concentration. The values obtained experimentally are

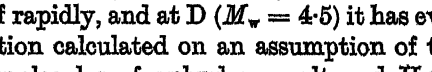

FIG. 2.

quoted in the sixth column of the table and they are plotted against M_w in curve ABCD of Fig. 2. For comparison, curves E and F give the molar fractions calculated on the assumptions that the solute particles are simply $Mg(C_2H_3O_2)_2$ and the solvent H_4O_2 (E) or H_2O (F). Lastly, the curve G shows $1 - P_D/P_B$ for magnesium chloride calculated from values obtained by extrapolation to 25° of Tammann's figures for vapour-pressure lowerings (Landolt–Börnstein Tabellen, 5th edition, p. 1386). The contrast with the acetate is very marked, just as it has been found to be in other physical properties.

The "molar fraction" $1 - P_D/P_B$ represents the ratio between

the number of entities of magnesium acetate or its derived products (hydrates, polymerides, or ions) in a given solution and the sum of this number plus that of the free solvent entities. What the latter are, we do not know, but to assume that the molecule is H_4O_2 is probably less incorrect than to take it as H_2O. In any case the qualitative argument is not greatly affected. In dilute solution (A, Fig. 2) the relatively high value of the molar fraction given by the vapour-pressure measurements is undoubtedly due mainly to ionisation of the salt and consequent increase of the numerator in relation to its value calculated on an assumption of the presence of molecules only. The degree of ionic dissociation decreases as concentration increases, so the gradient is not maintained; but after about $M_w = 1$ (B) there is a steady rise which one may assume to be due to a continuous decrease in the denominator of the molar fraction consequent upon the removal of solvent molecules to form hydrates. No doubt such hydration occurs from the beginning, but in dilute solutions the effect on the denominator will be relatively small. In any case it will be in the same direction as the ionisation effect. Presumably the water (whether as single or double molecules or as chains) attaches itself to the Mg radical through the oxygen atom (acting as donor of electrons) to the extent required by the co-ordination number of the ion, which may or may not be also attached to acetate radicals. With magnesium chloride, this continues steadily to high concentrations, but with the acetate a counter-influence of some kind overcomes this hydration effect at C (M_w about 3·25), the curve passing through a maximum. After this point it falls off rapidly, and at D ($M_w = 4·5$) it has even come below the molar fraction calculated on an assumption of the presence of undissociated molecules of anhydrous salt and H_4O_2 only. Evidently some cause has reduced the numerator, or increased the denominator, of the molar fraction, or both.

A simple explanation is that at these higher concentrations of magnesium acetate, polymerisation begins to dominate the situation; added molecules link up with others to form complexes of the indeterminate type  , in which the magnesium co-ordination number of four is satisfied by two ordinary attachments to hydroxylic oxygen (the respective atoms contributing an electron apiece) and two to the doubly bound oxygen atoms of other acetate radicals (oxygen here contributing both electrons to the covalent bond). When this occurs, any water previously bound will be set free, and so we should get diminution of the numerator as the result of polymerisation, and increase of the denominator as the result of this freeing of previously bound water. Magnesium

chloride cannot form similar rings and chains, so that with it the hydration effect continues unchecked as concentration increases.

The vapour-pressure evidence for magnesium acetate thus supports the view deduced from viscosity and other properties (*loc. cit.*). Lithium acetate, but not potassium, is similar to magnesium acetate, as will be shown later. The property of polymerisation in the way suggested would be expected to appear in the initial rather than the later members of periodic groups.

CCLVI.—*The Addition of Halogens to Unsaturated Acids and Esters. Part I. The Addition of Equimolecular Mixtures of Bromine and Chlorine to Cinnamic Acid and its Derivatives in Non-hydroxylic Solvents.*

By NORMAN WILLIAM HANSON and THOMAS CAMPBELL JAMES.

THERE is no direct physicochemical evidence for the existence of a chloride of bromine BrCl, either in the liquid or the solid state (compare Karsten, *Z. anorg. Chem.*, 1907, **53**, 365; Lebeau, *Compt. rend.*, 1906, **143**, 589), but many cases are on record showing that a mixture of bromine and chlorine, dissolved in a suitable solvent, behaves towards ethylenic compounds as though at least some bromine chloride, capable of reacting as a molecule of such, were present. For instance, the addition of the mixed halogens in hydrochloric acid solution to several ethylenic hydrocarbons has been accomplished, the addition products being termed "chlorobromides" (Simpson, *Bull. Soc. chim.*, 1879, **31**, 409; J. W. James, J., 1883, **43**, 37; Delépine and Ville, *Compt. rend.*, 1920, **170**, 1390). Further, the last-named authors obtained indications that an equimolecular mixture of dry bromine and chlorine at 0° is much more reactive towards ethylene than either of its constituents separately. By employing a chloroform solution of the mixed halogens, Walden (*Ber.*, 1897, **30**, 2883) achieved their simultaneous addition to maleic anhydride, the product being chlorobromosuccinic anhydride.

By allowing a solution of the mixed halogens in hydrochloric acid to react with cinnamic acid, Erlenmeyer (*Annalen*, 1896, **289**, 250) obtained, along with ω-bromostyrene and phenyl bromohydrocrylic acid, about a 50% yield of an acid which he proved to be [illegible] α-bromo-β-phenylpropionic acid. This was only one of four products

addition products, *viz.*, the two pairs of externally compensated stereoisomerides corresponding to the formulæ

$C_6H_5 \cdot CHCl \cdot CHBr \cdot CO_2H$ (I) and $C_6H_5 \cdot CHBr \cdot CHCl \cdot CO_2H$ (II).

The structural isomerides having these formulæ and melting at 182° (I) and 184·5° (II), respectively, have already been described (Glaser, *Annalen*, 1868, **147**, 78; Erlenmeyer, *ibid.*, 1896, **289**, 259).

In the present paper, the addition of equimolecular mixtures of bromine and chlorine, dissolved in carbon tetrachloride or chloroform, to cinnamic acid and some of its derivatives is described. The products of the addition to cinnamic acid have been found to be two acids, both possessing the structure $C_6H_5 \cdot CHCl \cdot CHBr \cdot CO_2H$, melting at 182° and 75°, analogous to the cinnamic acid dihalides (higher-melting) and *allo*-dihalides (lower-melting), respectively, and therefore stereoisomeric. The structure of these acids has been established by an examination of their behaviour when treated with two equivalents of methyl-alcoholic potash. This treatment caused elimination of a mixture of hydrogen chloride and bromide from both acids—no detectable substitution of methoxyl for halogen occurring—and the consequent production of the corresponding monohalogenocinnamic acids. The acid melting at 182° evolved 39% by weight of the available hydrogen bromide, and 61% by weight of the available hydrogen chloride, the products of this elimination being a mixture of acids from which α-bromo-, α-bromo-*allo*-, and β-chloro*allo*-cinnamic acids were isolated and identified. The isomeric acid melting at 75° evolved 15% of hydrogen bromide and 84% of hydrogen chloride, the only product isolated being α-bromocinnamic acid. These results demonstrate that the acids are stereoisomerides having the structure $C_6H_5 \cdot CHCl \cdot CHBr \cdot CO_2H$. Further evidence in favour of such a structure is afforded by the fact that a specially prepared specimen of α-chloro-β-bromo-β-phenylpropionic acid proved to be isomeric and not identical with the higher-melting (182°) of these acids, in that it evolved hydrogen bromide only, to the extent of 95% by weight of the available hydrogen bromide, when similarly treated.

These results are in conformity with those obtained from the cinnamic acid dihalides. It is well known that α-hydrogen and β-halogen split off from these acids in preference to the alternative, and also that hydrogen bromide is evolved from the dibromide more readily than hydrogen chloride from the dichloride. The ultimate result in the case of the various chlorobromo-β-phenylpropionic acids would be due to a combination of these two factors. The nature of the products of elimination harmonises with the conclusion that the configurations of the higher- and lower-melting addition products of "bromine chloride" to cinnamic acid are analogous to

those of the cinnamic acid dihalides (higher-melting) and *allo*-dihalides (lower-melting), respectively.

Regarding the relative positions in the molecule taken up by the component atoms of " bromine chloride " when this combines with cinnamic acid, the general rule relating to the addition of diatomic molecules is obeyed, the more negative (*i.e.*, the chlorine) atom attaching itself to the β-carbon atom.

That the rate of addition of " bromine chloride " to cinnamic acid is considerably more rapid than is the case with either of the pure halogens has been shown by a series of kinetic experiments similar in method to those described by Williams and James (this vol., 344). In this case the reaction is bimolecular in type and there is no inhibition period. Corresponding experiments have been carried out with certain substituted cinnamic acids and esters, and in every case examined " bromine chloride " has proved much more reactive than bromine alone, the reaction generally being of the bimolecular type.

Modern theory regarding the interpretation of addition reactions (see Lowry, J., 1923, **123**, 832; Norrish, *ibid.*, p. 2008) postulates a process of unsymmetrical activation, of both the unsaturated molecule and the addendum, which precedes or accompanies such reactions. The cinnamic acid and bromine molecules in this activated state may be represented thus : $C_6H_5\cdot\overset{+}{C}H=\overset{-}{C}H\cdot CO_2H$ and $\overset{+}{Br}\text{–}\overset{-}{Br}$, the bromine molecule breaking up, not into two neutral atoms, but into two ions. Since the rate of addition of bromine to cinnamic acid and its derivatives is generally slow, the ionisation in solution of the former probably occurs to a limited extent.

Experimental evidence points to the conclusion that if a compound of bromine and chlorine—" bromine chloride "—does exist, it must undergo dissociation in solution to such an extent that it escapes physicochemical methods of detection. If—and there is no evidence to the contrary—this dissociation is ionic in nature, then the molecules in solution undergo almost complete disruption into the ions Br^+ and Cl^-, which, being in the activated state, combine rapidly with cinnamic acid. The final interaction between these ions and the activated cinnamic acid molecule would amount merely to a neutralisation of oppositely charged ions, the chlorine ion becoming neutralised by, and uniting with, the β-carbon atom; a similar reaction occurring between the bromine ion and the α-carbon atom.

Experimental.

A finely divided suspension of cinnamic acid in carbon tetrachloride was mixed with one molecular proportion of a solution in

the same solvent of an equimolecular mixture of bromine and chlorine. Complete addition had occurred after exposure to dull light for 4 days. The white powdery product, after filtration and crystallisation from chloroform–carbon tetrachloride, melted at 182° as described by Erlenmeyer (*loc. cit.*) (Found: Br, 30·9; Cl, 13·5. Calc. for $C_9H_8O_2ClBr$: Br, 30·3; Cl, 13·5%).

The filtrate after removal of this product yielded on evaporation a thick, colourless oil which solidified in a vacuum. After crystallisation from light petroleum the substance consisted of small colourless prisms, m. p. 75°. Analysis and the reactions described below indicate that it is stereoisomeric with the substance melting at 182° and is therefore the lower-melting (*allo*-) *β-chloro-α-bromo-β-phenylpropionic acid*, $C_6H_5{\cdot}CHCl{\cdot}CHBr{\cdot}CO_2H$ (Found: Br, 30·9; Cl, 13·2. $C_9H_8O_2ClBr$ requires Br, 30·3; Cl, 13·5%).

In a series of experiments carried out under the conditions described, the proportion of the higher- to the lower-melting product was approximately 1 : 3.

The isomeric α-chloro-β-bromo-β-phenylpropionic acid was prepared by converting cinnamic acid into its chlorohydrin (compare Read and Andrews, J., 1921, **119**, 1774), and replacing the hydroxyl group by bromine by means of concentrated hydrobromic acid (Glaser, *Annalen*, 1868, **147**, 78). The distinction between this acid, m. p. 184·5°, and the acid described above, m. p. 182°, has been established by Erlenmeyer (*loc. cit.*).

The action of methyl-alcoholic potash on these three acids has been investigated, under conditions which would extract one equivalent only of hydrogen halide. About 0·5 g. of each acid was warmed with exactly 2 equivalents of alkali on a water-bath, the alcohol being subsequently evaporated. The residues were dissolved in water and acidified with dilute nitric acid, the precipitated organic acids were filtered off and washed, and the filtrate was analysed for chloride and bromide. The results indicated that the following proportions of hydrogen chloride and hydrogen bromide were extracted:

Acid, m. p.	% HCl extracted.	% HBr extracted.
182°	61	39
75	84	15
184·5	0	95

The products of these reactions were isolated in experiments conducted on a larger scale.

Acid, m. p. 182°. The acid (7 g.) was dissolved in methyl alcohol and treated with methyl-alcoholic potash (2 equivs.). The solvent was evaporated, the residue taken up with water, and a slight excess of 10% barium chloride solution added (compare Sudborough and

Thompson, J., 1903, **83**, 673; Sudborough and James, J., 1906, **89**, 107). After 3 hours, the sparingly soluble barium salt was removed and this and the filtrate were treated separately with dilute acid. The sparingly soluble salt yielded 1·3 g. of acid which on recrystallisation from benzene had melting point 131° and proved to be α-bromocinnamic acid. The filtrate gave 3·5 g. of acid of low melting point from which by fractional crystallisation from chloroform and light petroleum were isolated (1) α-bromo*allo*cinnamic acid, m. p. 120°, and (2) β-chloro*allo*cinnamic acid, m. p. 131—132°.

Acid, m. p. 75°. 5 G. were treated as above and yielded 3·5 g. of α-bromocinnamic acid (m. p. 131°) as the only recognisable product.

The results of kinetic experiments are summarised in the tables. Table I gives the values for the bimolecular velocity coefficient $k=1/t \cdot x/a(a-x)$, based upon time (t) in hours and concentrations (a and x) in g.-mols. per litre for "bromine chloride," and for comparison Table II gives results for bromine alone under similar conditions.

The substances examined were (1) † cinnamic acid, (2) † α-methylcinnamic acid, (3) † methyl *o*-methoxycinnamate, (4) † methyl *o*-methoxy*iso*cinnamate, (5) * α-bromo-*o*-methoxycinnamic acid, (6) * *m*-methoxycinnamic acid, and (7) † methyl *m*-methoxycinnamate.

TABLE I.

Temperature 0°.

Substance.	Limits of k.	Mean k.
1	113—96·3	104
2	2·83—2·07	2·51
3	2730—2032	2382
4	5682—4412	5009
5	124 (0·038)—59·2 (2·51)	—
6	4166 (0·016)—922 (0·292)	—
7	243—182	199

TABLE II.

Temperature 0°.

Substance.	Limits of k.	Mean k.
1	0·173—0·041	0·146
2	0·018—0·011	0·012
3	13·3 (0·117)—5·47 (9·27)	—
4	44·9 (0·209)—18·9 (8·29)	—
5	0·158—0·123	0·137
6	79·2 (0·030)—3·97 (61·5)	—
7	1·24—0·717	1·09

The figures in parenthesis denote the time (in hours) at which the value of k is that which precedes them. In such cases the reaction is not bimolecular and k varies with t.

The value of the velocity coefficient for the addition of chlorine to cinnamic acid under similar conditions was found to be 0·209.

Summary.

An equimolecular mixture of bromine and chlorine, dissolved in carbon tetrachloride, has been found to react additively with cinnamic acid as bromine chloride, were such a compound existent, the

* Indicates reactions in chloroform as solvent.

† Indicates reactions in carbon tetrachloride as solvent.

product of addition being the two stereoisomeric β-chloro-α-bromo-β-phenylpropionic acids.

Such a "bromine chloride" solution has been shown kinetically to react at a far more rapid rate with cinnamic acid and some of its derivatives than bromine solution itself. These phenomena appear to be readily explicable along the lines of modern polarity theories.

One of us (N. W. H.) desires to express his indebtedness to the Department of Scientific and Industrial Research for a maintenance grant.

CCLVII.—*Steric Hindrance in Reactions of Substituted Quinoxalines.*

By GEORGE MACDONALD BENNETT and GERVASE HEWITSON WILLIS.

IT has long been known that a methyl group occupying the α- or the γ-position to the nitrogen atom of a pyridine or quinoline nucleus possesses a high reactivity towards aldehydes and other reagents, which in the β-position it does not possess. The methyl groups of 2 : 3-dimethylquinoxaline, $C_6H_4<\begin{matrix}N{:}CMe\\ N{:}CMe\end{matrix}$, are each in the α-position with respect to one nitrogen atom of the heterocyclic nucleus, but each is at the same time in the β-position with respect to the second nitrogen atom. It therefore seemed possible that these methyl groups would be of the non-reactive or at least of a less reactive type. The observation that in this dimethylquinoxaline both methyl groups have a high reactivity of the kind specified was of sufficient interest to warrant a detailed study.

We have examined the behaviour of 2-methyl-, 2 : 3-dimethyl-, and 2 : 3 : 6-trimethyl-quinoxalines, 2-phenyl-3-methylquinoxaline, 2-benzylquinoxaline, and 2-*p*-methoxy- and 2-*p*-chloro-benzyl-3-phenylquinoxaline with a number of aldehydes and with bromine. The 2 : 3-dimethyl base has also been condensed with ethyl oxalate.

Although a quantitative comparison was not practicable, it is clear that 2 : 3-dimethylquinoxaline reacts with aromatic aldehydes with approximately the same ease as does quinaldine. The reactivity is no doubt due to the simultaneous effects of general and alternating polar influences. Polarisations leading to reaction are possible if a methyl group is placed α- to a nuclear nitrogen atom and the second nitrogen atom does not interfere with this. Its general polar

effect will in fact tend to increase the reactivity of the molecule. The experiments of Mills and others (J., 1922, **121**, 2724; 1925, **127**, 2466) indicate that the polarisation in question here may proceed as far as complete tautomeric change into a more reactive isomeride. From this point of view it is not surprising that Lapworth and Higginbotham (J., 1922, **121**, 2823) found no reactivity in the methyl groups of *m*-methoxytoluene and 3 : 5-dimethoxytoluene and that we similarly failed to induce reaction between an aromatic aldehyde and *m*-dimethylaminotoluene. A possible reactive tautomeric form cannot in these cases be formulated.

It should, however, be pointed out that even if this reactivity of the methyl group arises only where tautomeric change is possible it does not follow that completed isomeric change precedes reaction. The activated molecule which reacts may, in fact, occupy an intermediate position between the methylene base $-NH\cdot\dot{C}:CH_2$ and the methyl base $-N:\dot{C}\cdot CH_3$. In the closely analogous case of keto-enolic tautomerism, where the enolic forms are known to be more reactive with bromine than the keto-forms, the experiments of Leuchs (*Ber.*, 1913, **46**, 2435 : compare Robinson, J., 1917, **111**, 963) indicate that complete enolisation does not precede the reaction.

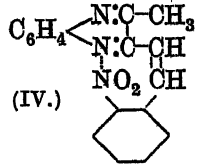
The products of condensation of 2 : 3-dimethylquinoxaline with aromatic aldehydes are distyrylquinoxalines (I), but in the reactions with certain aldehydes such as *o*- and *p*-methoxybenzaldehydes and *m*-nitrobenzaldehyde a monostyryl derivative was isolated in place of, or in addition to, the other. The formula (II) was a conceivable alternative to (III) for these substances, but the latter is undoubtedly correct, since the products decolorise cold solutions of bromine and permanganate. Moreover, the substance from *m*-nitrobenzaldehyde was shown to react further with the nitro-aldehyde with production of the distyrylquinoxaline of type (I), a reaction which points conclusively to the formula (III).

(I.) $C_6H_4\langle\begin{matrix}N:C\cdot CH:CHAr\\N:C\cdot CH:CHAr\end{matrix}\rangle$ $\qquad$ $C_6H_4\langle\begin{matrix}N:C\cdot CH_2\\N:C\cdot CH_2\end{matrix}\rangle CHAr$ (II.)

$$C_6H_4\langle\begin{matrix}N:C\cdot CH_3\\N:C\cdot CH:CHAr\end{matrix}\rangle \quad \text{(III.)}$$

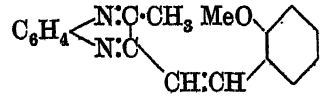
Condensation with benzaldehyde and piperonal was best brought about by heating the mixture to the boiling point in the absence of catalysts, but in all other cases the reactants were heated together in boiling acetic anhydride for a few hours. A comparison of the behaviour of some fifteen aromatic aldehydes with the 2 : 3-dimethyl base shows that those containing the nitro-group are distinguished by their rapid condensation, yielding styryl derivatives which are

easily isolated, as they crystallise directly from the reaction mixture. 2 : 3-Dimethylquinoxaline furnishes upwards of 50% of the calculated yield of product when condensed in acetic anhydride with *o*-, *m*-, or *p*-nitrobenzaldehyde, 2 : 4-dinitrobenzaldehyde, or *o*- or *p*-chlorobenzaldehyde. In particular, *p*-nitro- and 2 : 4-dinitrobenzaldehydes are convenient reagents for detecting the reactive methyl group of a base. There is little doubt that these aldehydes will react equally readily with other heterocyclic bases, and we have confirmed this in the case of three substituted quinolines.



On the other hand, the products from the three methoxybenzaldehydes were obtained in lower yield. Although this may have been partly due to the greater difficulty of their isolation, there can be no doubt that the methoxy-aldehydes react more slowly. Moreover *o*-methoxybenzaldehyde yielded solely the monostyryl derivative (III; Ar = C_6H_4·OMe). This compound decolorises cold solutions of permanganate and bromine and yet was recovered unchanged after a second heating with *o*-methoxybenzaldehyde.

It is thus clear that the reaction of 2 : 3-dimethylquinoxaline proceeds easily with most substituted benzaldehydes, including those with a nitro-group or a chlorine atom in the *o*-position, yet the second stage of the reaction is inhibited when an *o*-methoxy-group is present. If this effect were solely due to steric hindrance, the nitro-group would be expected to have at least as great an influence as the methoxy-group. We suggest that the explanation is to be found in the polar characters of the various atoms and groups and in the forces of attraction and repulsion which arise between them. It is known that nitro-compounds are able to unite with bases, union presumably taking place between the nitro-group and the nitrogen atom of the base, and an attraction must therefore exist between a nitro-group of the mono- or di-nitrobenzaldehyde and the nitrogen atom of the quinoxaline. Direct confirmation of this was obtained by the isolation of a " molecular " *compound*,



$$C_{10}H_{10}N_2,2C_6H_3(NO_2)_2\cdot CHO,$$

from the two reactants in a case where high reactivity had been found. This is of interest as affording evidence of direct union of the reacting molecules as a prelude to [illegible] Moreover it appears probable that this attraction of the nitro-group to the tertiary nitrogen atom will [illegible] operate within the molecule of the nitrostyryl [illegible] formed. Consequently the latter substance will for a large proportion of the time assume a [illegible] in which the large nitrostyryl [illegible] shield [illegible] second methyl group in the quinoxaline nucleus. [illegible] with a second molecule of *o*-nitrobenzaldehyde will be [illegible], a similar force operating between the second nitrogen

atom of the base and the nitro-group of this aldehyde so as to keep this nitro-group also away from the region of reaction, and a di(*o*-nitrostyryl)quinoxaline results.

(IV.)

(V.)

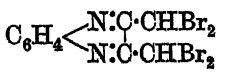
The force which is involved in the condensation with *o*-methoxybenzaldehyde, on the other hand, should be one of repulsion between the methoxy-group and the basic nitrogen atoms. The reaction is therefore slower and the monostyrylquinoxaline first produced tends for the greater portion of the time to adopt a spatial arrangement such as (V). Access of a second molecule of the aldehyde to the remaining methyl group of the base will now be very difficult. If further reaction were to take place, the adjacent nitrogen atom would tend to force the methoxy-group of this aldehyde molecule into the space around the methyl group already crowded in (V). The second stage of the reaction is thus completely arrested by a steric hindrance depending for its operation on the polar nature of the groups involved.

In order to test this conception we examined the reaction of the quinoxaline with *o*-iodobenzaldehyde. The iodine atom is known to have a large steric effect in such reactions as the esterification of acids, but it has the same type of general polar effect as the nitro-group and might be expected to have a similar attraction for a basic nitrogen atom. Experiment confirmed the expectation that steric hindrance would therefore be absent, for a good yield of di(*o*-iodostyryl)quinoxaline was isolated.

The effect here discussed is seen to be a true steric hindrance, although its operation may depend on the control of configuration by polar forces. The apparent steric hindrance of a reaction may arise from at least three distinct causes, namely (*a*) true steric hindrance, (*b*) the influence (other than steric) of the hindering group on the reactivity of the active group, (*c*) direct chemical action between the groups of the kind suggested by Sidgwick and Callow (J., 1924, 125, 527). The distinction between these may be uncertain in some cases, and a polar force may, as above suggested, be involved in evoking effects of type (*a*). A similar explanation may be offered of the observation of Remsen and Reid (*Amer. Chem. J.*, 1899, 21, 940) that *o*-methoxybenzamide is hydrolysed faster than *o*-chlorobenzamide, a true steric hindrance (*a*) being controlled by repulsion and an attraction respectively between the polar [illegible]

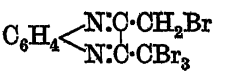
The variations in reactivity recorded by Dyson, George, and Hunter (J., 1927, 436), however, are apparently due to effects of type (*b*) and not to steric hindrance.

A less extended series of experiments with 2 : 3 : 6-trimethylquinoxaline served on the whole to confirm the conclusions arrived at with the dimethyl base. The third methyl group is not in a position to be reactive, but it shows its presence by a distinct increase of reactivity in the other two methyl groups. The 6-methyl group no doubt exerts an effect on the nitrogen atoms similar to that which causes *m*- and *p*-toluidines to be stronger bases than aniline. The nitrogen atoms of the quinoxaline consequently cause a somewhat greater activation of the 2- and 3-methyl groups.



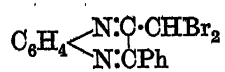
The base 2-phenyl-3-benzylquinoxaline was included in our study because the methylene group of the benzyl group seemed likely to show an enhanced reactivity due to the attached phenyl nucleus (compare Skraup and Böhm, *Ber.*, 1926, **59**, 1007). Substituted benzyl bases could easily be prepared by the method of Malkin and Robinson (J., 1925, **127**, 369), but we found that neither the benzyl nor the *p*-methoxy- nor *p*-chloro-benzyl bases reacted at all under the conditions of our experiments. The reaction is here inhibited by the combined steric hindrance of the phenyl radicals in position 2 and in the benzyl group of position 3, for we obtained good yields of styryl derivatives from 2-phenyl-3-methylquinoxaline on the one hand and from 2-benzylquinoxaline on the other. That a single *o*-methyl group exerts little or no steric hindrance in this reaction is shown by the easy condensation with 2 : 3-dimethylquinoline.

Through the kindness of Dr. F. M. Hamer, who supplied us with a specimen of the quinoxaline of *cyclo*pentadione, we were able to examine this base also. It reacts readily with aldehydes, although markedly less rapidly than the 2 : 3-dimethyl base, and the products have the structure $C_6H_4<\begin{matrix}N{:}C\cdot C(:CHAr)\\ N{:}C\cdot C(:CHAr)\end{matrix}>CH_2$.



The *methiodide* of 2 : 3-dimethylquinoxaline was prepared in order to test its capacity to undergo condensations similar to those of quinaldine methiodide. Unexpected difficulty was found in its preparation, only resinous products being at first produced. Subsequently a good yield of a monomethiodide was obtained by heating the base in a large excess of methyl iodide. It is possible that this method would yield quaternary salts in some other cases of recorded difficulty (*e.g.*, the substituted quinazolines; Bogert and Clark, *J. Amer. Chem. Soc.*, 1924, **46**, 1294). The methiodide reacted with aldehydes and with nitrosodimethylaniline, but the products were black, insoluble solids which it was found impossible to purify. Repeated trials showed no reaction between the methiodide and

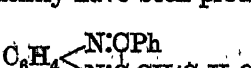
quinoline methiodide in alkaline solution to yield a dye of the *iso*cyanine type, nor with formaldehyde present to give a carbocyanine.



The bromination of these quinoxalines was studied under the standard conditions of heating the substance at 100° in acetic acid with bromine and sodium acetate. 2-Methylquinoxaline yielded the expected ω-tribromo-compound analogous to that obtained from quinaldine. In other cases, steric hindrance supervened, 2 : 3-dimethylquinoxaline being converted into a tetrabromo-derivative which resisted further bromination. This may be compared with the tetrabromo-compound from *o*-xylene (Gabriel and Müller, *Ber.*, 1895, **28**, 1830). It has the symmetrical structure (VI) and not the alternative (VII), for on hydrolysis with silver acetate it is converted into a substance giving an immediate precipitate with *p*-nitrophenylhydrazine. A similar steric hindrance is apparent in the formation of the dibromo-derivative (VIII) from phenylmethylquinoxaline.

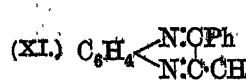
(VI.)

(VII.)

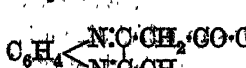


(VIII.)

When benzyl- and chlorobenzyl-phenylquinoxalines were subjected to the same reaction, the products isolated were free from bromine, and were identified as the acetoxy-compounds (IX) and (X). These substances must evidently have been produced by the



(IX.)



(X.)

interaction of a monobromo-compound with the sodium acetate present. The bromo-compound (XI), which must thus be an intermediate product, would have a particularly reactive bromine atom similar to that of diphenylmethyl bromide.

(XI.)

(XII.)

2 : 3-Dimethylquinoxaline reacts with ethyl oxalate, in the presence of either sodium or potassium ethoxides (compare the reactions of quinaldine examined by Wislicenus, *Ber.*, 1897, **30**, 1479; 1909, **42**, 1140) to yield *ethyl 2-methylquinoxaline-3-pyruvate* (XII), the structure of which is confirmed by the formation of a *p-nitrophenylhydrazone*.

The 2 : 3-dimethyl base did not react with amyl nitrite, Michler's hydrol, nitrosodimethylaniline, or a 2 : 4-dinitrobenzenediazonium salt.

EXPERIMENTAL.

Preparation of the Quinoxalines.—The method of Böttcher (*Ber.*, 1913, **46**, 3084) for preparing 2-methylquinoxaline was modified as follows: *iso*Nitrosoacetone (37 g.) and *o*-phenylenediamine (44 g.) were boiled in a mixture of hydrochloric acid (15 g.; *d* 1·19), glacial acetic acid (25 c.c.), and water (75 c.c.). The resultant mixture was made alkaline and benzoylated by means of benzoyl chloride (50 g.). The product was removed in a current of steam, and the distillate extracted with ether. The extract was dried over anhydrous sodium sulphate, the ether removed, and the residue distilled in a vacuum. The substance had b. p. 118°/16 mm. (yield, 13 g. or 45%).

2 : 3-Dimethylquinoxaline was obtained from methyl ethyl ketone through the *iso*nitroso-compound (compare Gabriel and Sonn, *Ber.*, 1907, **40**, 4850), the latter being used in the form of the crude oil which separates on acidification of the alkaline reaction mixture (yield, 70%).

2 : 3 : 6-Trimethylquinoxaline was readily obtained by a similar process.

2-Phenyl-3-methylquinoxaline (Auwers, *Ber.*, 1917, **50**, 1182) was not detected in the products of interaction of *iso*nitrosopropiophenone and *o*-phenylenediamine, but was prepared by heating the diketone (Smedley, J., 1909, **95**, 218) and the diamine together in ethyl alcohol for ½ hour.

Benzylglyoxal was prepared as described by Dakin and Dudley (*J. Biol. Chem.*, 1914, **18**, 42), except that the presence of any large amount of dibenzyl was avoided by preparing the magnesium benzyl chloride as recommended by Gilman and Myers (*J. Amer. Chem. Soc.*, 1923, **45**, 2462). Hydrolysis of the acetal (b. p. 131°/4 mm., 148—151°/18 mm.) from 20 g. of diethoxyacetopiperidide yielded at once the practically pure benzylglyoxal of m. p. 117—118° (3·8 g.).

2-*Benzylquinoxaline* was obtained as a dark oil, which did not solidify, by heating benzylglyoxal and *o*-phenylenediamine (1 mol.) for 20 minutes in ethyl alcohol. The *picrate* forms yellow needles, m. p. 117°, from ethyl alcohol (Found: N, 15·9. $C_{21}H_{15}O_7N_5$ requires N, 15·6%).

Phenyl β-methoxy-p-chlorostyryl ketone, Ph·CO·C(OMe):CH·C_6H_4Cl, was obtained from ω-methoxyacetophenone (4·6 g.) by condensation with *p*-chlorobenzaldehyde and was isolated as an oil, b. p. 238°/16 mm. (yield, 5·7 g.), which solidified on keeping and was crystallised (m. p. 45°) from light petroleum (Found: Cl, 13·0. $C_{16}H_{13}O_2Cl$ requires Cl, 13·0%).

Phenyl p-Chlorobenzyl Diketone.—A solution of the foregoing substance (2 g.) in acetic acid (9 c.c.) and concentrated hydrobromic acid (4 c.c.) was heated until the yellow solution acquired a greenish

hue; it was then cooled and diluted. The product (1·8 g.) was isolated by means of ether and recrystallised from light petroleum; m. p. 85° (Found: Cl, 13·4. $C_{15}H_{11}O_2Cl$ requires Cl, 13·7%). This substance differs from the corresponding methoxybenzyl compound (Malkin and Robinson, *loc. cit.*) in not being appreciably extracted from its ethereal solution by aqueous alkalis.

2-p-*Chlorobenzyl*-3-*phenylquinoxaline*.—The diketone condensed with *o*-phenylenediamine in alcoholic solution to yield this quinoxaline, but a more convenient mode of procedure was as follows: To the solution obtained by heating phenyl β-methoxy-*p*-chlorostyryl ketone (5 g.) in acetic acid (22 g.) and hydrobromic acid (10 c.c.), as previously described, *o*-phenylenediamine (2 g.) was added, and the mixture boiled with addition of ethyl alcohol until a homogeneous solution resulted. Crystals of the quinoxaline separated as the solution cooled, and after recrystallisation from ethyl alcohol had m. p. 142° (yield, 5·5 g.) (Found: Cl, 10·6. $C_{21}H_{15}N_2Cl$ requires Cl, 10·7%).

Phenyl β : 3-*Dimethoxystyryl Ketone*.—The product from ω-methoxyacetophenone (27·2 g.) and *m*-methoxybenzaldehyde was an oil of b. p. 245°/18 mm. (27·8 g.) (Found: C, 75·5; H, 6·0. $C_{17}H_{16}O_3$ requires C, 76·1; H, 6·0%). Hydrolysis of this with acetic and hydrobromic acids yielded a pinkish solid which, after being crystallised from light petroleum, melted at 175—180° (decomp.) when rapidly heated. This *substance* was not the expected diketone but apparently a polymeride, which did not react with *o*-phenylenediamine and was not further investigated (Found: C, 75·6; H, 5·7; *M*, 474. $C_{16}H_{14}O_3$ requires C, 75·6; H, 5·5%; *M*, 254).

Condensation of 2-*Methylquinoxaline with Aldehydes*.—In each case a solution of the base (1 mol.) and an aldehyde (1 mol.) in acetic anhydride (5—6 mols.) was boiled for a certain period of time; the product separated in the crystalline condition on cooling.

2 : 4-Dinitrobenzaldehyde gave 2-(2 : 4-*dinitrostyryl*)*quinoxaline* (yield, after 1 hour, 80%), which was recrystallised from hot aqueous acetic acid; m. p. 219—220° (decomp.) (Found: N, 17·6. $C_{16}H_{10}O_4N_4$ requires N, 17·4%).

2-o-*Nitrostyrylquinoxaline*, formed from *o*-nitrobenzaldehyde (yield, after 3 hours, 78%), crystallised from toluene in pale yellow needles, m. p. 156° (Found: N, 15·1. $C_{16}H_{11}O_2N_3$ requires N, 15·2%).

2-m-*Nitrostyrylquinoxaline*, from *m*-nitrobenzaldehyde (yield, after 4 hours, 68%), crystallised from equal volumes of benzene and petroleum (b. p. 60—80°) in almost colourless needles, m. p. 199·5° (Found: N, 15·3%).

2-p-*Nitrostyrylquinoxaline*, from *p*-nitrobenzaldehyde (yield, after

¾ hour, 65%), crystallised from toluene in pale yellow needles, m. p. 200° (Found: N, 15·3%).

The base appeared to react with benzaldehyde, but the product was not obtained crystalline.

Condensation of 2 : 3-Dimethylquinoxaline with Aldehydes.—2 : 3-Dimethylquinoxaline was boiled in solution in excess of benzaldehyde for 2 hours. On cooling, 2 : 3-*distyrylquinoxaline* was deposited as a yellow solid which crystallised from a mixture of equal proportions of xylene and light petroleum (b. p. 90—120°) in yellow monoclinic needles, m. p. 190·5° (yield, 50—70%) (Found: C, 86·2; H, 5·3; N, 8·5; *M*, 363. $C_{24}H_{18}N_2$ requires C, 86·25; H, 5·4; N, 8·4%; *M*, 334). No monostyrylmethylquinoxaline could be detected whatever the conditions of the reaction. Oxidation of the substance in acetone solution by potassium permanganate yielded no crystalline product other than benzoic acid. The action of bromine in boiling chloroform produced after 3 hours a *tetrabromide*, which was isolated by evaporation of the solvent and obtained in silvery plates, m. p. 190° (depressed to 177° by admixture of distyrylquinoxaline), by crystallisation from benzene (Found: Br, 48·1. $C_{24}H_{18}N_2Br_4$ requires Br, 48·3%).

2 : 3-Dimethylquinoxaline was boiled with piperonal (1 mol.) in acetic anhydride (5—6 mols.) for 5 hours, and the mixture distilled in a current of steam. The residue of 2-*methylenedioxystyryl*-3-*methylquinoxaline* solidified on keeping (yield, 20%) and after crystallisation from benzene–light petroleum and again from methyl alcohol was obtained in lemon-yellow needles, m. p. 150° (Found: N, 9·5. $C_{18}H_{14}O_2N_2$ requires N, 9·7%). When the heating was prolonged, a trace of a substance of higher melting point was observed among the products. This was prepared in quantity by boiling 2 : 3-dimethylquinoxaline with an excess of piperonal for 4 hours, removing the latter in boiling water, and crystallising the crude solid product from ethyl alcohol. 2 : 3-*Di*(*methylenedioxystyryl*)*quinoxaline* was then obtained in yellow monoclinic needles, m. p. 208° (yield, 30%) (Found: C, 73·8; H, 4·4; N, 6·8. $C_{26}H_{18}O_4N_2$ requires C, 73·9; H, 4·3; N, 6·6%). Addition of zinc chloride to the reaction mixture in this preparation did not improve the yield and made the purification less easy.

In the following preparations the base (1 mol.) and the required aldehyde (1 mol.) were heated in boiling acetic anhydride (5—6 mols.) for varying periods. The mixture was distilled in a current of steam, and the residue dried and crystallised.

The product obtained with *m*-nitrobenzaldehyde after 6 hours' heating was fractionally crystallised from benzene. The larger and more insoluble portion was recrystallised from this solvent and

2 : 3-*di*(m-*nitrostyryl*)*quinoxaline* obtained in small yellow bipyramids, m. p. 237° (yield, 10%) (Found : C, 67·8; H, 3·8; N, 13·3. $C_{24}H_{16}O_4N_4$ requires C, 67·9; H, 3·8; N, 13·2%). The smaller, more soluble, fraction was 2-m-*nitrostyryl*-3-*methylquinoxaline*, which crystallised from aqueous methyl alcohol in almost colourless needles, m. p. 184° (yield, 1—2%) (Found : C, 70·0; H, 4·4; N, 14·5. $C_{17}H_{13}O_2N_3$ requires C, 70·1; H, 4·5; N, 14·4%). This substance rapidly decolorised solutions of potassium permanganate and of bromine. When it was heated in boiling acetic anhydride with *m*-nitrobenzaldehyde it was converted into the foregoing di(*m*-nitrostyryl)quinoxaline of m. p. 237°.

The oily product from *p*-methoxybenzaldehyde, after 7 hours' heating, solidified on keeping. It was separated into two fractions by means of methyl alcohol. The less soluble portion was 2 : 3-*di*(p-*methoxystyryl*)*quinoxaline*, which crystallised from light petroleum (b. p. 90—120°) in yellow needles, m. p. 163° (yield, 10%) (Found : N, 7·3. $C_{26}H_{22}O_2N_2$ requires N, 7·1%). The more soluble fraction was 2-p-*methoxystyryl*-3-*methylquinoxaline*, which crystallised in rosettes of yellow needles, m. p. 122·5° (yield, 10%) (Found : N, 10·3. $C_{18}H_{16}ON_2$ requires N, 10·1%).

The following preparations were carried out as before, except that two molecular proportions of aldehyde were used.

2 : 3-*Di*(m-*methoxystyryl*)*quinoxaline* was obtained with *m*-methoxybenzaldehyde after 4 hours' heating and crystallised from ethyl alcohol in yellow prisms, m. p. 126° (yield, 10%) (Found : N, 7·3. $C_{26}H_{22}O_2N_2$ requires N, 7·1%).

2-o-*Methoxystyryl*-3-*methylquinoxaline* was isolated with some difficulty from the reaction with *o*-methoxybenzaldehyde after 6½ hours' heating. It was extracted in light petroleum, and crystallised from methyl alcohol in microscopic yellow crystals, m. p. 112° (yield, 1—2%) (Found : N, 10·1. $C_{18}H_{16}ON_2$ requires N, 10·1%). This compound rapidly decolorises solutions of permanganate and of bromine. It was recovered entirely unchanged after being heated in boiling acetic anhydride for 12 hours with *o*-methoxybenzaldehyde (2 mols.).

2 : 3-*Di*(3 : 4-*dimethoxystyryl*)*quinoxaline* was obtained from 3 : 4-dimethoxybenzaldehyde in a similar manner. It crystallised from ethyl alcohol in yellow needles, m. p. 208° (yield, 10%) (Found : N, 6·3. $C_{28}H_{26}O_4N_2$ requires N, 6·2%).

2 : 3-*Di*(β-*furylvinyl*)*quinoxaline* was obtained from furfural after 5 hours' heating, and crystallised from light petroleum (b. p. 90—120°) in yellow crystals, m. p. 169° (yield, 5%) (Found : N, 8·9. $C_{20}H_{14}O_2N_2$ requires N, 8·9%).

In the following preparations with nitro- and halogen-substituted

aldehydes distillation in steam was unnecessary, as the product crystallised when the mixture cooled.

2 : 3-*Di*(o-*nitrostyryl*)*quinoxaline* (yield, after 3 hours, 80%) crystallised from benzene in star-shaped groups of needles, m. p. 194·5°. (Found: N, 13·5. $C_{24}H_{16}O_4N_4$ requires N, 13·2%).

2 : 3-*Di*(p-*nitrostyryl*)*quinoxaline* (yield, after 1½ hours, 75% crystallised from nitrobenzene in deep yellow crystals, m.p. 288° (decomp.) (Found: N, 13·3%).

2-(2 : 4-*Dinitrostyryl*)-3-*methylquinoxaline* (yield, after 1 hour, 80%) separated from *cyclo*hexanol in orange-yellow crystals, m. p. 224—225° (decomp.) (Found: C, 60·5; H, 3·4; N, 16·9. $C_{17}H_{12}O_4N_4$ requires C, 60·7; H, 3·6; N, 16·7%). This substance rapidly decolorised solutions of permanganate and of bromine. The only product isolated after oxidation with potassium permanganate in acetone solution was 2 : 4-dinitrobenzoic acid (m. p. 177—179°). It was found possible also to produce the above compound by condensation in glacial acetic acid, or in xylene in the presence of a trace of zinc chloride. On the other hand, molecular proportions of the base and dinitrobenzaldehyde in solution in benzene were found to yield, after the expiration of 10 days, a considerable quantity of crystals of m. p. 96—97°. Admixture with a little of the base lowered the m. p. Fractional crystallisation from light petroleum yielded the quinoxaline and the aldehyde. The substance is, in fact, an *addition compound* of the base and the aldehyde, decomposed in hot petroleum. The variation of m. p. with composition of a mixture of the two substances shows the compound to contain 2 molecules of aldehyde to 1 molecule of base:

Dinitrobenzaldehyde (mols. %)	100	97·6	75	66·7	52·4
M. p.	71°	71°	75°	91°	80·5°
Dinitrobenzaldehyde (mols. %)	50	47·6	33·3	25·0	0
M. p.	72°	74°	81°	88°	106°

In view of the direct formation of a di-(2 : 4-dinitrostyryl) derivative from 2 : 3 : 6-trimethylquinoxaline (p. 1972) it seemed likely that an analogous compound would be formed from the 2 : 3-dimethyl base. The isolation of the above monostyryl derivative might be accounted for by its relative insolubility and its consequent removal from the reaction by crystallisation. This was confirmed as follows. The 2 : 3-dimethyl base, heated for 8 hours with the dinitro-aldehyde (3 mols.) in an excess of acetic anhydride, furnished 2 : 3-*di*(2 : 4-*dinitrostyryl*)*quinoxaline* (yield, 75%), which crystallised in brown needles from hot nitrobenzene and melted at 295—297° (decomp.) (Found: C, 56·1; H, 3·0. $C_{24}H_{14}O_8N_6$ requires C, 56·0; H, 2·7%).

2-(2 : 4 : 6-*Trinitrostyryl*)-3-*methylquinoxaline* (yield, after 1½

hours, 25%) crystallised from *cyclo*hexanol in brown crystals, m. p. 250—251° (decomp.) (Found: C, 53·6; H, 3·0. $C_{17}H_{11}O_6N_5$ requires C, 53·5; H, 2·9%).

2 : 3-*Di*(o-*chlorostyryl*)*quinoxaline* (yield, after 2½ hours, 60%) crystallised from benzene in long, yellow needles, m. p. 189·5° (Found: Cl, 17·5. $C_{24}H_{16}N_2Cl_2$ requires Cl, 17·6%). A careful search gave no indication of the presence of any monostyryl derivative among the products of this reaction.

2 : 3-*Di*(m-*chlorostyryl*)*quinoxaline* (yield, after 5 hours, 30%) was obtained solid with difficulty; the product was distilled in steam, purified by means of ethyl alcohol, and crystallised from light petroleum, forming yellow needles, m. p. 149° (Found: Cl, 17·5%).

2 : 3-*Di*(p-*chlorostyryl*)*quinoxaline* (yield, after 2½ hours, 60%) crystallised from benzene in small, star-shaped clusters of needles, m. p. 218° (Found: Cl, 17·4%).

2 : 3-*Di*(o-*iodostyryl*)*quinoxaline* (yield, after 5 hours, 40%) crystallised from light petroleum (b. p. 90—120°) in pale yellow plates, m. p. 179° (Found: I, 43·4. $C_{24}H_{16}N_2I_2$ requires I, 43·3%).

No crystalline product was isolated when condensations were attempted between 2 : 3-dimethylquinoxaline and dimethylaminobenzaldehyde, chloral, cinnamaldehyde, phenylacetaldehyde, benzil, glyoxal, phthalic anhydride, *p*-nitrosodimethylaniline, Michler's hydrol, or xanthydrol.

Condensation of 2 : 3 : 6-*Trimethylquinoxaline with Aldehydes.*—The base was boiled with benzaldehyde in excess for 2 hours; 2 : 3-*distyryl*-6-*methylquinoxaline* crystallised from the cooled reaction mixture (yield, 81%) and by recrystallisation from xylene was obtained in small, yellow needles, m. p. 193° (Found: N, 8·3. $C_{25}H_{10}N_2$ requires N, 8·3%).

The following condensations were carried out in acetic anhydride, and the products worked up as described on p. 1968.

2 : 3-*Di*(*methylenedioxystyryl*)-6-*methylquinoxaline* (yield, after 4 hours, 10%) was crystallised from dilute alcohol; m. p. 168° (Found: N, 6·6. $C_{27}H_{20}O_4N_2$ requires N, 6·4%).

2-p-*Methoxystyryl*-3 : 6-*dimethylquinoxaline* (yield, after 5 hours, 1—2%) separated from methyl alcohol in small yellow crystals, m. p. 116° (Found: N, 9·8. $C_{19}H_{18}ON_2$ requires N, 9·7%), and 2 : 3-*di*(p-*methoxystyryl*)-6-*methylquinoxaline* (yield, after 10 hours, 15%) in yellow needles, m. p. 136° (Found: N, 7·1. $C_{27}H_{24}O_2N_2$ requires N, 6·9%).

2 : 3-*Di*(3 : 4-*dimethoxystyryl*)-6-*methylquinoxaline* (yield, after 5 hours, 5%) separated from light petroleum (b. p. 90—120°) in orange-yellow crystals, m. p. 205° (Found: N, 6·1. $C_{29}H_{28}O_4N_2$ requires N, 6·0%).

In the following preparations steam distillation was dispensed with, as the product crystallised from the cooling reaction mixture.

The product from *m*-nitrobenzaldehyde (after 5 hours' heating) was separated into two portions by means of benzene. The less soluble portion was 2 : 3-*di*(m-*nitrostyryl*)-6-*methylquinoxaline*, which was crystallised from *cyclo*hexanol; m. p. 244·5° (yield, 10%) (Found: N, 12·9. $C_{25}H_{18}O_2N_4$ requires N, 12·8%). The more soluble portion was 2-m-*nitrostyryl*-3 : 6-*dimethylquinoxaline* and was crystallised from light petroleum; m. p. 165° (yield, 1—2%) (Found: N, 13·5. $C_{18}H_{15}O_2N_3$ requires N, 13·8%).

2 : 3-*Di*(2 : 4-*dinitrostyryl*)-6-*methylquinoxaline* (yield, after 1¼ hours, 80%) separated from *cyclo*hexanol in orange-yellow crystals, m. p. 251—255° (decomp.) (Found: C, 57·0; H, 3·4; N, 15·7. $C_{25}H_{16}O_8N_6$ requires C, 56·75; H, 3·0; N, 15·9%).

Condensation of 3-*Phenyl*-2-*methylquinoxaline with Aldehydes.*—The base was heated with boiling benzaldehyde (4 mols.) for 1 hour. 2-*Styryl*-3-*phenylquinoxaline* crystallised as the mixture cooled (yield, 90%) and separated, on recrystallisation from ethyl alcohol, in pale yellow needles, m. p. 149° (Found: N, 9·3. $C_{22}H_{16}N_2$ requires N, 9·1%).

2-*p*-*Nitrostyryl*-3-*phenylquinoxaline* was prepared from the base and *p*-nitrobenzaldehyde in acetic anhydride (yield, after 2 hours, 80%). It crystallised from benzene–light petroleum in bright yellow needles, m. p. 283° (Found: N, 12·1. $C_{22}H_{15}O_2N_3$ requires N, 11·9%).

2-(2 : 4-*Dinitrostyryl*)-3-*phenylquinoxaline* (yield, 90%) separated from light petroleum in yellow needles, m. p. 215° (Found: N, 14·1. $C_{22}H_{14}O_4N_4$ requires N, 14·1%).

Behaviour of Phenylbenzylquinoxaline with Aldehydes.—The substances were recovered unchanged when 3-phenyl-2-benzylquinoxaline and *p*-nitrobenzaldehyde; 3-phenyl-2-*p*-methoxybenzylquinoxaline and *p*-nitro- or 2 : 4-dinitro-benzaldehyde; 3-phenyl-2-*p*-chlorobenzylquinoxaline and *p*-nitro- or 2 : 4-dinitro-benzaldehyde or dimethylaminobenzaldehyde were heated together for 6—10 hours in boiling acetic anhydride. The phenylchlorobenzylquinoxaline was unaffected by boiling with benzaldehyde for 3 hours.

Condensation of 2-*Benzylquinoxaline with Aldehydes.*—The crude benzylquinoxaline was heated with an excess of *p*-nitrobenzaldehyde in boiling acetic anhydride for 5 hours.

2-(β-*Phenyl*-p-*nitrostyryl*)*quinoxaline* separated from the cooling mixture (yield, 1·2 g. from 1·4 g. of benzylglyoxal). It crystallised from ethyl alcohol in pale yellow needles, m. p. 149° (Found: N, 12·0. $C_{22}H_{15}O_2N_3$ requires N, 11·9%).

Condensation of the crude base with dinitrobenzaldehyde (7 hours'

heating) yielded a trace of a crystalline product, m. p. 261—262°, which was insufficient for analysis, but was probably the corresponding 2-(β-*phenyl*-2 : 4-*dinitrostyryl*)*quinoxaline*.

*Condensation of Quinoxalino*cyclo*pentane with Aldehydes.*—Quinoxalino*cyclo*pentane was converted by heating in boiling benzaldehyde for 2 hours into the *dibenzylidene* derivative (yield, 40%), brownish crystals, m. p. 213°, from ethyl alcohol (Found : N, 8·4. $C_{25}H_{18}N_2$ requires N, 8·1%), and by heating with *p*-nitrobenzaldehyde in acetic anhydride into the *di*-p-*nitrobenzylidene* derivative (yield, after 1 hour, 85%), which crystallised from hot nitrobenzene in yellow needles, decomp. 268—270° (Found : N, 12·8. $C_{25}H_{16}O_4N_4$ requires N, 12·8%). This base also condensed rapidly with 2 : 4-dinitrobenzaldehyde, but the product was so insoluble that it was impossible to purify it.

Condensation of Some Quinoline Bases with 2 : 4-*Dinitrobenzaldehyde.*—The products were obtained crystalline in 60—80% yield in 1—2 hours' heating. Quinaldine yielded 2-(2 : 4-*dinitrostyryl*)-*quinoline*, crystallising from benzene in pale yellow needles, m. p. 200° (Found : N, 13·1. $C_{17}H_{11}O_4N_3$ requires N, 13·1%). 2 : 8-Dimethylquinoline was converted into 2-(2 : 4-*dinitrostyryl*)-8-*methylquinoline*, crystallising from benzene in bright yellow needles, m. p. 198° (Found : C, 64·5; H, 4·5. $C_{18}H_{13}O_4N_3$ requires C, 64·5; H, 3·9%). 2 : 3-Dimethylquinoline gave 2-(2 : 4-*dinitrostyryl*)-3-*methylquinoline*, crystallising from benzene in brown needles, m. p. 257° (Found : C, 64·6; H, 3·7%). The same base, heated in excess of benzaldehyde at 150—160° for 6 hours, was converted into 2-*styryl*-3-*methylquinoline*, which separated as almost colourless crystals, m. p. 102°, from light petroleum (yield, 50%) (Found : C, 88·2; H, 6·4. $C_{18}H_{15}N$ requires C, 88·2; H, 6·1%).

Condensation of 2 : 3-*Dimethylquinoxaline with Ethyl Oxalate.*—To a suspension of sodium ethoxide (2 mols.) in dry ether, mixed with a little xylene, was added an ethereal solution of 2 : 3-dimethylquinoxaline (1 mol.) and ethyl oxalate (2 mols.). At the end of 12 hours a pale yellow colour had developed and traces of a solid were to be seen separating. After 4 weeks, the accumulated solid was collected and washed thoroughly with dry ether. It crystallised from acetic acid or ethyl alcohol in orange-yellow needles, m. p. 129° (yield, 2·5 g. from 4·7 g. of base). This was *ethyl* 2-*methylquinoxaline*-3-*pyruvate* (Found : C, 65·6; H, 5·5. $C_{14}H_{14}O_3N_2$ requires C, 65·2; H, 5·5%). When potassium ethoxide was substituted for sodium ethoxide in the preparation (compare Wislicenus, *Ber.*, 1909, **42**, 1140), the yield was improved (3·2 g. from 4·7 g. of base). The *p-nitrophenylhydrazone* crystallised in orange needles, m. p. 182° from ethyl alcohol (Found : N, 18·0. $C_{20}H_{19}O_4N_5$ requires N, 17·8%).

After dimethylquinoxaline had been kept with amyl nitrite and sodium or potassium ethoxide for 12 days, no condensation product could be detected.

Bromination of the Quinoxaline Bases.—2-Methylquinoxaline, brominated as described by Hammick (J., 1923, **123**, 2883), yielded an oil which solidified 2 days later. After several recrystallisations from ethyl alcohol, 2-*ω-tribromomethylquinoxaline* was obtained (yield of pure substance, 10%) in pink plates, m. p. 109° (Found: Br, 62·7. $C_9H_5N_2Br_3$ requires Br, 63·0%).

2 : 3-Dimethylquinoxaline, brominated with 6 molecular proportions of bromine under similar conditions, gave a quantitative yield of 2 : 3-*di*(*ω-dibromomethyl*)*quinoxaline*, which crystallised from glacial acetic acid in colourless needles, m. p. 228° (Found: Br, 66·9. $C_{10}H_6N_2Br_4$ requires Br, 66·95%). This substance was recovered unchanged after boiling in glacial acetic acid for 1 hour with a large excess of bromine. When this compound was boiled in glacial acetic acid solution with silver acetate, the halogen was removed. The resulting solution gave a precipitate with *p*-nitrophenylhydrazine which was sparingly soluble in the common solvents and could not be obtained pure. The di-aldehyde was too unstable to be isolated by evaporation even under reduced pressure in an inert atmosphere.

Bromination of 3-phenyl-2-methylquinoxaline gave 3-*phenyl*-2-*ω-dibromomethylquinoxaline* (yield, 90%), which separated from light petroleum in clusters of needles, m. p. 148° (Found: Br, 42·1. $C_{15}H_{10}N_2Br_2$ requires Br, 42·25%).

To 3-phenyl-2-benzylquinoxaline (1·5 g.), dissolved in glacial acetic acid containing sodium acetate (2·3 g.), was added bromine (1·5 g.; 2 mols.) in a little acetic acid at 70°. After the reaction had been completed on the water-bath, the product obtained on pouring the mixture into water proved to be 3-*phenyl*-2-*phenylacetoxymethylquinoxaline* (yield, 90%), which crystallised from light petroleum in colourless prisms, m. p. 126°. It was free from halogen and after hydrolysis gave a test for acetic acid (Found: C, 78·3; H, 5·3. $C_{23}H_{18}O_2N_2$ requires C, 78·0; H, 5·1%).

3-Phenyl-2-*p*-chlorobenzylquinoxaline underwent a similar change with bromine and sodium acetate in glacial acetic acid solution, giving in quantitative yield the bromine-free product, 3-*phenyl*-2-*p-chlorophenylacetoxymethylquinoxaline*, colourless prisms from light petroleum, m. p. 119° (Found: Cl, 9·4. $C_{23}H_{17}O_2N_2Cl$ requires Cl, 9·1%).

3-Phenyl-2-*p*-methoxybenzylquinoxaline did not react with bromine under similar conditions to the above, nor when the reaction mixture was boiled for 1 hour.

Action of Methyl Iodide on Dimethylquinoxaline.—When 2 : 3-di-

methylquinoxaline was heated at various temperatures with methyl iodide (2 or 3 mols.), no crystalline product could be isolated, nor could the methosulphate be obtained by means of methyl sulphate. However, the base, heated in a sealed tube at 90° for 6½ hours with methyl iodide (10 mols.), furnished a *monomethiodide* (yield, 80%) which crystallised from ethyl alcohol in greenish-yellow needles, m. p. 192° (Found : I, 42·6. $C_{11}H_{13}N_2I$ requires I, 42·4%). Addition of sodium hydroxide to the aqueous solution precipitated an oil which could not be obtained crystalline.

The methiodide was boiled in ethyl alcohol with benzaldehyde or nitrosodimethylaniline and a trace of piperidine. In each case a brilliant colour change occurred and a black solid was precipitated, which, however, was insoluble in all solvents including phenol, nitrobenzene, *cyclo*hexanone, and acetic acid.

We are indebted to the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the cost of this investigation.

THE UNIVERSITY, SHEFFIELD. [*Received, May 14th*, 1928.]

CCLVIII.—*The Relative Reactivity of Methylene Groups in* 1 : 3-*Diketones.*

By ARTHUR BERTRAM EDMUND LOVETT and ELWYN ROBERTS.

THE present investigation was designed to discover which methylene group, in a diketone of the general formula $CH_2R{\cdot}CO{\cdot}CH_2{\cdot}COR'$, would be the more reactive as regards condensation with aldehydes. Bülow and Grotowsky (*Ber.*, 1901, **34**, 1479) assumed that in ω-phenylacetylacetophenone, $CH_2Ph{\cdot}CO{\cdot}CH_2{\cdot}COPh$, the methylene group adjacent to the benzoyl radical was the more reactive towards nitrous acid and diazo-compounds. Different aldehydes, however, behave very differently towards phenylacetylacetophenone in presence of piperidine; for instance, benzaldehyde and cinnamaldehyde give resins, but salicylaldehyde readily condenses in alcohol or benzene solution. Since the resulting *o-hydroxybenzylidenephenylacetylacetophenone* is readily convertible, in good yield, into acetophenone and 3-phenylcoumarin, it must have the formula $OH{\cdot}C_6H_4{\cdot}CH{:}CPh{\cdot}CO{\cdot}CH_2{\cdot}COPh$, and not

$$OH{\cdot}C_6H_4{\cdot}CH{:}C(COPh){\cdot}CO{\cdot}CH_2Ph.$$

The more reactive methylene group in ω-phenylacetylacetophenone is therefore that adjacent to the phenyl group. The formation of 3-phenylcoumarin cannot be attributed to an initial hydrolysis

giving rise to phenylacetic acid and acetophenone, since phenylacetic acid does not condense with salicylaldehyde under the same conditions to give the coumarin. Furthermore, the intermediate product on continued recrystallisation from a non-aqueous solvent such as benzene gives a mixture in which 3-phenylcoumarin increasingly preponderates. It reacts with concentrated sulphuric acid and acetic anhydride to give products of undetermined constitution.

5-Methyl, 5-chloro-, 5-bromo-, 5-nitro-, 3-nitro-, 3 : 5-dichloro-, 3 : 5-dibromo-, and 3-nitro-5-methyl-salicylaldehydes condense with ω-phenylacetylacetophenone under similar conditions to give substituted 3-phenylcoumarins, but in no case could the intermediate product be isolated. The yield of coumarin, except from salicylaldehyde and its 5-methyl derivative, was small, indicating the influence of substituents on the condensation. From 5-bromo-3-nitrosalicylaldehyde a trace only of the coumarin, and from 5-chloro-3-nitro- and 3 : 5-dinitro-salicylaldehydes no coumarin was obtained; these three aldehydes react with piperidine to give stable piperidides of undetermined constitution. Phenylacetylacetophenone and 2-hydroxy-α-naphthaldehyde in the presence of piperidine give, not the expected 3-phenylbenzcoumarin, but a red *compound* probably having formula $C_{27}H_{18}O_2$. 2-Hydroxy-α-naphthaldehyde, however, condenses with ethyl acetoacetate to give 3-acetobenzcoumarin (Knoevenagel and Schrötter, *Ber.*, 1904, **37**, 4484; compare Bülow and Grotowsky, *Ber.*, 1902, **35**, 1803).

ω-Propionyl- and butyryl-acetophenones and propionylacetone were condensed with salicylaldehyde and substituted salicylaldehydes in the presence of piperidine. Resin-like products were obtained from which no crystalline solid could be isolated. The effect of the nature of the groups R, R′ on the reactivity of the methylene groups could not therefore be readily determined by this method.

In all cases the coumarins were synthesised for identification purposes by the Perkin reaction. The yield of coumarin by this method was good, in contradistinction to the poor yields obtained by condensation of aldehyde and ketone.

Experimental.

ω-Phenylacetyl-, propionyl-, and butyryl-acetophenones and propionyl-acetone were prepared by a modification of Claisen's method, a suspension of powdered sodium in xylene being used instead of anhydrous sodium ethoxide.

Propionylacetophenone.—The green copper salt crystallised from acetone in needles, m. p. 151—152°. The pure ketone boils at

149°/17 mm. or 151°/19 mm. Beyer and Claisen (*Ber.*, 1887, **20**, 2178) give b. p. 170—172°/30—31 mm.

The p-*nitrophenylhydrazone* was obtained by heating 1·76 g. (1 mol.) of the ketone and 1·53 g. (1 mol.) of *p*-nitrophenylhydrazine at 100° for 7 hours. The product, a thick gum, when covered with 96% alcohol and kept for 3 days, set to a solid mass. It was crystallised from aqueous alcohol, in which it was fairly easily soluble, and then from light petroleum (b. p. 80—100°), fine yellow needles (1·3 g.), m. p. 67—68°, being obtained (Found: N, 13·4. $C_{17}H_{17}O_3N_3$ requires N, 13·5%).

Propionylacetophenoneanil.—A mixture of 5 g. (1 mol.) of the ketone and 2·64 g. (1 mol.) of freshly distilled aniline was heated under reflux for ½ hour; no more water then appeared to separate. Benzene extracted from the product a dark brown, mobile oil which deposited a solid after a few days. This, after being pressed on porous porcelain, crystallised from light petroleum (b. p. 40—60°), in which it was readily soluble, in prisms (1·8 g.), m. p. 48—49° (Found: N, 5·7. $C_{17}H_{17}ON$ requires N, 5·6%).

Condensation of Salicylaldehydes with ω-Phenylacetylacetophenone.—A solution of salicylaldehyde (7·5 g.; 1 mol.) and phenylacetylacetophenone (14·6 g.; 1 mol.) in 25 c.c. of absolute alcohol was treated with piperidine (45 drops; which produced a marked development of heat and deepening of colour) and heated on the water-bath; *o-hydroxybenzylidenephenylacetylacetophenone* separated in prisms from the hot liquor. The latter was decanted, and the solid washed with alcohol and collected (13·3 g.; m. p. 171—174°) (Found: C, 80·6; H, 5·3. $C_{23}H_{18}O_3$ requires C, 80·7; H, 5·3%). Recrystallisation from alcohol or benzene lowers the melting point. The yield of product depends upon the amount of piperidine used, the above quantity giving the maximum yield.

The mother-liquor was heated on the water-bath for a further hour; 3-phenylcoumarin (2·4 g.) separated on cooling.

If the intermediate product was not isolated, it gradually dissolved on prolonged heating (5 hours); on cooling, almost pure 3-phenylcoumarin (7·0 g.) separated, m. p. 140—141° (Found: C, 81·1; H, 4·5. Calc.: C, 81·1; H, 4·5%).

The same products were obtained on varying the molecular proportion of aldehyde and ketone.

Ethyl phenylacetate (1 mol.) and salicylaldehyde (1 mol.), on heating on the water-bath for 4 hours in presence of piperidine, gave a 16% yield of pure 3-phenylcoumarin.

In the condensations of ω-phenylacetylacetophenone and substituted *o*-hydroxyaldehydes the same method was employed, the period of heating varying from 7 to 11 hours. In some cases

coumarin was deposited from the hot solution. Unless otherwise stated in the following table, the coumarin was crystallised from alcohol, in which it was very sparingly soluble. The yields obtained (I) by ketone condensation and (II) by the Perkin reaction are given.

Substituted 3-*phenyl-coumarin.*	Form.	M. p.	% found.	% calc.	Yield. (I).	(II).

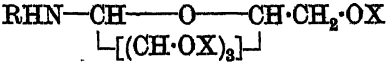
* From acetic acid. † From acetic anhydride.

3 : 5-*Dinitrosalicylaldehyde.*—The mixture of 3- and 5-nitrosalicylaldehydes (33 g.) obtained by the nitration of salicylaldehyde (von Miller, *Ber.*, 1887, **20**, 1927) was added cautiously, with cooling in ice and salt, to a mixture (100 g.) of concentrated sulphuric acid (2 parts) and nitric acid (*d* 1·5; 1 part). After 30 minutes the nitration mixture was poured on ice, and the yellow product was washed with ice-water, dried, and crystallised three times from benzene, giving lemon-yellow prisms (20 g.), m. p. 58—60° (Found : N, 13·1. $C_7H_4O_6N_2$ requires N, 13·2%). Its constitution was proved by oxidising it by alkaline permanganate to 3 : 5-dinitrosalicylic acid.

5-*Chloro*-3(?)-*nitrosalicylaldehyde.*—A solution of 8·1 g. of 5-chlorosalicylaldehyde in 100 c.c. of glacial acetic acid was slowly treated at 60—70° with nitric acid (*d* 1·42; 8 c.c.). The solution was then cooled slowly, the yellow, crystalline product removed, the filtrate diluted with 100 c.c. of water, and the precipitated solid collected. The combined product was crystallised twice from light petroleum (b. p. 80—100°), from which it separated in yellow needles (5·5 g.), m. p. 105—107° (Found : Cl, 17·4. $C_7H_4O_4NCl$ requires Cl, 17·6%). The constitution of this aldehyde was inferred by analogy, since 5-bromosalicylaldehyde nitrates under identical conditions (von Auwers and Bürger, *Ber.*, 1898, **31**, 3934) to give 5-bromo-3-nitrosalicylaldehyde.

Condensation of 2-Hydroxy-α-naphthaldehyde and ω-Phenylacetylacetophenone.—A solution of 2·4 g. (1 mol.) of the ketone, 1·72 g. (1 mol.) of the aldehyde, and 7 drops of piperidine in 5 c.c. of

absolute alcohol was heated on the water-bath for 2 hours. On cooling, no separation of solid occurred. The mixture was then heated for a further 9 hours; on cooling, a red crystalline mass was now obtained. After being washed with spirit, this crystallised from alcohol, in which it was very sparingly soluble (1 g. in 200 c.c.), in small, deep blood-red prisms (0·9 g.), m. p. 155—156·5° (Found: C, 86·8; H, 4·9. $C_{27}H_{18}O_2$ requires C, 86·6; H, 4·8%).



The authors desire to thank the Research Fund Committee of the Chemical Society for a grant which has partly defrayed the cost of this investigation.

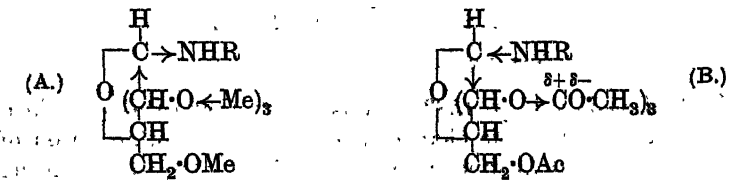
CCLIX.—*The Mechanism of Tautomeric Interchange and the Effect of Structure on Mobility and Equilibrium. Part III. The Function of Alkaline and Acid Catalysts in the Mutarotation of some Derivatives of Tetramethyl Glucose.*

By JOHN WILLIAM BAKER.

IN Part II (this vol., p. 1583) it was shown that catalysts which facilitate the prototropic change involved in the mutarotation of sugars may be of two kinds: (*a*) those which attack the ionising proton directly, and (*b*) those which facilitate its liberation indirectly. Experiments on the relative velocity of mutarotation of a series of nitrogen derivatives of tetra-acetyl glucose of type I (X = Ac) suggested that acids, which fall within the second category

(I.)



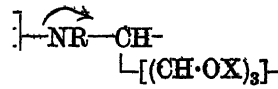
of catalysts, function by inducing a positive charge on the nitrogen atom, which in turn facilitates the liberation of the attached proton. Unfortunately, in this series of sugar derivatives a study of the action of catalysts of the first type, of which alkalis are an example, is rendered difficult by the tendency of the acetyl groups to hydrolysis. Such an investigation is, however, possible in the case of the corresponding derivatives of tetramethyl glucose, and this communication deals with the effect of acid and alkaline catalysts on the relative velocities of mutarotation of a series of *p*-substituted anilides of tetramethyl glucose (type I, X = Me) (prepared by the direct interaction of the sugar and the bases when

the group R is varied. With acid catalysts, it is again found, as is the case in the corresponding tetra-acetyl derivatives, that, as the group R is varied, the velocity of the mutarotation runs parallel with the strengths as bases of the compounds RNH_2, *viz.*,

$$-C_6H_4\cdot OMe(p) > -C_6H_4Me(p) > -C_6H_5 > -C_6H_4Cl(p) > -C_6H_4Br(p)$$

a sequence which is in agreement with the prediction based on the mechanism previously suggested, but opposed to that required by the extension of a duplex theory (Part II, *loc. cit.*).

The solvent * used was one in which a determination of the velocities of mutarotation of three of the corresponding derivatives of tetra-acetyl glucose had already been made, and hence data are now available for a comparison of the effect, on the velocity of mutarotation, of structural changes in the non-tautomeric glucose portion of the molecule. By analogy with the known effect of the acetyl group in diminishing, and of the methyl group in increasing, the basic character of the nitrogen atom in $NHR\rightarrow\overset{\delta+\ \delta-}{CO}\cdot CH_3$ and $NHR\leftarrow Me$, it would be expected that the anilides of tetramethyl glucose (A) would be more basic in character than the corresponding derivatives of tetra-acetyl glucose (B),



and hence, under identical conditions of acid catalysis, the velocity of mutarotation of derivatives of the former should be greater than that of corresponding derivatives of the latter. The experimental results given below, which refer to the velocity of mutarotation in a 0·9*N*-solution of acetic acid in ethyl acetate at 25°, are in agreement with this prediction.

Mutarotation of p-substituted anilides in 0·9N-*acetic acid in ethyl acetate at* 25°.

R.	Unimolecular velocity coefficient (hr.$^{-1}$). (*a*) Derivatives of tetramethyl glucose.	(*b*) Derivatives of tetra-acetyl glucose.
C_6H_4Br	0·39	—
C_6H_4Cl	0·46	—
C_6H_5	1·30	0·21
C_6H_4Me	4·12	0·58
$C_6H_4\cdot OMe$	12·0	1·69

* Alcohol-free ethyl acetate (but not an arrest sample) was used in the preparation of the solution; but the *same* solution was used throughout, since the object was merely to obtain constant catalytic conditions.

The results obtained for alkaline catalysis are more complicated and their interpretation much less clearly defined than in the case of acid catalysis. It would be expected that the primary function of alkaline catalysts, which are included in the first class, would be the direct attack of the ionising proton of the sugar molecule by the negative ion of the catalyst in accordance with the scheme

Other structural and experimental conditions being equal, the velocity of mutarotation based on this mechanism will depend on the relative ease with which the H of the –NHR group can separate as a proton. This, in turn, as indicated in Part II, will depend on the extent to which the group R collaborates with the catalyst proton acceptor. Approximate data of the order of this effect may be obtained from the relative strengths as acids of the compounds $R{\cdot}CO_2H$ or $R{\cdot}OH$. This for the series of *p*-substituted anilides studied is

$$(-C_6H_4Br, -C_6H_4Cl) > -C_6H_5 > -C_6H_4Me > -C_6H_4{\cdot}OMe.$$

On the other hand, experimentally it is difficult completely to eliminate catalysts of the second type, such as water and possibly alcohol, which may function in an indirect manner by a mechanism analogous to that shown to exist in the case of catalysis by acids, *viz.*, by inducing a fractional positive charge on the nitrogen atom. Such catalytic action would be most effective with the derivative of the strongest base, the sequence in the series under consideration being that given for acid catalysis on p. 1980. Therefore in alkaline catalysis it seems probable that at least two different types of mechanism may function, one of which is most powerful with the derivative of the weakest base, the other reaching its maximum with the derivative of the strongest base. The superimposition of these two mechanisms may therefore lead to the existence of a minimum value for the velocity of mutarotation at some intermediate point in the series. This theory is tentatively suggested as one satisfactory explanation of the experimental results obtained. These refer to the mutarotation of a series of *p*-substituted anilides of tetramethyl glucose in ether containing a small concentration of an alcoholic solution of sodium ethoxide. In the first two series of experiments, the concentration of sodium ethoxide was approximately 0·0006*N*, and a small (constant but undetermined) quantity of water was present. The values of the unimolecular velocity coefficients of the various derivatives at 25° are as follows: $-C_6H_4Cl$, 1·33; $-C_6H_4Br$, 1·24; $-C_6H_5$, 1·13; $-C_6H_4Me$, 1·21; $-C_6H_4{\cdot}OMe$,

2·41 (hr.$^{-1}$). In this series a minimum value for the velocity coefficient is found in the case of the unsubstituted anilide.

With the object of accelerating the direct mechanism and impeding the indirect type of catalytic action, another series of experiments was carried out in which a higher proportion (0·001*N*) of sodium ethoxide was used, and in which water was rigidly excluded. These measures were calculated to shift the position of the minimum velocity to the right in the above series, so that a greater number of the derivatives would fall into the sequence demanded by the direct mechanism alone (p. 1981). The following experimental values of the unimolecular velocity coefficients confirm this expectation:

$-C_6H_4Cl$, 11·4; $-C_6H_4Br$, 9·1; $-C_6H_5$, 7·7; $-C_6H_4Me$, 6·1 (minimum); $-C_6H_5{\cdot}OMe$, 14·7.

EXPERIMENTAL.

I. *Preparation of* p-*Substituted Anilides of Tetramethyl Glucose.*—These were prepared by boiling a mixture of tetramethyl glucose with an excess of the appropriate base in alcoholic solution for several hours in accordance with the method used by Irvine and Gilmour (J., 1908, **93**, 1440) for the preparation of the anilide.

p-*Bromoanilide*, after crystallisation from methyl alcohol, has m. p. 154° (Found: C, 48·8; H, 6·1. $C_{16}H_{24}O_5NBr$ requires C, 49·2; H, 6·2%).

p-*Chloroanilide*, after crystallisation from methyl alcohol–ligroin (b. p. 60—80°), has m. p. 141° (Found: C, 55·3; H, 7·0. $C_{16}H_{24}O_5NCl$ requires C, 55·5; H, 7·0%).

p-*Toluidide*, after crystallisation from absolute alcohol, has m. p. 151° (Found: C, 62·7; H, 8·0. $C_{17}H_{27}O_5N$ requires C, 62·8; H, 8·4%).

p-*Anisidide*, after crystallisation from ether–ligroin (b. p. 40—60°), has m. p. 110° (Found: C, 59·8; H, 8·0. $C_{17}H_{27}O_6N$ requires C, 59·8; H, 8·0%).

The anilide had m. p. 135° (Found: C, 61·7; H, 8·0. Calc.: C, 61·7; H, 8·1%).

II. *Relative Velocity Experiments.*—(A) *With acid catalysts.* The solution employed was one previously used in the determination of the relative velocities of mutarotation of the corresponding derivatives of tetra-acetyl glucose, and consisted of pure ethyl acetate to which acetic acid in a concentration 0·9*N* had been added (see footnote, p. 1980).

All polarimetric measurements were carried out in a 2-dcm. silica polarimeter tube with optically ground silica endplates fused on. The tube was jacketed for temperature control, the temperature

readings recorded being those of the jacket. Measurements were made on the mercury green line, the light source being a powerful Kelvin, Bottomley, and Baird mercury vapour lamp. The velocity determinations were carried out consecutively, each series being completed within a few days in order to avoid any possibility of change in the composition of the solvent during a series of comparative experiments.

The value of $[\alpha]_0$ was determined by extrapolation to zero time of the straight line obtained by plotting $\log([\alpha]_0 - [\alpha]_\infty)$ against time. Details of the polarimetric measurements are given only in the first set of each series.

(B) *With alkaline catalysts. Series I and II.*

Preparation of solution. A 0·1*N*-solution of sodium ethoxide in alcohol was prepared by addition of the required quantity of sodium to absolute alcohol (calcium-dried). 1·5 C.c. of this solution were added to about 246 c.c. of sodium-dried ether, and the solution made up to 250 c.c. by addition of ordinary absolute alcohol (99·5%) to keep the sodium ethoxide in solution. The solution was therefore approximately 0·0006*N* in sodium ethoxide.

Mutarotation of tetramethyl glucose anilides in an approximately 0·0006N-*solution of sodium ethoxide in ether at* 25°.

OMe.....	1·0016	257	155	6·4

* Obtained graphically from the straight line obtained by plotting t against log ($[\alpha]_0 - [\alpha]_\infty$).

In the next series, the alcohol used was refluxed over metallic calcium until a large amount of calcium ethoxide was formed. It was then transferred to a dry distillation apparatus closed

drying-tubes containing phosphoric oxide, and, after 12 hours, distilled directly into a dried burette closed with a drying-tube containing phosphoric oxide. The sample so obtained had $d_4^{18°}$ 0·7909, the value for 100% alcohol given in Landolt-Börnstein's tables being 0·79074 at 18°. The sample therefore contained less than 0·1% of water.

The 0·1*N*-sodium ethoxide solution was prepared by the addition of the calculated quantity of clean dry sodium to the known volume of alcohol in the burette, and 2·5 c.c. of this solution were run directly (avoiding long contact with the air) into about 245 c.c. of ether which had been dried and distilled over sodium. The solution was made up to 250 c.c. with a few c.c. of the sample of anhydrous alcohol obtained above, and was left tightly stoppered in a thermostat at 25° overnight before the first set of velocity measurements was taken.

Values of $[\alpha]_\infty$ *in Alkaline and Acid Catalysis Experiments.*—It will be noticed that the end values obtained in the alkaline catalysis experiments agree amongst themselves, but are very different from

those obtained in acid catalysis. This was shown to be due entirely to the difference in solvents used—ether in the alkaline catalysis and ethyl acetate in the acid catalysis. The final, constant, value of a solution of tetramethyl glucose *p*-toluidide (0·8416 g.) in 100 c.c. of a 0·9*N*-solution of acetic acid in ether was $\alpha = 2{\cdot}60°$, whence $[\alpha]_{5461} = 155°$, in good agreement with the end values obtained for this derivative in the alkaline catalysis experiments, and differing from the value (110°) obtained in a 0·9*N*-solution of acetic acid in ethyl acetate.

The author desires to express his thanks to the Royal Society for a grant with which some of the expense incurred in this investigation has been met.

THE UNIVERSITY, LEEDS. [*Received, May 16th*, 1928.]

NOTES.

The Nature of the Deposit formed during the Electrolysis of Neutral and Alkaline Solutions with an Antimony Cathode. By JULIUS GRANT.

ACCORDING to Weeks and Druce (J., 1925, **127**, 1069) a solid hydride of antimony (Sb_2H_2) is produced when stibine is passed into a concentrated solution of sodium hydroxide, and the black deposit found on the bottom of the cell after the electrolysis of such a solution with an antimony cathode is ascribed to the same reaction. In the course of some earlier investigations (*Trans. Faraday Soc.*, in the press) fifteen of these deposits, produced under widely varying conditions, were examined. They included those produced (i) in the cathode compartment and on the cathode after electrolysis of (*a*) sodium hydroxide solutions (0·05—3*N*) with an antimony cathode, (*b*) solutions containing suspended metallic antimony or its compounds with a lead cathode, and (ii) by reduction of antimony compounds with nascent hydrogen. The anode was platinum and the current densities varied from 1 to 4 amps./cm.^{2}.

The deposits were filtered off, washed free from alkali, and dried as rapidly as possible by alcohol and ether, or by prolonged desiccation, and analysed by the measurement, using a Töpler pump, of the volume of hydrogen from 10 mg. liberated in a vacuum at a bright red heat. The amount of gas obtained varied from 0·01 to 0·25%, and was usually 0·1%. It burnt in a manner similar to hydrogen, but was not otherwise examined.

Since the compound Sb_2H_2 would contain 0·83% of hydrogen,

seems probable that the deposits consisted of metallic antimony in a finely divided state, with small traces of adsorbed hydrogen which is removed only by the effect of heat at a low pressure. Further, the deposits resembled finely powdered pure metallic antimony both in appearance and in chemical properties, whereas those of antimony hydride behave quite differently (Weeks and Druce, *loc. cit.*). The deposits are produced by decomposition of the electrolytic stibine and not by cathodic disintegration, since they are obtained even with lead cathodes, and whereas the yield of stibine (calculated from the sum of that evolved as gas and that decomposed into metal and hydrogen) varies regularly with variations in the conditions of electrolysis, the relative proportions obtained in the form of gas or deposit are dependent only on the structure of the apparatus (Sand, Grant, and Lloyd, J., 1927, 378).—Sir John Cass Technical Institute, London, E.C.3. [*Received, May 16th*, 1928.]

NN'-*Diphenyl-o-phenylenediamine.* By Charles Stanley Gibson and John Dobney Andrew Johnson.

From *o*-aminodiphenylamine and iodobenzene in boiling nitrobenzene solution, Wieland and Müller (*Ber.*, 1913, **46**, 3303) obtained a substance, m. p. 152·5°, which they described as *NN'*-diphenyl-*o*-phenylenediamine, $C_6H_4(NHPh)_2$. Clemo, Perkin, and Robinson (J., 1924, **125**, 1780 : errata, p. 2796) condensed 2'-aminodiphenylamine-6-carboxylic acid with *o*-chlorobenzoic acid and distilled the resulting 2'-*o*-carboxyphenylaminodiphenylamine-6-carboxylic acid ; loss of carbon dioxide then took place and the product melted at 109°. They described this as *NN'*-diphenyl-*o*-phenylenediamine and suggested that the compound obtained by Wieland and Müller was not this substance but the isomeric *o*-aminotriphenylamine, $NH_2{\cdot}C_6H_4{\cdot}NPh_2$. This suggestion is correct.

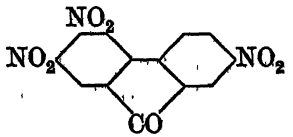
On carrying out the preparation described by Wieland and Müller, the product obtained had m. p. 149—150° and behaved like a primary amine towards nitrous acid. The monoacetyl derivative, prepared by boiling this substance for 15 minutes with an excess of acetyl chloride, had m. p. 131—132° after recrystallisation from aqueous alcohol (Found : N, 9·4. Calc. : N, 9·3%). *o*-Aminotriphenylamine was prepared by the method of Piccard and Brewster (*J. Amer. Chem. Soc.*, 1921, **43**, 2630). This and the corresponding monoacetyl derivative proved to be identical with Wieland and Müller's *NN'*-diphenyl-*o*-phenylenediamine and its monoacetyl derivative respectively. *o*-Nitrotriphenylamine (Piccard and Brewster, *J. Amer. Chem. Soc.*, 1917, **39**, 2006), crystallised from ligroin (b. p. 60—80°), had m. p. 100°.

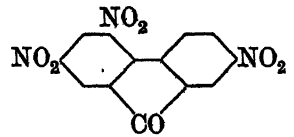
For the purposes of another investigation, we have prepared *NN'*-diphenyl-*o*-phenylenediamine in quantity by the method of Clemo, Perkin, and Robinson and through the kindness of these authors have been able to compare the final and intermediate compounds with original specimens.

In the condensation of *o*-aminodiphenylamine with iodobenzene it is therefore the secondary amino-group which is the more reactive, but in the condensation of 2'-aminodiphenylamine-6-carboxylic acid it is the primary amino-group which reacts. It is suggested that in the latter case the activity of the secondary amino-group is diminished or inhibited by internal salt formation with the adjacent carboxyl group.—Guy's Hospital Medical School (University of London), S.E.1. [*Received, May 15th*, 1928.]

The Action of Disilicon Hexachloride on Ether. By Frederic Stanley Kipping and Reginald Aubrey Thompson.

It has been shown by Kipping and Murray (J., 1927, 2734) that ether reacts with silicon tetrachloride to a slight extent, giving some compound from which alcohol is produced on treatment with aqueous alkali. Disilicon hexachloride seems to behave in a similar manner.





A sample of the hexachloride (5—6 g.), carefully freed from titanium tetrachloride (this vol., p. 1377), was left in contact with [redacted] ether. (The latter had been purified with sodium and by leaving it in contact with disilicon hexachloride during a week; it gave no reaction for alcohol.) Most of the ether was then distilled on the water-bath, excess of sodium hydroxide solution was added to the residue, and 4—5 c.c. of the aqueous solution distilled; the distillate gave with iodine and alkali a distinct precipitate of iodoform. The ether recovered from the first distillation was again mixed with the hexachloride, and the above operations repeated; iodoform was again obtained, and a further experiment with the same ether gave a like result. The quantity of iodoform produced in each experiment was only a few milligrams and was not appreciably increased by gently heating the mixture of the two substances: it seems, therefore, that the interaction is very limited, as in the case of silicon tetrachloride and ether.

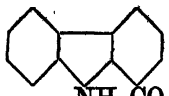
It may be suggested that both the silicon chlorides form with ether additive products, corresponding with the compound $TiCl_4,Et_2O$ (Bedson, J., 1876, 29, 311), and that these decompose at the ordinary temperature, or when they are gently heated, with formation of ethyl chloride and chloroethoxysilicon derivatives which are analogous to Bedson's titanium compounds, [redacted]

A sample of the silicon tetrachloride which had been used by Kipping and Murray in their experiments with ether was proved to have been free from titanium tetrachloride.—UNIVERSITY COLLEGE, NOTTINGHAM. [*Received, June 6th*, 1928.]

2 : 4 : 7-*Trinitrofluorenone.* By FRANK BELL.

THE interest attaching to heavily substituted fluorenones (Bell and Robinson, J., 1927, 1695) directed attention to the statement that fluorenone on nitration yields the 2 : 3 : 7-trinitro-derivative (I) (Schmidt and Bauer, *Ber.*, 1905, **38**, 3758). Apart from the exceptional orientation of this compound, its oxidation to yield 3 : 4-dinitrobenzoic acid called for further examination (for normal method of oxidation of fluorenone derivatives, see Moore and Huntress, *J. Amer. Chem. Soc.*, 1927, **49**, 1324).

(I.)  (II.) 



4-Nitrofluorenone, prepared from 4-nitrophenanthraquinone (Schmidt and Bauer, *ibid.*, p. 3741; Morgan and Thomason, J., 1926, 2695), was nitrated as follows: 1·25 g. in nitric acid (*d* 1·5; 25 c.c.) were warmed on a steam-bath for 2 hours, cooled, and poured into water. The precipitate after several crystallisations from benzene had m. p. 175° (Found: C, 49·5; H, 1·6. $C_{13}H_5O_7N_3$ requires C, 49·5; H, 1·6%). This trinitro-derivative must therefore be 2 : 4 : 7-*trinitrofluorenone* (II).

Fluorenone nitrated by the method of Schmidt and Bauer (*loc. cit.*) gave a product, m. p. 176° after repeated crystallisation from acetic acid or benzene (Found: C, 49·9; H, 1·8%). When mixed with the 2 : 4 : 7-trinitrofluorenone described above, it melted at the same temperature. Oxidation of this trinitro-derivative gave a very small amount of an impure acid, m. p. 165—170°. The m. p. of the purified acid would obviously exceed that of 3 : 4-dinitrobenzoic acid (164°).—BATTERSEA POLYTECHNIC, S.W.11. [*Received, June 8th*, 1928.]

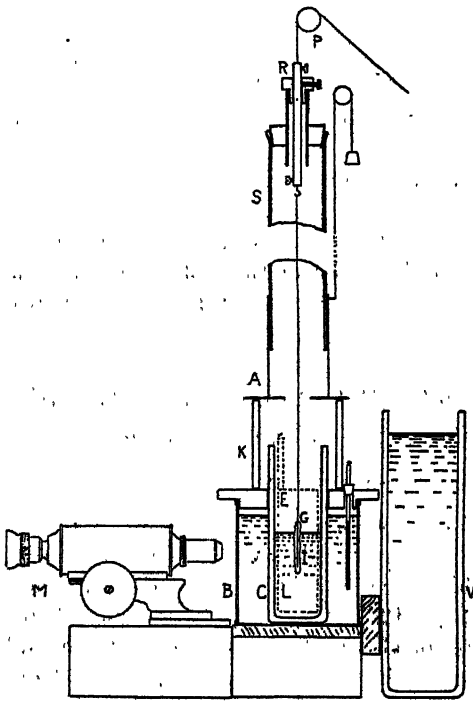
Carbazole-1-carboxylic Acid. By EDWARD FULLER BRISCOE and SYDNEY GLENN PRESTON PLANT.

THE proof, hitherto lacking, that the acid obtained by the action of carbon dioxide on potassium carbazole at 270° (Ciamician and Silber.

Gazzetta, 1882, **12**, 272) or on magnesium 9-carbazyl iodide at 265—270° (Oddo, *ibid.*, 1911, **41**, i, 255) is carbazole-1-carboxylic acid, has now been furnished by boiling a mixture of tetrahydrocarbazole-8-carboxylic acid (Collar and Plant, J., 1926, 808) (12 g.), sulphur (3 g.), and pure quinoline (80 c.c.) under reflux for 12 hours and then pouring it on ice–dilute hydrochloric acid. The sticky product was dissolved in dilute aqueous sodium hydroxide, and the solution was boiled with charcoal, filtered, and acidified with hydrochloric acid. The crude acid was dried and then boiled for 6 hours with methyl-alcoholic hydrogen chloride. The methyl ester, obtained by pouring the solution into dilute ammonia, was distilled under reduced pressure, further purified by crystallisation from aqueous alcohol, and then hydrolysed with methyl-alcoholic sodium hydroxide. After recrystallising twice from toluene–petroleum, the resulting acid was obtained in yellowish plates, m. p. 268—269° (Found: C, 73·8; H, 4·5. Calc.: C, 73·9; H, 4·3%), which did not depress the m. p. (270—271°) of a specimen of carbazole-1-carboxylic acid prepared by the method of Ciamician and Silber.—THE DYSON PERRINS LABORATORY, OXFORD. [*Received, June 22nd*, 1928.]

CCLX.—*The Electrokinetic Potential between the Solid and Liquid States of a Single Substance.*

By FRED FAIRBROTHER and FRANK WORMWELL.



THE first observation of the production of an electric charge by the friction of a liquid against the same substance in the solid state appears to have been made in 1843 by Faraday ("Experimental Researches," 2, No. 2131, p. 122), who, in the course of his researches on the production of electricity by escaping steam and air, allowed "undried common air" to issue under pressure from an orifice and flow along a cone of wood or metal which thereby became electrified, acquiring a negative charge. He showed that this electrification was due to the "particles of water suddenly condensed from the expanding and cooled air rubbing against the metal or wood" and that dry air produced no such electrification. When, however, undried air was let out against *ice*, it rendered the ice positive in contrast to the negative charge given to wood or metal.

Schmidt (*Wied. Ann.*, 1886, **28**, 550), on account of its bearing on the production of storm electricity, examined closely by different methods the electrification produced by the friction of water against ice. He allowed a jet of water from the ordinary tap [illegible]

a plate covered with ice, and also forced water through a capillary formed along the axis of a rod of ice. By both methods he found the water to be negatively charged, thus confirming the results of Faraday.

The phenomenon seemed worthy of attention on account of its bearing on the structure of the interface between a solid and the melt from which it is crystallising or into which it is passing, as well as of its bearing on the general question of interfacial potentials. The sign of the electrokinetic potential of ice against water has therefore been examined by another method which has also permitted of the experiments being extended to other substances, with the result that, not only have the experiments of Faraday and Sohncke been confirmed, but in all cases where an electrokinetic potential was detected the solid was found to be positively charged relatively to the liquid.

FIG. 1.

EXPERIMENTAL.

Modifications of the stream potential method of Sohncke were tried but were discontinued on account both of the experimental difficulties and of the uncertainty of interpretation of experiments which included the friction of the liquids against the electrodes. Electroendosmosis measurements were also attempted with little success. The chief difficulty here lay in the preparation of suitable capillaries or diaphragms, and in their retention for a time sufficiently long to permit of the determination of the direction of electroendosmosis. The observations now recorded were made by a cataphoresis method. In essentials the method is somewhat similar to that used by Kleeman and Fredrickson (*Physical Rev.*, 1923, **22**, 134) for the determination of the sign of the electrocapillary charge on thin metallic wires in water.

The apparatus employed is shown in Fig. 1. A rod or "icicle" I of the solid, formed round a thin glass rod G, was suspended at the end of a single unspun silk fibre, 141 cm. in length, in the corresponding liquid L. The glass rod was 3 cm. in length and 0·3 mm. in diameter. About three-quarters of the length of the rod of solid was immersed in the liquid, which was contained in the parallel-sided glass observation cell, C. This cell with its contents was surrounded by a water-jacket, B, with glass windows and a tightly fitting lid, whereby the liquid could be kept at a suitable temperature. With the present apparatus it was impracticable to keep the temperature at the triple point where solid, liquid, and vapour are in equilibrium. Temperatures slightly above or slightly below the melting point were therefore used, so that the rod of solid gradually melted away during the observations or gradually grew in size. This continual formation of a fresh interface also reduced the probability of erroneous observations conceivably due to the possible deposition of atmospheric moisture on the rod of solid during its formation. An electric field of 400 volts, giving about 50 or 100 volts per cm. according to the position of the electrodes, was applied through the electrodes, E, in a direction perpendicular to the plane of the paper. These electrodes in the preliminary experiments were of copper, but were later replaced by platinum electrodes, consisting of platinum foil stretched over rectangular frames of glass rod, and "soldered" in position by small [illegible] fusible lead glass. The suggestion that the observed effect might be due in part to the electrostatic attraction of such part of the suspended system as lay above the surface of the liquid but within the electric field was carefully examined and eliminated by control experiments. The lateral movement of the rod of solid in the electric field was followed by means of the microscope, M, which was provided with an ocular micrometer. The suspended system was protected from draughts by the glass tube, S, over the lower end of which passed an earthed brass tube with a wide flange, A. The latter fitted on to the top of a light wooden box, K, formed on the top of the water-jacket lid. Slots were cut in the sides of this box to allow of the passage of the ends of the electrodes. A large glass cell W, filled with acidified ferrous sulphate solution, minimised the passage of heat from the lamp used for illumination. The rod of solid was formed as follows. A glass tube, about 4 cm. long, 2 mm. internal diameter, and closed at one end, was cleaned with chromic–sulphuric acid, washed with distilled water, and dried at 130° before each experiment. The tube was then filled with the liquid under investigation and arranged in the position later to be occupied by the rod of solid [illegible]

lowered into the liquid. For this purpose the observation cell with its contents and jacket was removed and the suspended system raised and lowered by a small winch operating a cord passing over a small pulley P. The weight necessary to the system was provided by a brass rod R working in a brass collar. The liquid was then allowed to solidify. For most purposes, in particular with substances melting below 30°, it was found advantageous to surround the small tube with dry, solid carbon dioxide. This quickened solidification and greatly facilitated the arrangement of the glass rod G in a central position in the "icicle." With substances melting above 30°, the final results were the same whether or not solid carbon dioxide was used. When the liquid was frozen, the glass tube was gently warmed with the fingers and the solid next to the glass melted sufficiently to allow the withdrawal of the remaining rod of solid. (In the case of substances melting above 30° this operation was usually carried out by immersing the tube in a small quantity of the warm liquid.) The observation cell was then replaced, the rod of solid lowered into the liquid, and the cover A placed in position. Usually about 15 seconds elapsed between the removal of the rod from the mould and its focussing in the field of the microscope. By means of a reversing switch, observations were taken with the electric field in both directions. Only observations which showed a definite reversal of direction of movement with reversal of the applied potential were taken as indicative of the electrokinetic charge. In all such cases the solid was positively charged whether melting in a liquid a little warmer than itself or growing in a supercooled liquid. In no case was a reversible movement observed in a direction indicating that the solid had a negative charge. On the other hand, in every case, except in benzene and in *o*-chlorophenol, the (cleaned) glass rod alone in the liquid moved as if negatively charged, giving reversible deflexions usually greater than those of the rod of solid in the same liquid.

The width of the cell and the diameter of the rod of solid substance were such as to render negligible the effect of electroendosmosis along the walls of the observation cell. In any case this would tend to produce an effect in a direction opposite to that actually observed.

The choice of substances for examination was somewhat restricted. With the present form of apparatus it was inconvenient to use substances melting below 0° or above 40°. In the second place, it was very desirable to use substances which formed coherent crystalline rods. Several substances which were tried gave only soft, non-coherent masses or very viscous liquids. In all the observations now recorded, even with the rapid cooling employed, it could be observed that the icicle was a compact *crystalline* mass, except in

the case of ice, which had the usual glassy form. The materials other than water were obtained initially in a fairly pure condition and were carefully fractionated after having been dried with the appropriate reagents, phosphoric oxide being used where permissible. No attempt, however, was made at intensive drying.

In the following table are given the substances examined, together with the typical deflexions from the mean position in terms of the divisions of the eyepiece micrometer, ten such divisions corresponding to an actual movement of 0·5 mm. In all cases, except with pure benzene and *o*-chlorophenol, for which no movement could be detected,* the sign of the charge on the solid was *positive*.

The deflexion is greatest in the cases of water and acetophenone, and non-existent for *pure* benzene. It seems justifiable to conclude that it is only with "polar" compounds that the effect is observable, and that the more polar the substance is, the greater is the deflexion likely to be.

The movement in the case of acetophenone may seem surprisingly great compared with that of the other substances examined. The solid phase, however, owing to the manner of crystallisation when the rod was allowed to grow, had generally a very large surface compared with its weight. The positive charge on the solid acetophenone was also confirmed by the following observations. When slowly crystallising from a slightly super-cooled liquid, acetophenone forms large, very thin plates; when solidification was allowed to proceed in an electric field, it was clearly seen that more crystallisation occurred round the negative electrode than

* Another sample of benzene, which had not been completely freed from thiophen, gave indications of a positive charge on the solid state.

round the positive electrode. Also, plates of the solid lying in the surface of the liquid could occasionally be seen to move towards the negative electrode, reversing their movement when the direction of the applied potential was reversed.

In the case of *p*-cresol and *o*-chloronitrobenzene, too, small crystals in the interior of the liquid were seen to move towards the negative electrode.

The present data do not permit of any quantitative estimation of the charge on the solid, but an idea of the magnitude of the electrification may be gained from the fact that on the application of a field of 50 volts/cm., the small glass rod G alone, when suspended in distilled water, moved through 21 divisions of the eyepiece scale, having a negative charge. The electrification between the solid and liquid states of a substance is thus generally much less than the electrocapillary charge of glass in distilled water.

Discussion.

Some uncertainty exists regarding the change of dielectric constant on passing from the liquid to the solid state at the moment of solidification. There is considerable evidence from the results of several authors to show that at a temperature several degrees below the melting point, the dielectric constant of many solids is much less than that of the corresponding liquid, particularly when the latter is large, but that, as the melting point is approached, the dielectric constant of the solid becomes dependent to a greater extent upon the frequency of the measuring current, and may at low frequencies approach that of the liquid state. At the lower temperatures, the degree of freedom of the permanent dipoles in the solid is insufficient to permit of their contributing much to the dielectric constant.

If we regard the dielectric constant of the solid as being greater than that of the liquid during a change of state, then the observations now recorded are in contradiction to the rule formulated by Coehn (*Wied. Ann.*, 1898, **64**, 217), according to which the phase with the higher dielectric constant should become positively charged. Coehn (*loc. cit.*) realised this apparent anomaly in the case of ice and water, and suggested in explanation that probably it was not a matter of water rubbing against ice, but of water at a higher temperature rubbing against cooler water which was adhering to the ice. It seems very improbable, however, that the temperature coefficient of the dielectric constant of liquid water could account for such a degree of electrification as exists.

On the other hand, some recent work by Errera (*Trans. Faraday Soc.*, 1928, **24**, 162) indicates that in the neighbourhood of the melting point, the dielectric constant of a polar substance in the

solid state may, when measured at low frequencies, be even higher than in the liquid state. His figures for acetic acid show a sharp rise to a dielectric constant of 18 at a frequency of 680 cycles, in the neighbourhood of the solidification point, the dielectric constant of liquid acetic acid measured at the same frequency being about 6. Errera suggests in explanation of this rise that there is a formation at the moment of solidification of structures in a state of colloidal association, and he assumes further that "the arrangement of the molecular dipoles inside the colloidal structures is such that these last have a high electric moment, higher indeed than that of the molecular dipoles." If this phenomenon is general with polar substances, whatever its cause, then the sign of the electrification between the liquid and solid states of the same substance follows the general rule of contact electrification between different dielectrics as given by Coehn (*loc. cit.*).

It would appear, however, to be a general rule that, where there is an electrokinetic potential between the liquid and solid states, the solid is positively charged relative to the liquid.

THE UNIVERSITY, MANCHESTER. [*Received, May 7th*, 1928.]

CCLXI.—*Studies of Valency. Part X. Electrometric Titration of Vernon's α- and β-Dimethyltelluronium Bases.*

By FRANK LATHE GILBERT and THOMAS MARTIN LOWRY.

IN a previous paper of this series (this vol., p. 307), it was shown that the isomeric bases from which the α- and β-dimethyltelluronium dihalides are derived are of the same order of strength as ammonia. The hydroxy-halides, on the other hand, although readily convertible into normal salts, are acid rather than basic in character, since they are approximately neutral towards indicators (such as methyl-orange and methyl-red) which give an end-point a little on the acid side of neutrality. This result can be interpreted more readily by saying that the kation of the hydroxy-halide $[TeMe_2OH]^+Cl^-$ is more ready to lose a hydrogen

scheme 1, which leaves the octet intact, than to lose a second *hydroxyl ion*, as in scheme 2, in which the octet is converted into a sextet.

1. $[TeMe_2OH]^+ \rightleftharpoons [TeMe_2O] + H^+$;

compare $[NH_4]^+ \rightleftharpoons NH_3 + H^+$.

2. $[TeMe_2OH]^+ \rightleftharpoons [TeMe_2]^{++} + OH^-$.

An anomaly was encountered, however, in the fact that, whereas the molecular conductivities of the α-base varied from 1·9 to 3·4 ($v = 16$—256), those of the β-base varied only from 33 to 37 ($v = 32$—512), in spite of the much larger absolute values of the conductivities. By way of contrast, it may be recalled that the conductivity of diethylmercury hydroxide varies from 1·2 to 1·9 and that of hydrazine from 1·7 to 5·5, in the range $v = 16$—256, whilst the conductivity of methylamine varies from 21 to 70, that of dimethylamine from 24 to 81, and that of diethylamine from 31 to 93 in the same range. An electrometric investigation was therefore undertaken in order to compare the relative strengths of the two bases by the various electrical methods now available.

Conductivity of Bases.—Since the bases cannot be purified by crystallisation from solution, it was necessary to adopt other methods for checking their purity. The high conductivity of the β-base and the small increment on dilution might have been due to the presence of (i) undecomposed halide, (ii) silver compounds derived from the silver oxide used in the preparation of the bases, or (iii) trimethyltelluronium compounds formed by a molecular rearrangement of the β-base which is known to take place under the influence of alkalis. Since the β-base had been prepared by evaporating a solution of the α-base to dryness under reduced pressure, it was unlikely that its high conductivity could be due to undecomposed halide, for this must have been present also as an impurity in the α-base; and the presence, in solutions of the β-base, of dissolved silver compounds which were not also present in the α-base was even less probable, since they would be likely to be removed during the conversion of the α- into the β-base by evaporation. The possible presence of trimethyltelluronium salts was eliminated by preparing a solution of the β-base from the β-dibromide, in just the same way as the α-base was prepared from the α-salts.

The molecular conductivities of seven solutions of the two bases are in Table I. The values are rather less concordant than those of compounds which can be purified by ordinary methods; but the equivalent conductivities of the β-base were found to be consistently greater by about 30 units than those of the α-base, and to vary over the same small range on dilution. The most trustworthy values were obtained by preparing the β-base from a β-salt instead of

directly from the α-base, and their validity was confirmed by their close agreement with the conductivities of a sample which Vernon had obtained in a solid form by evaporating a solution of the base to dryness in a tube which was then sealed. The close concordance of these additional data shows that the results recorded in the previous paper were substantially correct, even although they may not be easy to explain.

* This solution was evaporated *twice* to dryness, since a solution which had been evaporated only once gave conductivities about 2 units less than those recorded above.

† $\Lambda^{25°}$ = 6·0 at v = 1024.

Conductivity of Carbonates.—Since it appeared possible that some of the variations of conductivity might be due to the conversion of the bases into carbonates by absorption of atmospheric carbon dioxide, experiments were made to determine the magnitude of this effect, and the results are in Table II. The solutions of the

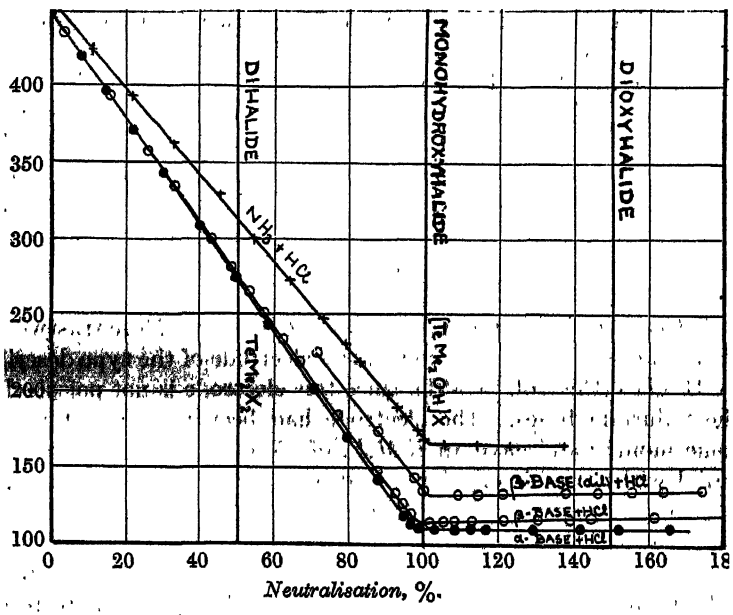
two bases were standardised by titration in the presence of bromophenol-blue. Since the molecular conductivity of a saturated solution of carbon dioxide (M/30·3) is $\Lambda^{25°}$ = 1·3 (approx.), the molecular conductivities at M/32 would be increased by 1·3 × 32/30·3 = 1·4 on saturation with carbon dioxide, if no chemical combination occurred. In general, the conductivity of a base

decreased by the presence of carbon dioxide, since the bicarbonate ion is much less mobile than the hydroxyl ion; but in the present instance the bases are so weak that this effect was reversed, and the conductivity was increased in each case to about 40 units. The carbonates are, however, so unstable, and their formation is so incomplete, that the maximum conductivity of the carbonated solutions was only about one-third of that of a typical binary electrolyte. Since, then, only about one-third of the base is present as carbonate, the carbon dioxide must also be held only reversibly; it was therefore removed completely by a current of purified air, the conductivities of the solutions falling again to values similar to those recorded in Table I.

$$TeMe_2(OH)_2 + CO_2 \underset{2}{\overset{1}{\rightleftharpoons}} [TeMe_2OH]^+ + HCO_3^-$$

It will be seen that the two bases are practically equal in their power of holding carbon dioxide. This result is not in agreement with the simple (but incorrect) deduction from the conductivities, that the β-base is perhaps 10 times stronger than the α-base; but it is in harmony with the results of the potentiometric titrations described below, which show that there is an intermediate stage of neutralisation within which the two bases are of nearly equal strength.

Conductivity Titrations.—In doing a conductivity titration it is usual to add a mineral acid to a solution of the base, and to observe the decrease of conductivity which takes place as the hydroxyl ions are replaced by chloride or bromide ions. In the case of the dimethyltelluronium bases this method cannot be used, since the conductivity undergoes only an insignificant increase as the feebly ionised base is converted into a more strongly ionised salt. A large decrease of conductivity was produced, however, when the α- or β-base was added to a mineral acid, since the mobile hydrogen ions of the acid were then replaced by the much more sluggish $[TeMe_2OH]^+$ ions of the hydroxy-salt.



The titration curves are reproduced in Fig. 1, together with a curve for the neutralisation of $N/10$-hydrochloric acid by $N/10$-ammonia. The addition of the α-base (about $N/7$) to $N/10$-hydrochloric acid produced a continuous decrease of equivalent conductivity up to 100% neutralisation, after which the conductivity remained almost constant, since further additions of the weak base did not contribute substantially to the conductivity of the solution. The neutralisation curve shows a well-defined break, corresponding to the formation of the hydroxy-halide [α-$TeMe_2OH$]Cl; but no discontinuity at all can be seen at the composition $TeMe_2Cl_2$, which would be represented by the addition of *half* a molecular

proportion of the base to a molecule of the acid; and in the same way, no break was observed at points corresponding in composition to substances more basic than the hydroxy-halide.

The β-base (about $N/11$) gave a neutralisation curve of the same form as that of the α-base, with a well-defined break at the composition [β-$TeMe_2OH$]Cl, but no perceptible change of direction at the composition of the normal salt. In this case the specific conductivity was increased by adding an excess of the base, which has a substantial conductivity of its own; but no further discontinuity was observed in these more basic solutions. A duplicate deter-

FIG. 1.

Conductivity titrations.

Neutralisation, %.

mination with the β-base gave slightly higher molecular conductivities during neutralisation (perhaps because the acid was slightly stronger), but the remaining data agreed so closely with the earlier values that they could not be represented by a separate curve. On the other hand, a more dilute solution ($N/110$ approx.) gave higher equivalent conductivities throughout, the value at the neutral point being $\Lambda^{25°} = 116$ (approx.) at $N/176$ as compared with 108 (approx.) at $N/29$.

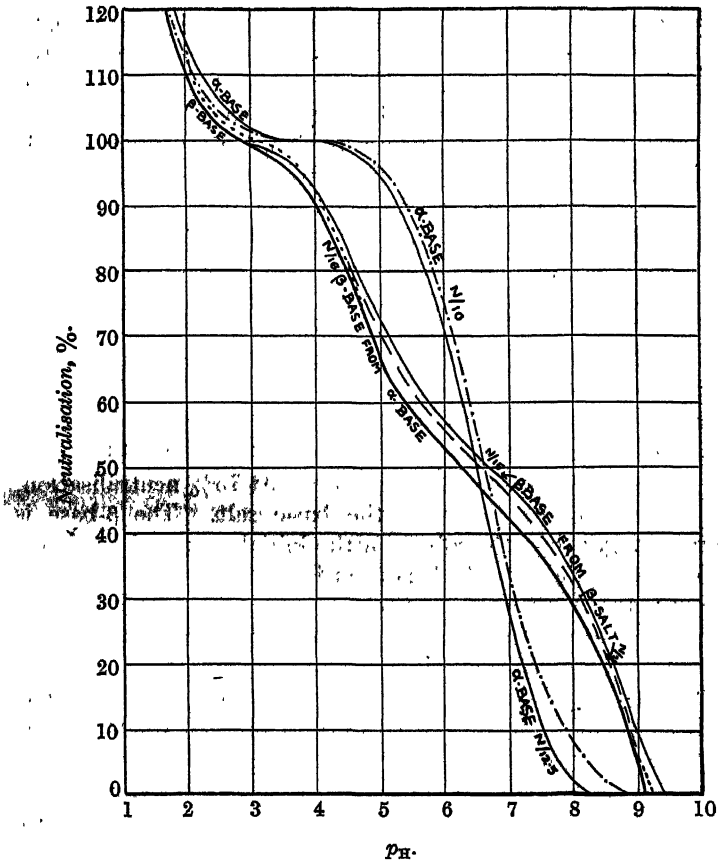
Potentiometric Titrations with a Hydrogen Electrode.—α-Base. For these titrations, 20 c.c. of an $N/10$-solution of the α-base, which had been standardised by titration with methyl-orange as indicator,

were neutralised with 0·962*N*-hydrobromic or 0·198*N*-hydrochloric acid. The results were not very trustworthy, since the α-base poisoned the hydrogen electrode, giving rise to a progressive decrease of *E.M.F.* with time. An approximate result, obtained by passing a rapid stream of purified hydrogen over the electrode, showed, however, that equivalence was reached at the composition $TeMe_2(OH)Br$, and that there was no second inflexion at the point represented by $TeMe_2Br_2$.

β-*Base.* Similar experiments with the β-base gave two inflexions, one at 100%, corresponding to the formation of the hydroxy-halide [β-$TeMe_2OH$]Cl, and the other (much less sharply defined) at about 50% neutralisation, corresponding to the formation of a basic salt containing 2 mols. of the base to 1 mol. of acid. A white precipitate appeared in every case at about 75% neutralisation, reached a maximum, and then redissolved sharply at 100% neutralisation. A small quantity of the precipitate formed during the titration of the β-base with hydrobromic acid was collected, dried, and weighed. It was dissolved in water and acidified with nitric acid,* and silver nitrate added (0·0152 gram gave 0·0039 gram AgBr: Br = 10·9. $TeMe_2Br_2$,7$TeMe_2O$ requires Br, 10·5%). The precipitate, although collected from a nearly neutral solution, is therefore far more basic than the crystalline dioxy-iodide which Vernon prepared from the α-base.

Potentiometric Titrations with a Glass Electrode.—More trustworthy results were obtained by using a glass electrode of the type described by Hughes (this vol., p. 491), since this electrode is not poisoned by the tellurium bases. The electrode had been in constant use for some months and gave an *E.M.F.* of 55 millivolts per p_H, as compared with 58 millivolts for a hydrogen electrode. The titrations were made at atmospheric temperature (about 16°). The curves for six titrations are reproduced in Fig. 2.

α-*Base.* A solution of the α-base was standardised by titration with bromophenol-blue as indicator, since the approximate results obtained with the hydrogen electrode showed that the end-point of the titration would be given more correctly with this indicator than with methyl-orange. An *N*/10-solution (20 c.c.) was then titrated with *N*-hydrochloric acid. The potentiometric curve was confirmed by a duplicate determination in which the strength of the base was *N*/12·5. The foot of the curve was at 8·2 instead of 8·9; but the two curves then converged, and became coincident as the neutral point was approached.



The curves have the characteristic form for a weak base, with

* No precipitate of dihalide was formed, such as always appears when acid is added to the α-hydroxy-salts.

a single inflexion at the composition of the hydroxy-halide [α-$TeMe_2OH$]Cl. The "equivalence point" is at $p_H = 3{\cdot}9$, and the inflexion is quite well defined, since $p_H = 4{\cdot}8$ at 98% and 3·0 at 102% neutralisation. Half-neutralisation occurs at $p_H = 6{\cdot}5$, from which it follows that $-\log K_b = 7{\cdot}5$. These results confirm the conclusion that $N/10$-solutions of the base can be titrated with

FIG. 2.

Potentiometric titrations.

methyl-orange ($p_H = 2{\cdot}9$—$4{\cdot}0$), but would give a more trustworthy end-point with bromophenol-blue ($p_H = 3{\cdot}0$—$4{\cdot}6$); for weaker solutions, a more acid indicator should be used.

β-Base. Four curves for the β-base are shown in Fig. 2. The full curve is for an $N/16$-solution freshly prepared from the α-base, and it agrees closely with the dotted curve for an $N/32$-solution of Vernon's crystalline sample of the β-base (compare p. 1993).

solutions, $N/15{\cdot}4$ and $N/21$, prepared from the β-dibromide, were slightly more alkaline during the first half of the titration, but then the curves converged upon and became identical with the two curves for samples prepared from the α-base.

All the curves show an inflexion at the composition of the hydroxy-halide, [β-$TeMe_2OH$]Cl, together with a weaker inflexion at about 50% neutralisation; a white precipitate was also seen again between 75 and 100% neutralisation. The "equivalence point" is at $p_H = 3{\cdot}0$, but the inflexion is less well defined than in the case of the α-base, since $p_H = 3{\cdot}4$ at 98% and $2{\cdot}6$ at 102% neutralisation, giving a range of only $0{\cdot}8$ in place of $1{\cdot}8$ units; the end-point, even with the most suitable indicator (*e.g.*, methyl-orange), is therefore not likely to be very sharp.

The second inflexion, at 50% neutralisation, indicates that a basic salt is formed in solution at a composition corresponding to the formula $2TeMe_2O,HCl$; but, since the inflexion occurs at $p_H = 6{\cdot}5$, it follows that this basic salt is acid rather than alkaline in its reaction, and that (like the hydroxy-halide) it is therefore more ready to part with a hydrogen than with a hydroxyl ion.

The formation of this basic salt makes it impossible to deduce the strength of the base in the usual way from the p_H at half-neutralisation. Since, however, $p_H = 8{\cdot}3$ at 25% neutralisation, the strength of the β-base may be deduced from the relation $-\log K_b = \log(1-x)/x + p_{K_w} - p_H$, where x is the degree of neutralisation, whence $-\log K_b = 6{\cdot}2$ for the free base. At 75% neutralisation, $p_H = 4{\cdot}8$ and $-\log K_b = 8{\cdot}7$ for the basic salt. The β-base is therefore stronger than the α-base in the initial stages of neutralisation, but the basic salt which is then formed is not so strong as the α-base; the weaker α-base thus gives a sharper end-point at 100% neutralisation, and yields an α-hydroxy-halide which is more nearly neutral than the isomeric β-hydroxy-halide.

Hydrolysis of Basic and Normal Salts.—From the potentiometric curves it is possible to deduce a series of theoretical values for the percentage hydrolysis of the hydroxy-salts as follows:

	$-\log K_b$.	K_b.	Hydrolysis at $v=100$.	Hydrolysis at $v=1000$.
[α-$TeMe_2OH$]Cl to free base ...	7·5	$3{\cdot}1\times10^{-8}$	0·6%	2%
[β-$TeMe_2OH$]Cl to basic salt ...	8·7	2×10^{-9}	2%	7%

The normal salts, on the other hand, are shown to be almost completely hydrolysed in water; but the percentage of unhydrolysed salt can be deduced from the fact that a saturated solution of the α-di-iodide in cold water, which has a concentration of $N/235$, shows an absorption band with a maximum extinction coefficient, $\log\varepsilon = 2{\cdot}4$ at 3340 Å.U. Since a dry *alcoholic* solution of the

di-iodide gives a maximum extinction coefficient, $\log \varepsilon = 3{\cdot}7$, at a slightly longer wave-length, we can (by ignoring the influence of the solvent) calculate that the *aqueous* solution contains only about 1/20 of its nominal content of iodide, or that the α-di-iodide is hydrolysed, to the extent of about 95%, to the hydroxy-iodide and hydriodic acid.

Basic Salts.—The potentiometric titrations of solutions of the β-base provide conclusive evidence of the formation of a basic salt, in which the acid and base are united in the ratio $2TeMe_2O,HCl$, to form (in Vernon's nomenclature) a "β-trioxychloride," since it could also be derived from three molecules of the base and one molecule of the normal salt. On the other hand, the potentiometric curves for the α-base agree with the conductivity titrations in giving no indications of the existence in solution of any salt but the hydroxy-halide. This result is remarkable in view of the fact that Vernon prepared from the α-base two basic salts which he formulated as follows:

(i) Di-iodotetramethylditelluronium oxide, $O(TeMe_2I)_2$.

(ii) Di-iodohexamethyltritelluronium dioxide, $TeMe_2(O{\cdot}TeMe_2I)_2$.

The "α-dioxyiodide" (ii) separates from water in large transparent plates, with about $\frac{1}{2}H_2O$ of crystallisation; but it can also be obtained in anhydrous, colourless scales, *e.g.*, from concentrated ammonia, and can be prepared quite readily in this form by grinding the solid α-di-iodide with concentrated ammonia and then recrystallising it from aqueous ammonia. The "α-monoxyiodide" (i) separates as a bright yellow powder when an aqueous solution of the "dioxyiodide" is boiled for some minutes and then cooled quickly.

Vernon states that the melting point of the monoxyiodide "fluctuates between 112° and 125°" and that "repeated analyses have shown considerable variations in both carbon and hydrogen." Our own experiments have shown that the yellow powder, which generally melts at about 116°, is stable if dried immediately; but, if it is allowed to stand in contact with water (or even in moist air) for some hours, it changes to a colourless form, which melts at 122°. Since it appeared likely that the pure monoxyiodide would be colourless like the dioxyiodide, we thought at first that the coloured form might be an aquo-compound, but this conclusion could not be confirmed by analysis. For instance, no difference could be detected between the halogen content of the yellow and the colourless form of the salt; and no change in weight was produced when a weighed quantity of the coloured powder was transformed to the colourless form by the action of water, and then dried. The conversion of the unstable into the stable form is therefore not accompanied by any important change of composition.

may perhaps be formulated as depending on an interaction of the type $TeMe_2O + TeMe_2I_2 \rightleftharpoons I[TeMe_2{\cdot}O{\cdot}TeMe_2]I$, whereby a trace of coloured di-iodide is converted into a colourless oxyiodide. This change may perhaps be reversible in solution, but it proceeds to completion in one direction under the conditions of our experiments, and we have not yet been able to reproduce the yellow form from the stable colourless form by any direct process.

TABLE III.

Equivalent Conductivities of Basic Iodides at 25°.

	v = 128.	256.	512.	1024.	2048.
α-Monoxyiodide, $\frac{1}{2}(TeMe_2)_2OI_2$	94	98	100·5	102	105
α-Dioxyiodide, $\frac{1}{2}(TeMe_2)_2O_2I_2$	98	101	104	105	107

The equivalent conductivities of aqueous solutions of the monoxyiodide and dioxyiodide, reckoned in each case on the calculated concentration of iodine, are set out in Table III. The conductivities differ only by a small amount, which corresponds roughly with the conductivity of the extra molecule of base in the latter compound. The values for the monoxyiodide are about six units lower than those recorded (this vol., p. 314) for solutions of the α-hydroxyiodide made up by titration; but this discrepancy does not appear to have any theoretical significance. The basic salts are indeed disappointing compounds from the stoicheiometric point of view, and cannot be used with safety unless previously analysed. Thus, the yellow monoxyiodide is obviously a mixed product, and the anhydrous form of the dioxyiodide is prepared by a method which does not admit of any sharp separation from the less basic monoxyiodide. Finally, the crystalline form of the dioxyiodide contains "about half a molecule of water," which makes its chemical constitution difficult to interpret, and even throws doubt on the empirical composition of any individual sample which has not been analysed. That these doubts are well founded is shown by the fact that an equimolecular mixture of the di-iodide with the dioxyiodide gave an *i*-factor of 2·2 in a freezing-point determination, and equivalent conductivities ranging up to $\Lambda^{25°} = 140$ at $v = 2048$ litres; which we can only interpret on the supposition that the mixture was so deficient in base that it was "extensively hydrolysed" in solution, just as Vernon reported in the case of the monoxyiodide.

Freezing Points.—In addition to individual determinations of the freezing points of the α-monoxy- and dioxy-iodides, several series of measurements were made of the freezing points of solutions of the α- and β-bases during progressive neutralisation. In the earlier

series, the bases were neutralised with hydriodic acid; but, as these measurements were complicated by the separation of precipitates, they were repeated with hydrochloric acid, and only the β-base then gave a transient white precipitate. The data are set out in Tables IV and V.

* A white precipitate appeared and disappeared between these limits.

† The separation of a permanent red precipitate of the di-iodide was followed by an abrupt rise of freezing point.

The freezing-point data confirm the conclusion that the free bases are dissociated only to a small extent in solution, the *i*-factor for both bases being about 1·1. On the other hand, the freezing points indicate that the hydroxy-halides are dissociated almost completely, the *i*-factor recorded for the α-hydroxy-chloride

duplicate determinations being 1·79 and 1·73, whilst that for the β-hydroxy-chloride rose to 1·95 and 1·98 (corrected values, 1·90 and 1·84) in solutions from which a transient slight precipitate had been cleared by the addition of 5 and 14% excess of acid respectively. The lower values recorded for the α-hydroxy-chloride may be due to a partial formation, by loss of water, of a monoxy-chloride, which would give a maximum value $i = 1·5$ (compare footnote, this vol., p. 319).

The freezing-point depressions for the iodide solutions are rendered uncertain by the separation of insoluble basic iodides; but the values of the *i*-factor, 1·34 and 1·31, for solutions corresponding in composition with Vernon's α-dioxyiodide, are in close agreement with these values, 1·38, 1·37, and 1·34, for more dilute solutions (0·024—0·006*M*) of the crystalline salt, although they are rather lower than the factors 1·55 and 1·57 calculated from two determinations of molecular weight by Vernon (J., 1921, **119**, 693). These values, which have been reckoned on the concentration of the base,

in the solutions, are compatible with an almost complete dissociation of the α-dioxyiodide into α-hydroxy-iodide ($i = 1{\cdot}7$) and α-base ($i = 1{\cdot}1$), which would give an i-factor of 1·5.

Our own measurements of the freezing-point depression of a solution of the α-monoxyiodide lead to values, $M = 145$, $i = 2{\cdot}04$, which are in close agreement with the corresponding figures, $M = 143$, $i = 2{\cdot}07$, deduced from Vernon's measurements (J., 1921, **119**, 693); but, since they were made with the unstable yellow form, which is "extensively hydrolysed" by water (Vernon, *loc. cit.*), we do not regard them as trustworthy, and attach no importance to the fact that they are slightly in excess of the maximum theoretical value for complete hydrolysis of the oxyiodide, and complete ionisation of the resulting hydroxy-iodide. On the other hand, the i-factors for solutions prepared by adding hydriodic acid to the free base are too low, as a result of precipitation of insoluble products from the solution. The most trustworthy value, therefore, was obtained by dissolving the colourless oxyiodide (m. p. 122°) to a dilute solution, of concentration 0·0254N, which gave an i-factor 1·82, in good agreement with the values given by the soluble hydroxy-chlorides.

The i-factor for the β-base at 50% neutralisation is about 1·4 for each molecule of base, or 2·8 for a salt of the composition $2TeMe_2O,HCl$.

The following notes are made in reference to the products which separate from solution at different stages of neutralisation of the two bases by hydriodic acid.

α-Base. At 67% neutralisation (dioxyiodide) the solution first deposits the less soluble monoxyiodide, and then gives crystals of the hydrated dioxyiodide. The precipitate seen at about 80% neutralisation consists entirely of the monoxyiodide, but at 100% neutralisation the solution deposits both the monoxyiodide and the di-iodide.

β-Base. At 50% neutralisation (trioxyiodide) the solution slowly deposits a brown precipitate with no definite melting point; this precipitate is probably analogous to the basic bromide which is formed during the potentiometric titration of the β-base. At 67% neutralisation (dioxyiodide) the separation of the brown precipitate leaves a colourless solution from which the β-di-iodide is obtained. At 100% neutralisation, the normal product would be either a hydroxy-iodide, or a monoxyiodide formed from it by loss of water; actually, however, the solution deposits the β-di-iodide, leaving behind an alkaline solution of the base.

Summary.

(*a*) The molecular conductivity of the α-base at 25° varies from 3 to 6, and that of the β-base from 31 to 36, in the range from $v = 32$—512. The molecular conductivities are increased to about 40 (at $v = 32$) by saturation with carbon dioxide, but are reduced to normal values by passing a current of purified air through the solutions.

(*b*) Conductivity titrations of the bases show a break at the composition of the hydroxy-halide, but give no indication of the presence in the solutions either of the normal salt or of any more basic compound than the hydroxy-halide.

(*c*) Potentiometric titrations of the α-base with a glass electrode show the typical behaviour of a weak base, forming a nearly neutral hydroxy-salt; but they give no indication of the presence in solution of the dioxyiodide which Vernon prepared in a crystalline form. The curve for the β-base, on the other hand, shows an inflexion at about 50% neutralisation, corresponding with the formation of a basic salt of the composition $2TeMe_2O,HCl$, which has not been obtained in the free state.

We are indebted to the Department of Scientific and Industrial Research for a maintenance grant to one of us (F. L. G.) during the period within which the research now described was carried out.

CCLXII.—*Syntheses of Cyclic Compounds. Part III. The Reduction of Some Unsaturated Cyano-esters by Moist Aluminium Amalgam. A New Synthesis of Mono-substituted Malonic Acids and of ββB′β′-Tetramethyladipic Acid. Further Evidence for the Multiplanar Configuration of the* cyclo*Heptane Ring.*

By ISRAEL VOGEL.

In previous communications (J., 1927, 1985; this vol., p. 1013) it has been shown that whereas ethyl ethylidenemalonate (I) on reduction with moist aluminium amalgam yields almost exclusively the bimolecular compound (II), ethyl benzylidenemalonate (III) yields a mixture of the trimolecular compound (IV) and the bimolecular compound (V) in the proportion of approximately 2 to 1, a result which is obviously due to the presence of the phenyl group (compare Haerdi and Thorpe, J., 1925, 127, 1237). It was clearly

desirable to study the corresponding *gem*-dimethyl, *cyclo*pentane, and *cyclo*hexane compounds in order to obtain some further inform-

(I.) $CHMe{:}C(CO_2Et)_2$ $\quad$ $\begin{matrix}CHMe\cdot CH(CO_2Et)_2\\ CHMe\cdot CH(CO_2Et)_2\end{matrix}$ (II.)

(III.) $CHPh{:}C(CO_2Et)_2$ $\quad$ $\begin{matrix}CHPh\cdot CH(CO_2Et)_2\\ CHPh\cdot CH(CO_2Et)_2\end{matrix}$ (V.)

(IV.) $CH_2Ph\cdot CH(CO_2Et)_2$

ation as to the effect of substituents. The *gem*-dimethyl compound, ethyl *iso*propylidenemalonate (VI), had already been prepared in poor yield by Meyenberg (*Ber.*, 1895, **28**, 785), but although an improved method for its preparation has been developed, this compound was not considered suitable for investigation, since it could not be completely freed from ethyl malonate by simple means.

$CMe_2{:}C(CO_2Et)_2$ (VI.)

$\begin{matrix}CH_2\cdot CH_2\\ CH_2\cdot CH_2\end{matrix}\!>\!C{:}C(CO_2Et)_2$ (VII.) $\qquad$ $CH_2\!<\!\begin{matrix}CH_2\cdot CH_2\\ CH_2-CH\end{matrix}\!>\!C\cdot CH(CO_2Et)_2$ (VIII.)

The *cyclo*pentane analogue (VII) is likewise difficult to prepare in a state of purity (Kon and Speight, J., 1926, 2727); and the *cyclo*hexane compound (VIII) normally possesses the $\beta\gamma$-structure (Kon and Speight, *loc. cit.*), rendering it valueless for the work in view. The unsaturated cyano-esters, however, were obtained in good yield and in a state of purity.

Ethyl isopropylidenecyanoacetate (IX) (Komppa, *Ber.*, 1900, **33**, 3530; Scheiber and Meisel, *Ber.*, 1915, **48**, 238; Birch and Kon, J., 1923, **123**, 2443) on reduction with moist aluminium amalgam in ether gave ethyl *r-iso*propylcyanoacetate (XI) (main product)

(IX.) $CMe_2{:}C(CN)\cdot CO_2Et$ $\quad$ $\begin{matrix}CMe_2\cdot CH(CN)\cdot CO_2Et\\ CMe_2\cdot CH(CN)\cdot CO_2Et\end{matrix}$ (X.)

(XI.) $CHMe_2\cdot CH(CN)\cdot CO_2Et$

together with the bimolecular compound, *ethyl* $\alpha\delta$-*dicyano*-$\beta\beta\gamma\gamma$-*tetramethylbutane*-$\alpha\delta$-*dicarboxylate* (X). The constitution of (XI) was established by hydrolysis with alcoholic potash to *iso*propylmalonic acid (Conrad and Bischoff, *Annalen*, 1880, **204**, 144; Stohmann, Kleber, and Langbein, *J. pr. Chem.*, 1889, **40**, 211), and that of (X) by conversion into the crystalline *amide* on treatment with concentrated ammonia and into $\beta\beta\beta'\beta'$-tetramethyladipic acid (Farmer and Kracovski, J., 1926, 2318; 1927, 681) by hydrolysis with concentrated hydrochloric acid. Condensation of ethyl *iso*propylidenecyanoacetate with alcoholic potassium cyanide (compare Lapworth and McRae, J., 1922, **121**, 2741) gave a 60% yield of *as*-dimethylsuccinic acid—this appears to be the best method of preparing this compound; Higson and Thorpe's process (*loc.*

89, 1463) is less convenient and gives a smaller yield (40—45%; Farmer and Kracovski, *loc. cit.*).

The reduction of ethyl *cyclo*pentylidenecyanoacetate (XII) (Harding and Haworth, J., 1910, **97**, 486) with moist aluminium

(XII.)

(XIII.)

(XIV.) 

(XV.)

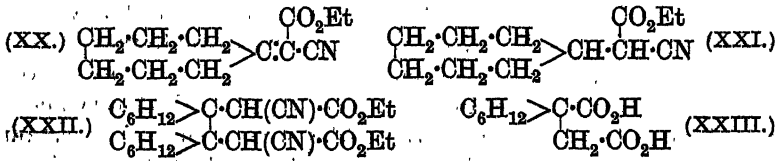
amalgam gave *ethyl* r-cyclo*pentylcyanoacetate* (XIII) (which on hydrolysis with alcoholic potassium hydroxide yielded cyclo*pentyl-malonic acid*) and a small quantity of a high-boiling bimolecular compound (XIV). Condensation of (XII) with alcoholic potassium cyanide gave a good yield of 1-carboxy*cyclo*pentane-1-acetic acid (XV), a compound first prepared in small quantity by Norris and Thorpe (J., 1921, **119**, 1208) by the oxidation of *cyclo*pentane-*spirocyclo*hexane-3 : 5-dione. The *anhydride* of this substituted succinic acid is only relatively slowly affected by water, concentrated hydrochloric acid, and by alkalis in the cold but is converted into the acid on boiling for a short time.

In a similar manner the main product of the reduction of ethyl *cyclo*hexylidenecyanoacetate (Harding, Haworth, and Perkin, J., 1908, **93**, 1943) (XVI) with moist aluminium amalgam was *ethyl* r-cyclo*hexylcyanoacetate* (XVII), characterised by conversion into *cyclo*hexylmalonic acid on hydrolysis with alcoholic potassium hydroxide; a small quantity of the dicyano-ester (XVIII) was also produced. 1-Carboxy*cyclo*hexane-1-acetic acid is obtained in good

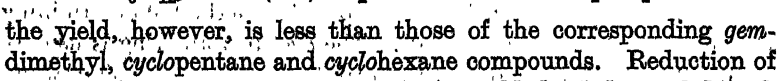
(XVI.) 

(XVII.)

(XVIII.) 



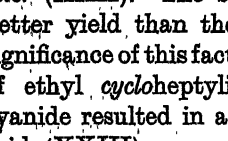
(XIX.)



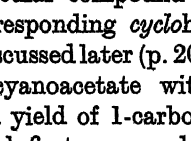
yield by the interaction of the unsaturated cyano-ester (XVI) and alcoholic potassium cyanide (Lapworth and McRae, J., 1922, **121**, 2741; compare Norris and Thorpe, J., 1921, **119**, 1209), and its anhydride has the remarkable property of being only slowly affected by water, aqueous sodium carbonate and by hydrochloric acid even on boiling. The anhydrides of these "cyclic" succinic acids appear to be intermediate in chemical properties between ordinary unsubstituted anhydrides and those of tetraethyl- and tetrapropyl-succinic acids (Walker and Walker, J., 1905, **87**, 961; Crichton, J., 1906, **89**, 929), which are derived almost spontaneously from the

acids—an experimental fact in striking agreement with the Thorpe–Ingold theory. It is hoped to make a quantitative study of the ease of fission and of formation of these substituted anhydrides in the near future.

Suberone reacts with ethyl cyanoacetate in the presence of piperidine with the formation of *ethyl* cyclo*heptylidenecyanoacetate* (XX);

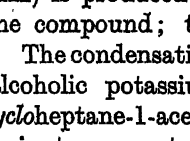


(XX.) (XXI.)



(XXII.) (XXIII.)

the yield, however, is less than those of the corresponding *gem*-dimethyl, *cyclo*pentane and *cyclo*hexane compounds. Reduction of (XX) with moist aluminium amalgam yielded *ethyl* r-cyclo*heptyl-cyanoacetate* (XXI) (characterised by the formation of cyclo*heptyl-malonic acid* on hydrolysis with alcoholic potash) and the *dicyano-ester* (XXII). The bimolecular compound (XXII) is produced in better yield than the corresponding *cyclo*hexane compound; the significance of this fact is discussed later (p. 2015). The condensation of ethyl *cyclo*heptylidenecyanoacetate with alcoholic potassium cyanide resulted in a good yield of 1-carboxy*cyclo*heptane-1-acetic acid (XXIII), a compound first prepared in minute amount by Dickens, Horton, and Thorpe (J., 1924, **125**, 1840) by the interaction of cyclo[illegible] cyanohydrin and ethyl sodiocyanoacetate and subsequent hydrolysis. The *anhydride* resembles the *cyclo*hexane analogue in properties.



trans-β-Decalone (Hückel, *Annalen*, 1925, **441**, 1) condenses more readily than suberone with ethyl cyanoacetate in the presence of piperidine, yielding *ethyl* trans-*decahydro*-β-*naphthylidenecyano-acetate* (XXIV), which on reduction with moist aluminium amalgam gave only one r-trans-*decahydro*-β-*naphthylcyanoacetate* (XXV or XXVI), and only one *decahydro*-β-*naphthylmalonic acid*

(XXIV.)

(XXV.)

(XXVI.)

X = $CH(CN)\cdot CO_2Et$

[X = $CH(CO_2H)_2$] was produced on hydrolysis of the latter with alcoholic potassium hydroxide. A careful search did not reveal the presence of the second theoretically possible saturated ester or malonic acid (compare Perkin and Sedgwick

2437; 1925, **127**, 439, who were able to isolate only one octahydroacridine by the reduction of tetrahydroacridone with sodium amalgam).

The results are in harmony with the complete mechanism of the aluminium amalgam reduction process (this vol., p. 1017). The poor yields of the bimolecular compounds must be attributed to the presence in $CR_1R_2{:}C(CN){\cdot}CO_2Et$ of groups R_1R_2 of relatively large molecular volume —" the volume factor "—and also to the presence of the strongly negative cyano- and carbethoxyl groups—" the polar factor "—both of which will tend to render the formation of bimolecular layers difficult. Since the second effect is constant throughout the series, one has here a possible method of determining the configuration of simple rings. The *cyclo*pentane ring is usually regarded as having the relatively strainless uniplanar configuration, and the work of Thorpe and Ingold and their collaborators on *spiro*-compounds (J., 1915—1926), of Thorpe and others on ring-chain tautomerism (J., 1922 *et seq.*), and numerous incidental observations make it extremely probable that the *cyclo*hexane ring is relatively strained and has a uniplanar structure. On this basis, *i.e.*, assuming the uniplanar configurations of these rings, the angle θ (*vide infra*) has been computed by Thorpe and Ingold. It is suggested that the yields of bimolecular products are probably dependent on the tetrahedral angle θ, *i.e.*, on the strain in the ring. If this were so and the *cyclo*heptane ring had a uniplanar configuration, one would anticipate a progressive decrease in the yields of the bimolecular compounds on reduction of the appropriate unsaturated cyano-esters under comparable conditions. If, on the other hand, the strain in the *cyclo*heptane ring is relieved by its having a multiplanar structure, an increased yield of the bimolecular compound would be anticipated in the *cyclo*heptane series. The experimental results are exhibited in Table I and it will be seen that in every case more

CR_1R_2 = *cyclo*heptane	105·3	72	12

than 80% of the initial material has been accounted for and that there is no doubt that the yield of the bimolecular compound is much greater in the *cyclo*heptane than in the *cyclo*hexane series.

This, then, would appear to provide evidence for the multiplanar configuration of the seven-membered ring, a result in accord with the conclusions reached by other workers (compare Baker and Ingold, J., 1923, **123**, 122; Dickens, Horton, and Thorpe, J., 1924, **125**, 1830; Baker, J., 1925, **127**, 1678; Meerwein, *J. pr. Chem.*, 1922, **104**, 161). Physico-chemical evidence in support of this view is provided by measurements of the parachor (*vide infra*, p. 2018).

A few preliminary experiments, for which no great accuracy is claimed, were made on the effect of substituent groups on the rate of esterification in the succinic acid series. The yields of the diethyl esters under fairly comparable conditions for succinic acid, *as*-dimethylsuccinic acid and 1-carboxy*cyclo*pentane-1-acetic acid were respectively 74%, 65% and 62%; these are in agreement with what would be anticipated from the angles 115·3°, 109·5° and 109·3° calculated on the Thorpe–Ingold theory of valency deflexion. The results of a detailed investigation, comprising all the substituted succinic acids described in this paper, on the rates of hydrolysis and of esterification will form the subject of a future communication.

Various physical constants of some esters have been determined or calculated (see Tables II and III). The refractive indices are for the D line at about 20°; the exact temperatures are given in the experimental section. The surface tensions and densities were determined over a range of temperatures and have been reduced to 20°, a linear variation with temperature being assumed. The parachors ([P]) are computed from the formula $P = \gamma^{\frac{1}{4}} M/d$, where M is the molecular weight, γ is the surface tension, and d is the density at the same temperature. For the calculated values of the parachor, $\Sigma[P]$ (calc.), the structural and the atomic constants of Sugden (J., 1924, **125**, 1187 and subsequent papers) have been employed. The constants for the *cyclo*heptane * and decahydro-β-naphthalene rings have been taken as 3·6 and 12·2 respectively (*vide infra*). It will be seen (Table II) that there is a regular increase in the boiling point, refractive index, and surface tension as the size of the substituent ring is increased. The agreement between the observed and the calculated values of the parachor for the cyclic compounds is satisfactory; ethyl *r*-*iso*propylcyanoacetate exhibits an anomaly of — 5·0 which is due to the presence of the *gem*-dimethyl group. This negative anomaly in compounds containing *gem*-dimethyl groups has been previously observed by Sugden and Wilkins (J., 1927, 139) for ethyl caronate and by Sugden (this vol., p. 410) for certain phorone derivatives, but no explanation has yet been advanced.

* A provisional value deduced from the parachors of ethyl *cyclo*heptylcyanoacetate and suberone.

The exaltations of molecular refractivity of the unsaturated compounds (Table III) are due to the presence of conjugated double bonds. The observed and the calculated values of the parachor agree to within 1% except for ethyl *cyclo*heptylidenecyanoacetate (XX), where the difference is slightly greater. The low values for the unsaturated cyano-esters may be due to the fact that these compounds may exhibit, in addition to ordinary three-carbon tautomerism ($A \rightleftharpoons B$), ring-chain valency tautomerism ($B \rightleftharpoons C$) to a very small degree (compare Ingold and Shoppee, this vol., p. 365; Sugden, *ibid.*, p. 410). No chemical evidence has yet been obtained in support of this suggestion.

The results for the homologous ketones *cyclo*pentanone (D), *cyclo*hexanone (E), and *cyclo*heptanone (F) and for *trans*-β-decalone (G), regenerated from their crystalline bisulphite compounds, are in Table IV. The refractive index and the surface tension both increase as the series is ascended. The line headed $\Sigma[P]$ (calc.) comprises the sum of the atomic constants plus the value for one double bond, and $[P]$ (obs.) $-$ $\Sigma[P]$ (calc.) therefore gives the value of the ring constant determined experimentally. The calculated values of the ring constant have been computed from the "degree of unsatur-

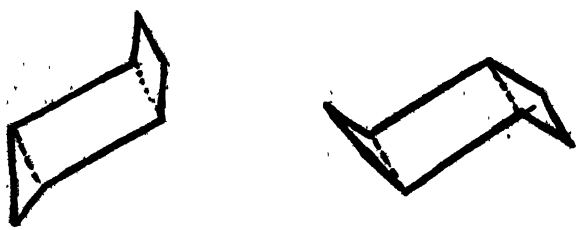
Ring constant (calc.)	9·3	7·7	6·6	15·4

ation" (Sugden and Wilkins, J., 1927, 142), and that for decahydronaphthalene is assumed to be the sum of the values for two *cyclo*hexane rings. The agreement between the observed and the calculated values of the ring constant is noteworthy, but the "constants" vary slightly from substance to substance, being influenced by substitution (compare Sugden and Wilkins, *loc. cit.*). The constants employed in computing $\Sigma[P]$ (calc.) in Tables III and IV are the mean *experimental* values of Sugden (J., 1924, **125**, 1185).

The constant obtained for the *trans*-decahydro-β-naphthalene ring (17·6) is practically twice that found for the *cyclo*hexane ring (8·4); this supports the view that the two rings from which the *trans*-decahydro-β-naphthalene molecule is built up are structurally similar (compare *Ann. Rep.*, 1927, **24**, 99). The ring constants for quinoline (Morgan and Thomssen, *J. Amer. Chem. Soc.*, 1911, **33**, 857; Sugden, J., 1924, **125**, 1187) and naphthalene (Bhatnagar and Singh, *J. Indian Chem. Soc.*, 1928, **25**, 21) are respectively 15·0 and 11·7, thus indicating that the structural constant in both cases is that for two six-membered rings.



Almost the only evidence which has been adduced in favour of the multiplanar configuration of large-membered rings (from seven upwards) is that based on the determination of the molecular volume (molecular weight/density) (Ruzicka, Brugger, Pfeiffer, Schinz, and Stoll, *Helv. Chim. Acta*, 1926, **9**, 499). The work of Sugden and his collaborators has shown that much more trustworthy values are obtained by comparing molecular volumes at temperatures at which the substances have the same surface tension, or, in other words, by the measurement of the parachor. Theoretically, it would be expected that the difference in the magnitude of the parachor for CH_2 in large rings would approximate to 39·0, the value for CH_2 in an open-chain system, if the large rings are multiplanar and therefore largely collapsed, so that the effect of an additional CH_2 group would be almost the same as its effect in a similarly crumpled aliphatic chain (compare *Ann. Rep.*, 1926, **23**, 117). No trustworthy surface tension data are available for cyclic hydrocarbons

parachors, however, can be readily calculated from the observed values for the cyclic ketones by substituting the value of 2H for :O, both of which are known with some accuracy; the results are under $[P]_1$ in Table V.

TABLE V.

	5-Ring.	6-Ring.	7-Ring.	15-Ring.	16-Ring.
$[P_1]$	205·2	242·4	279·0	—	—
$[P_1]/n$	41·0	40·4	39·7	—	—
$\Sigma[P]$ (calc.)	204·3	241·7	279·6	588·1	626·9
$\Sigma[P]/n$ (calc.)	40·9	40·3	39·9	39·2	39·2

$[P_1]/n$, where n is the number of CH_2 groups in the cyclic hydrocarbon, represents the observed volume occupied by the CH_2 group plus a share of the internal space of the ring. The value for CH_2 in the *cyclo*heptane ring approximates closely to that for CH_2 in an open-chain hydrocarbon and thus gives further support to the view that the seven-membered ring is multiplanar (p. 2015). According to Mohr (*J. pr. Chem.*, 1922, **103**, 316) there are two "strainless" forms of the *cyclo*heptane ring, each of which occupies three planes.

Since, however, the isomerism demanded by these forms has not yet been observed experimentally, it must be assumed that these merely represent phases of the contortions of the molecule.

The parachors of the cyclic hydrocarbons have been computed from the sum of the atomic constants plus the ring constant, the latter being derived from the "degree of unsaturation" (Sugden and Wilkins, J., 1927, 142), and are given in the line $\Sigma[P]$ (calc.); the contribution per CH_2 group is given in the last line of the table. The agreement between experiment and theory for the 5-, 6-, and 7-membered rings is satisfactory and it is hoped to extend the results to larger rings as soon as the necessary materials have been obtained.

The work is being continued and will include a study of the alkylation of the saturated cyano-esters and the optical resolution of the corresponding cyano-acids and their derivatives.

EXPERIMENTAL.

Ethyl iso*Propylidenemalonate* (VI).—Ethyl malonate (100 g.), acetone (54 g., dried over calcium chloride), acetic anhydride (80 g.),

and zinc chloride (23 g.) were heated in a closed vessel at 100° for 36 hours. The products of three such condensations were freed from most of the acetic anhydride and acetic acid by distillation (up to 140°); from the residue, a fraction distilling above 90°/20 mm. was collected, the distillation being stopped when the pressure had risen to 50 mm. On refractionation, ethyl malonate (40 g.) distilled at 90—110°/20 mm. and ethyl *iso*propylidenemalonate (195 g.) at 110—128°/20 mm. For use in syntheses, the latter was redistilled and the middle fraction collected.

Attempts to synthesise norpinic acid by the condensation of ethyl *iso*propylidenemalonate with ethyl sodiocyanoacetate, followed by treatment with methylene iodide and subsequent hydrolysis, under a large variety of conditions were all unsuccessful owing to the tendency of the initial Michael addition product to lose ethyl malonate.

gem-*Dimethyl Series.*

Ethyl α-Cyano-ββ-dimethylacrylate (IX).—A mixture of 200 g. of dry acetone and 200 g. of ethyl cyanoacetate was treated with 2 g. of piperidine. The deep yellow solution obtained was kept for 60 hours, refluxed for 4 hours, and again kept for 60 hours. Ether was then added and the solution was washed with dilute hydrochloric acid and with water, dried with anhydrous sodium sulphate, and distilled. The pure compound distilled at 114—116°/14 mm. (mainly at 115°/14 mm.) and, unless precautions were taken, solidified in the condenser. Yield, 147 g. or 54%. It had m. p. 33° after being spread on a porous tile (Komppa, *loc. cit.*, gives m. p. 28°; Birch and Kon, *loc. cit.*, p. 2447, give b. p. 117—127°/20 mm. and state that it "solidifies when cooled in ice.").

Reduction with Moist Aluminium Amalgam in Ether. Preparation of Ethyl r-iso*Propylcyanoacetate* (XI) *and of Ethyl αδ-Dicyano-ββγγ-tetramethylbutane-αδ-dicarboxylate* (X).—The ester (50 g.) was reduced with 75 g. of moist aluminium amalgam (J., 1927, 594), and the product worked up after 7 hours. On distillation, ethyl *iso*propylcyanoacetate (31·5 g.) passed over at 100—101°/15 mm., leaving a high-boiling residue (10·5 g.). The former on refractionation distilled at 99°/16 mm. (Fischer and Flatau, *Ber.*, 1909, 42, 2983, give b. p. 115—116°/24—25 mm.) and had $n_D^{17·2°}$ 1·4243, $d_4^{17·2°}$ 0·9880, $[R_L]_D$ 40·08 (calc., 39·62) (Found: C, 61·8; H, 8·3. Calc.: C, 61·9; H, 8·4%). The latter, an extremely viscid reddish-brown oil, was treated for 48 hours with a large excess of ammonia (*d* 0·88); the product, after being washed with dilute hydrochloric acid, was crystallised twice from dilute methyl alcohol, the *monoamide* of (X) separating in small, thin prisms, m. p. 95° (Found: C, 60·5; H,

M, in camphor by Rast's method, 275. $C_{14}H_{21}O_3N_3$ requires C, 60·2; H, 7·6%; *M*, 279).

Hydrolysis of the Ester (X). *Preparation of* ββ'β'-*Tetramethyladipic Acid.*—The high-boiling product was boiled for 5 hours with concentrated hydrochloric acid (10 parts); after 12 hours, ββ'β'-tetramethyladipic acid, accompanied by a very small quantity of carbonaceous matter, separated. The acid crystallised from hot water in colourless thin prisms, m. p. 207° alone or mixed with an authentic specimen (Farmer and Kracovski, J., 1926, 2322). This appears to be the most convenient mode of preparing this acid.

Hydrolysis of the Ester (XI). *Preparation of* iso*Propylmalonic Acid.*—Solutions of the ester (18 g.) in rectified spirit (36 g.) and of potassium hydroxide (31 g.) in water (62 g.) were mixed, refluxed for 14 hours, and evaporated to dryness. An aqueous solution of the residue was shaken with ether to remove any unchanged ester, if present, acidified with dilute sulphuric acid, and extracted five times with ether; from the extract, *iso*propylmalonic acid was obtained as an oil which crystallised completely when left over concentrated sulphuric acid in a vacuum desiccator (yield, 12·6 g. or 75%). The acid crystallised from hot chloroform in prisms containing chloroform of crystallisation which was lost on exposure to air; the opaque white residue had m. p. 87—88° after 24 hours, m. p. 88—89° (decomp.) after 48 hours, and was then unaffected by further exposure to the atmosphere (Found: C, 49·2; H, 6·9; equiv., by titration, 74. Calc.: C, 49·3; H, 6·9%; equiv., 73). Similar behaviour was observed by Romburgh (*Rec. trav. chim.*, 1886, 5, 238), who found that the acid crystallised from benzene with 2 molecules of benzene of crystallisation which were lost on exposure to the atmosphere; the residue melted at 87°.

Condensation of the Ester (IX) *with Alcoholic Potassium Cyanide. Preparation of* as-*Dimethylsuccinic Acid.*—The pure ester (10 g.) in 50 g. of rectified spirit was treated with a solution of 9·6 g. of 96% potassium cyanide (2 mols.) in 20 g. of water. The mixture, which became warm, was kept for 48 hours, the alcohol was then distilled off, a very large excess of concentrated hydrochloric acid added, and the liquid heated under reflux for 3 hours, cooled, diluted with water, and extracted six times with ether after addition of ammonium sulphate. The *as*-dimethylsuccinic acid obtained from the extract (yield, 6·2 g. or 60%) melted, after crystallisation from concentrated hydrochloric acid, at 141°; m. p. of a mixture with an authentic specimen (Higson and Thorpe, J., 1906, 89, 1465), 141—142°.

Ethyl as-*dimethylsuccinate* was prepared by heating a mixture of 8·0 g. of the crude acid, 40 g. of absolute alcohol, 40 g. of sodium-dried benzene, and 4 g. of concentrated sulphuric acid under reflux

for 5½ hours and was isolated, after the addition of water, from the benzene layer and an ethereal extract of the aqueous layer. It had b. p. 106—108°/20 mm. (yield, 6·9 g. or 62%). On redistillation, it had b. p. 101°/15 mm., $n_D^{22·7°}$ 1·4209, $d_4^{22·7°}$ 0·9945, $[R_L]_D$ 51·53 (calc., 51·69).

For purposes of comparison, ethyl succinate was prepared from Kahlbaum's succinic acid under similar conditions; the quantities employed were 15·0 g. of succinic acid, 75 g. of absolute alcohol, 75 g. of sodium-dried benzene, and 8 g. of concentrated sulphuric acid. The yield of ester, b. p. 102°/15 mm., at the first distillation was 16·3 g. or 74%. On redistillation, it boiled constantly at 103°/14 mm. and had $n_D^{21·6°}$ 1·4193, $d_4^{21·6°}$ 1·0384, whence $[R_L]_D$ 42·37 (calc., 42·45).

cyclo*Pentane Series.*

*cyclo*Pentanone was prepared by the catalytic decomposition of adipic acid (G.P., 1911, 256,622; Roger Adams, "Organic Syntheses," 1925, 5, 37), but in view of its volatility in ether vapour the crude *cyclo*pentanone was separated from the small aqueous layer, neutralised with anhydrous potassium carbonate, and distilled; the pure ketone passed over at 130°/755 mm. A further small quantity was obtained from the aqueous layer by extraction with ether.

Ethyl *cyclo*pentylidenecyanoacetate (XII) was prepared by the condensation of equimolecular quantities of *cyclo*pentanone and ethyl cyanoacetate in the presence of piperidine (for conditions, see ethyl *cyclo*heptylidenecyanoacetate). The solid obtained when the product was poured into water contained a considerable quantity of oil (compare Harding and Haworth, J., 1910, 97, 490); this was extracted with ether, washed in the ethereal solution with dilute hydrochloric acid and with water, dried with anhydrous sodium sulphate, and distilled; a mixture of *cyclo*pentanone and ethyl cyanoacetate passed over, followed by the ester (XII) as a viscid colourless oil which crystallised on cooling (yield, 55—60%).

Reduction with Moist Aluminium Amalgam. Preparation of Ethyl r-cyclo*Pentylcyanoacetate* (XIII).—The ester (50 g.) was reduced with 75 g. of aluminium amalgam under the usual conditions: there was a period of induction for 3 to 4 hours and the reaction was complete after 10 hours. On being worked up in the usual manner and distilled, the product gave *ethyl* r-cyclo*pentylcyanoacetate* (XIII), b. p. 130—131°/12 mm. (38·5 g.), and a high-boiling residue (XIV) (6·3 g.). The former on redistillation boiled at 129°/13 mm. and had $n_D^{19·8°}$ 1·4536, $d_4^{22·2°}$ 1·0242, $[R_L]_D$ 47·86 (calc., 47·65) (Found: C, 66·0; H, 8·2. $C_{10}H_{15}O_2N$ requires C, 66·3; H, 8·3%). The high-boiling residue, a very viscid reddish-brown oil, [illegible]

obtained crystalline. Its bimolecular character was established by a determination of its molecular weight in camphor by Houben's modification of Rast's method (*J. pr. Chem.*, 1923, **105**, 27) (Found: *M*, in camphor, 365. $C_{20}H_{28}O_4N_2$ requires *M*, 360). This and all the other bimolecular cyclic compounds are not readily hydrolysed and appear to have cyclic structures analogous to that of the reduction product of mesityl oxide with moist aluminium amalgam (compare Vogel, J., 1927, 594).

Hydrolysis of the Ester (XIII). *Preparation of* cyclo*Pentylmalonic Acid.*—The hydrolysis was carried out exactly as described under ethyl *iso*propylcyanoacetate. The quantities employed were 19 g. of ethyl *cyclo*pentylcyanoacetate, 40 g. of rectified spirit, 35 g. of caustic potash in 70 g. of water; the yield of the crude acid was almost quantitative. It separated from hot chloroform in small, glistening plates, m. p. 165° (decomp.) (Found: C, 55·6; H, 6·9; equiv., by titration, 86. $C_8H_{12}O_4$ requires C, 55·8; H, 7·0%; equiv., 86).

Condensation of Ethyl cyclo*Pentylidenecyanoacetate with Alcoholic Potassium Cyanide. Preparation of* 1-*Carboxy*cyclo*pentane*-1-*acetic Acid* (XV).—The condensation was carried out exactly as described for *as*-dimethylsuccinic acid: the quantities employed were 25·0 g. of ester, 125 g. of rectified spirit, 20·5 g. (2 mols.) of 96% potassium cyanide in 45 g. of water; the yield of crude acid was 19·5 g. or 81%. The acid crystallised from concentrated hydrochloric acid, in which it is much less soluble than the *gem*-dimethyl compound, in small glistening prisms, m. p. 160° (Found: C, 55·8; H, 7·0; equiv., by titration, 86. Calc.: C, 55·8; H, 7·0%; equiv., 86). The original specimen of Norris and Thorpe (J., 1921, **119**, 1209) was found to melt at 154·5—155·5°: mixed m. p. 155—158°.

The *anhydride* was prepared in 90% yield by heating the acid with 4 mols. of acetyl chloride and removing the excess of acetyl chloride in a vacuum over caustic potash. After two distillations it boiled at 135—137°/13 mm. as a fairly viscid, colourless liquid which crystallised when left in contact with light petroleum (b. p. 40—60°); m. p. 32° (Found: C, 62·0; H, 6·4. $C_8H_{10}O_3$ requires C, 62·3; H, 6·6%).

The *anilic acid* was formed when the anhydride and aniline were warmed in benzene solution. After removal of the excess of aniline in dilute hydrochloric acid, and spontaneous evaporation of the benzene layer, the residue was crystallised from dilute methyl alcohol, the anilic acid separating in thin, feathery plates which melted at 169° and decomposed with the evolution of steam at 170° (Found: C, 67·8; H, 7·1. $C_{14}H_{17}O_3N$ requires C, 68·0; H, 6·9%).

The *ethyl* ester was prepared exactly as described under ethyl

as-dimethylsuccinate: the quantities employed were 7·0 g. of crude acid, 35 g. of absolute alcohol, 35 g. of sodium-dried benzene, and 3·5 g. of concentrated sulphuric acid. The yield of ester at the first distillation was 5·9 g. or 65%. On redistillation, the ester boiled at 129°/13 mm. and had $n_D^{20\cdot2°}$ 1·4477, $d_4^{20\cdot2°}$ 1·0412, $[R_L]_D$ 58·63 (calc., 58·72) (Found: C, 63·0; H, 8·9. $C_{12}H_{20}O_4$ requires C, 63·1; H, 8·9%).

cyclo*Hexane Series.*

Ethyl *cyclo*hexylidenecyanoacetate (XVI) was prepared by the condensation of pure *cyclo*hexanone and ethyl cyanoacetate in the presence of piperidine (Harding, Haworth, and Perkin, *loc. cit.*) in *ca.* 60% yield. The pure ester, thrice distilled under reduced pressure, boiled at 151°/12 mm. and had $n_D^{18\cdot0°}$ 1·4974, $d_4^{18\cdot0°}$ 1·0556, $[R_L]_D$ 53·57 (calc., 51·80). Lapworth and McRae give b. p. 160—163°/15 mm. (J., 1922, **121**, 2754); Birch, Kon, and Norris (J., 1923, **123**, 1373) give b. p. 151°/10 mm., $d_4^{19\cdot5°}$ 1·05394, $n_D^{19\cdot5°}$ 1·49670, which give $[R_L]_D$ 53·59 in good agreement with the value determined by the present author: the values $[R_L]_D$ 53·94 (calc., 51·59) given by the latter authors are erroneous.

Reduction with Moist Aluminium Amalgam. Preparation of Ethyl r-cyclo*Hexylcyanoacetate* (XVII).—The ester (100 g.) was reduced with 150 g. of aluminium amalgam; there was a period of induction of about 3 hours and the reaction was complete after 9 hours. When the product was worked up in the usual manner and distilled, *ethyl* [illegible] (XVII) (85 g.) passed over at 144—146°/14 mm.: the viscid residue was dissolved in methyl alcohol, the solvent evaporated in a vacuum over concentrated sulphuric acid, and traces of impurities removed by repeated extraction with boiling light petroleum (b. p. 40—60°); the product crystallised completely when left in a vacuum over concentrated sulphuric acid for 24 hours (yield, 6 g.). It melted at 87° and was the bimolecular *cyano-ester* (XVIII) (Found: *M*, in camphor, 396. $C_{22}H_{32}O_4N_2$ requires *M*, 388). The liquid reduction product on redistillation boiled at 145°/14 mm., and had $n_D^{18\cdot5°}$ 1·4612, $d_4^{18\cdot5°}$ 1·0221, whence $[R_L]_D$ 52·39 (calc., 52·21) (Found: C, 67·5; H, 8·5. $C_{11}H_{17}O_2N$ requires C, 67·8; H, 8·7%).

Hydrolysis of the Ester (XVII). *Preparation of* cyclo*Hexylmalonic Acid.*—The hydrolysis was carried out as described under ethyl *iso*propylcyanoacetate and was considered to be complete after 18 hours. The quantities employed were 20 g. of ethyl *cyclo*hexylcyanoacetate, 40 g. of rectified spirit, and 30 g. of potassium hydroxide in 60 g. of water. The acid, which was obtained in practically quantitative yield, separated from acetone–chloroform in feathery plates, m. p. 178° (decomp.), and its [illegible]

*cyclo*hexylmalonic acid was established by direct comparison with an authentic specimen, m. p. 176—177° (decomp.), synthesised from bromo*cyclo*hexane and ethyl sodiomalonate; mixed m. p. 177—178° (decomp.).

The condensation of ethyl *cyclo*hexylidenecyanoacetate with alcoholic potassium cyanide had previously been carried out by Lapworth and McRae (J., 1922, **121**, 2754): the quantities here employed were 30 g. of ester, 150 g. of rectified spirit, and 21·1 g. (2 mols.) of 96% potassium cyanide in 45·5 g. of water. Hydrolysis was effected by boiling under reflux with a large excess of concentrated hydrochloric acid for 6 hours: the use of fuming hydrochloric acid (Lapworth and McRae) seems unnecessary. The 1-carboxy-*cyclo*hexane-1-acetic acid (yield, 24·7 g. or 86%) crystallised from concentrated hydrochloric acid in flat prisms, m. p. 134°, but was less soluble than the corresponding *gem*-dimethyl and *cyclo*pentane compounds. It may also be crystallised from chloroform–light petroleum (b. p. 40—60°). Its constitution was confirmed by a comparison with the original specimen of Norris and Thorpe (J., 1921, **119**, 1206), m. p. 132°, mixed m. p. 133—134°. The anhydride, prepared in 92% yield by the method described for the *cyclo*pentane analogue, crystallised from light petroleum (b. p. 40—60°) in plates, m. p. 56° (Norris and Thorpe, *loc. cit.*, give m. p. 57°). The anilic acid, prepared from the anhydride and aniline in benzene solution, crystallised from dilute methyl alcohol in lustrous, glistening plates, m. p. 181° (decomp.) (Norris and Thorpe, *loc. cit.*, give m. p. 180°).

cyclo*Heptane Series.*

Ethyl cyclo*Heptylidenecyanoacetate* (XX).—Suberone, b. p. 181°/769 mm., was prepared in 35—40% yield by the dry distillation of thorium suberate (Ruzicka, *Helv. Chim. Acta*, 1926, **9**, 715), and later by the catalytic decomposition of suberic acid, full details of which are given in the following communication.

A mixture of the ketone (44 g.), ethyl cyanoacetate (46 g.), and piperidine (1 g.) was after 48 hours heated on a steam-bath for 4 hours, cooled, and poured into water. The heavy oil produced was isolated by means of ether and, after the usual washing and drying, was distilled; suberone and ethyl cyanoacetate passed over first, and then the *cyano-ester* (XX) at 162—163°/14 mm. (yield, 27·3 g. or 31%). By treating the low fraction with a large excess of saturated aqueous-alcoholic sodium bisulphite solution (Ruzicka and Brugger, *Helv. Chim. Acta*, 1926, **9**, 339), 18 g. of pure suberone were recovered. On redistillation the ester boiled at 160°/12 mm. and had $n_D^{18\cdot6°}$ 1·5003, $d_4^{18\cdot6°}$ 1·0534, $[R_L]_D$ 57·86 (calc., 56·62) (Found: C, 69·4; H, 8·2. $C_{12}H_{17}O_2N$ requires C, 69·5; H, 8·3%).

Reduction with Moist Aluminium Amalgam. Preparation of Ethyl r-cyclo*Heptylcyanoacetate* (XXI).—17·2 G. of ethyl *cyclo*heptylidenecyanoacetate were treated with 35 g. of moist aluminium amalgam in ether; there was a period of induction for several hours and the reduction was considered complete after 18 hours. The product was isolated in the usual manner and distilled, *ethyl* r-cyclo*heptylcyanoacetate* (12·4 g.) passing over at 152—154°/12 mm., mainly at 152°/12 mm. The residue, which solidified to a transparent glassy solid on cooling, was treated several times with boiling light petroleum (b. p. 40—60°) to remove impurities; it crystallised after being left in a vacuum over concentrated sulphuric acid for 48 hours (yield, 2·1 g.). It had m. p. 74° and was the bimolecular compound (XXII) (Found: *M*, in camphor, 418. $C_{24}H_{36}O_4N_2$ requires *M*, 416). The liquid reduction product on redistillation boiled at 149°/11 mm. and had $n_D^{19·0°}$ 1·4664, $d_4^{19·7°}$ 1·0209, whence $[R_L]_D$ 56·78 (calc., 56·89) (Found: C, 68·7; H, 9·1. $C_{12}H_{19}O_2N$ requires C, 68·9; H, 9·2%).

Hydrolysis of the Ester (XXI). *Preparation of* cyclo*Heptylmalonic Acid.*—The hydrolysis was effected as described under ethyl *iso*propylcyanoacetate, the quantities employed being 6·5 g. of ethyl *cyclo*heptylcyanoacetate, 13 g. of rectified spirit, and 7·0 g. (4 mols.) of potassium hydroxide in 14 g. of water. The crude acid was only sparingly soluble in chloroform but crystallised from benzene–acetone in thin plates, m. p. 164·5° (decomp.) (Found: C, 60·0; H, 8·0%. $C_{10}H_{16}O_4$ requires C, 60·0; H, 8·0%).

Condensation of Ethyl cyclo*Heptylidenecyanoacetate with Alcoholic Potassium Cyanide. Preparation of* 1-*Carboxy*cyclo*heptane*-1-*acetic Acid* (XXIII).—The reaction was carried out as described for *as*-dimethylsuccinic acid: the quantities employed were 12 g. of the ester (XX), 60 g. of rectified spirit, and 8·1 g. (2 mols.) of 96% potassium cyanide in 18 g. of water (yield of crude acid, 9·9 g. or 86%). 1-Carboxy*cyclo*heptane-1-acetic acid is very sparingly soluble in concentrated hydrochloric acid, probably less so than its *cyclo*pentane analogue; it crystallises from dilute hydrochloric acid in small prisms, m. p. 159° (Found: C, 60·0; H, 8·0; equiv., by titration, 100. Calc.: C, 60·0; H, 8·0%; equiv., 100); Dickens, Horton, and Thorpe (*loc. cit.*) give m. p. 153°. The *anhydride*, m. p. 16°, b. p. 166°/13 mm., obtained in excellent yield by treatment of the crude acid with acetyl chloride, was converted in the usual manner into the *anilic acid*, which separated from dilute methyl alcohol in feathery plates, m. p. 159°, decomp. 160° (Found: C, 69·1; H, 7·6. $C_{16}H_{21}O_3N$ requires C, 69·3; H, 7·7%).

trans-*Decahydro*-β-*naphthalene Series.*

trans-Decahydro-β-naphthol (*trans*-β-decalol) was obtained from the "Dekahydro-β-naphthol rein" of the Deutsche Hydrierwerke Aktiengesellschaft by spreading the oily sticky solid, which probably consisted of a mixture of the *cis*- and *trans*-isomerides, on large porous plates: the resultant crystalline solid melted at 74° (Hückel, *Annalen*, 1925, **441**, 18, gives m. p. 75° for pure *trans*-β-decalol). The alcohol was dissolved in three times its weight of glacial acetic acid and gradually treated, under reflux, with half its weight of recrystallised chromic acid dissolved in the minimum quantity of water. When the initial vigorous reaction had subsided the whole was warmed on the steam-bath for 30 minutes and steam-distilled. The mixture of *trans*-β-decalone (which is only moderately easily volatile in steam) and acetic acid isolated from the distillate by means of ether (three extractions) was shaken for 1 hour with a large excess of saturated aqueous-alcoholic sodium bisulphite solution (Ruzicka and Brugger, *Helv. Chim. Acta*, 1926, **9**, 339). The bisulphite compound, which separated as a silky crystalline solid, was collected and decomposed with an excess of sodium hydroxide solution, and the *trans*-β-decalone isolated by extraction (twice) with ether. It distilled at 106°/12 mm. as a colourless, somewhat viscid liquid with a characteristic odour and had $d_4^{17\cdot7°}$ 0·9800, $n_D^{17\cdot7°}$ 1·4843, whence $[R_L]_D$ 44·44 (calc., 43·99) (Hückel, *loc. cit.*, gives for *trans*-β-decalone regenerated from the semicarbazone, $d_4^{20°}$ 0·975, $n_D^{19·6°}$ 1·48088). The yield of pure *trans*-β-decalone from 87 g. of *trans*-β-decalol was 48 g.

Ethyl trans-*Decahydro*-β-*naphthylidenecyanoacetate* (XXIV).—A mixture of 35·0 g. of pure *trans*-β-decalone, 26·5 g. of ethyl cyanoacetate, and 1 g. of piperidine was after 24 hours heated on the steam-bath for 6 hours. Ether was then added and the product was washed with dilute hydrochloric acid and with water and dried with anhydrous sodium sulphate. The residue after evaporation of the ether was fractionated: unchanged *trans*-β-decalone and ethyl cyanoacetate were first collected and the condensation product passed over at 190—205°/15 mm. The last on refractionation distilled at 197°/14 mm. (Found: C, 72·8; H, 8·5. $C_{15}H_{21}O_2N$ requires C, 72·8; H, 8·6%) and had $d_4^{19·4°}$ 1·0523, $n_D^{19·4°}$ 1·5108, whence $[R_L]_D$ 70·34 (calc., 68·08). Yield, 47 g. or 61%.

Reduction with Moist Aluminium Amalgam. Preparation of Ethyl α-trans-*Decahydro*-β-*naphthylcyanoacetate* (XXV or XXVI).—35·0 G. of the unsaturated cyano-ester (XXIV) were treated with 70 g. of moist aluminium amalgam in ether: there was a period of induction of at least 8 hours and the reduction was complete after 22 hours. The product was isolated in the usual manner and dis-

tilled and the following fractions were collected: (1) B. p. 184°/12 mm.; this had $n_D^{18\cdot9°}$ 1·4811, $d_4^{18\cdot9°}$ 1·0263. (2) A large middle fraction, b. p. 184—186°/12 mm., mainly 186°/12 mm., $n_D^{19\cdot9°}$ 1·4802, $d_4^{19\cdot9°}$ 1·0302, whence $[R_L]_D$ 68·73 (calc., 68·54). (3) A small tail fraction, b. p. 186—187°/12 mm., $n_D^{19\cdot3°}$ 1·4805, $d_4^{19\cdot3°}$ 1·0297. Total yield, 27·5 g. The distillate was obviously homogeneous and on redistillation boiled constantly at 186°/12 mm. (Found: C, 72·4; H, 9·2. $C_{15}H_{23}O_2N$ requires C, 72·3; H, 9·3%): no trace of a second isomeride could be detected by distillation. The residue was a very viscid yellow oil which did not crystallise when left for a week over concentrated sulphuric acid in a vacuum; yield, 2·5 g. (Found: *M*, in camphor, 488. $C_{30}H_{44}O_4N_2$ requires *M*, 496).

Hydrolysis with Alcoholic Potassium Hydroxide. Preparation of trans-*Decahydro-β-naphthylmalonic Acid.*—A mixture of 8·3 g. of the ester (b. p. 186°/12 mm.) in 16 g. of rectified spirit and 7·5 g. of potassium hydroxide in 15 g. of water was refluxed for 18 hours and then evaporated to dryness on the steam-bath. The residue was triturated with ether to remove unchanged ester, if any, and acidified with very dilute sulphuric acid, a sticky solid separating. The whole was extracted three times with ether: the ethereal solution, which soon deposited a crystalline acid, m. p. 122° (decomp.), was slightly concentrated, and the separated acid collected: this process was repeated five times until practically all the ether had been evaporated. The acid which separated at each crystallisation melted at 122° (decomp.) and the total yield was nearly quantitative (Found: C, 65·5; H, 8·1. $C_{13}H_{20}O_4$ requires C, 65·0; H, 8·4%). No isomeric acid was isolated. The acid crystallises from benzene or acetone–chloroform as a microcrystalline powder, m. p. 122° (decomp.).

Determinations of Surface Tension and of Density over a Range of Temperatures. Calculation of the Parachor.

The surface tension was determined by the method of Richards, Speyers, and Carver (*J. Amer. Chem. Soc.*, 1924, **46**, 1196) in an apparatus constructed entirely of Pyrex glass. Two capillary tubes of diameters approximately 0·5 mm. and 2 mm. respectively, of nearly circular cross-section and of uniform bore were joined together to form a U-tube, which was provided with a small opening at its lowest point. The U-tube was fused in a vertical position to the inside of a thin-walled glass cylinder, and this was fused to a larger tube, which could be surrounded by the vapour of boiling chloroform (*ca.* 61°) or trichloroethylene (*ca.* 86°); the exact temperature was indicated by a small standard Anschütz thermometer graduated in fifths of a degree. The difference in capillary

measured by means of a travelling microscope capable of reading directly to 0·02 mm. and by estimation to 0·01 mm. and provided with a 5-inch objective, for the construction of which the author is indebted to Mr. W. J. Colebrooke of the Physics Department of this College; it enabled both meniscuses to be observed simultaneously.

The apparatus was cleaned by being immersed in chromic acid mixture for 6 hours, washed with water, rectified spirit, and pure sodium-dried ether, and dried in the steam-oven. It was standardised with conductivity water, prepared in a modified Bourdillon still, in the manner suggested by Richards, Speyers, and Carver (*loc. cit.*).

The measurements of capillary rise for each liquid (about 3 c.c.) were made with the usual precautions. The vertical cross-wire in the eye-piece of the microscope was adjusted parallel to and approximately mid-way between the capillary tubes. At least six readings of each meniscus were taken from several directions, so as to minimise the effect of possible imperfections in the glass, the exact temperature at each adjustment being observed.

The corrections for the meniscus, determined by Poisson's equation $h_1 = h + r/3 - 0{\cdot}1288\ r^2/h$, where h_1 is the corrected capillary rise, h is the observed capillary rise, and r is the radius of the tube (Richards, Speyers, and Carver, *loc. cit.*), were 0·245 mm. for liquids of the water type ($h = ca.$ 50 mm.) and — 0·234 mm. for most organic liquids ($h = ca.$ 25 mm.). Throughout the present paper, the corrected difference in height between the meniscuses in the capillary tubes, H, is obtained from the observed difference, h (expressed in mm.), by subtracting 0·24. The constant of the apparatus, K, was obtained from the equation $\gamma = KHd$, where γ and d are respectively the surface tension and the density at the same temperature; the surface tension of water at 20° was taken as 72·80 (Harkins and Brown, *J. Amer. Chem. Soc.*, 1919, **41**, 499), and the temperature coefficient 0·15 dyne cm.$^{-1}$ (degree Cent.)$^{-1}$ (compare Ferguson and Vogel, *Proc. Physical Soc.*, 1926, **38**, 193). The mean of several concordant determinations gave $K = 1{\cdot}8805$.

The densities were determined with a pyknometer of about 1·5 c.c. capacity, carefully calibrated with conductivity water. The pyknometer was completely surrounded by a closely fitting, double-walled glass vessel, the annular space being filled with a suitable vapour.

In the tables, t is the temperature, h the observed difference in height, expressed in mm., of the liquid in the two arms of the U-tube, H the corrected value, d_4^t the density (in g./c.c.) calculated from the observed densities by assuming a linear variation with temperature, and γ the surface tension, expressed in dynes/cm., computed from

the equation $\gamma = KHd$. The parachor in the last column has been derived from the expression $[P] = \gamma^{\frac{1}{4}}M/d^{t°}_{4°}$, where M is the molecular weight; the density of the vapour has been neglected.

Except where stated otherwise, the liquids were thrice distilled under diminished pressure before use.

Ethyl r-iso*propylcyanoacetate*, $M = 155{\cdot}10$, b. p. 99°/16 mm. Densities determined: $d^{19{\cdot}2°}_{4°}$ 0·9862, $d^{32{\cdot}4°}_{4°}$ 0·9481, $d^{86{\cdot}8°}_{4°}$ 0·9261.

cyclo*Pentanone*, $M = 84{\cdot}06$. The middle fraction, b. p. 130·5°/765·5 mm., collected from the distillation of a large quantity of *cyclo*pentanone prepared from adipic acid was added to a large excess of saturated aqueous-alcoholic sodium bisulphite solution

bisulphite compound, which slowly separated in thin, silky plates, was removed and treated with an excess of a concentrated sodium carbonate solution, and the ketone was separated by steam-distillation and extraction (twice) with ether. The extracts were dried with anhydrous sodium sulphate and the ether was *slowly* distilled through a long column. The residue, after being twice fractionated under atmospheric pressure, boiled at 129·5°/761·5 mm. The pure ketone had $n_D^{16\cdot0°}$ 1·4383, $d_4^{16\cdot0°}$ 0·9524, whence $[R_L]_D$ 23·18 (calc., 23·10) (Wallach, *Annalen*, 1907, **353**, 331, gives $d^{20°}$ 0·948, n_D 1·4366, $[R_L]_D$ 23·19).

Densities determined: $d_4^{16\cdot4°}$ 0·9518, $d_4^{69\cdot8°}$ 0·9099, $d_4^{86\cdot4°}$ 0·8871.

CCLXIII.—*Syntheses of Cyclic Compounds. Part IV. The Catalytic Decomposition of Suberic Acid and the Preparation of Suberone directly from Mixtures of Suberic and Azelaic Acids.*

By ISRAEL VOGEL.

IT is proposed to investigate the decomposition, in the presence of various catalysts, of both simple and substituted dibasic acids in order (1) to develop simple methods for the preparation of cyclic ketones and (2) to study the effect of substituents on this method of ring formation. The present communication is concerned with suberic acid. The only previous work on this subject (D.R.-P. 256622) was the alleged production of suberone in good yield by the dry distillation of suberic acid in the presence of 5% by weight of iron filings; Aschan (*Ber.*, 1912, **45**, 1603), however, isolated a small quantity of suberone by the dry distillation of the acid. Day, Kon, and Stevenson (J., 1920, **117**, 639) were unable to obtain satisfactory results by this catalytic process and reverted to the dry distillation of the calcium salt as a method for the preparation of suberone.

The author finds that if an intimate mixture of suberic acid, an *equal weight* of iron filings (a quantity considerably greater than the equivalent quantity), and 5% by weight of crystallised baryta be subjected to dry distillation, a yield approaching 40% of suberone is obtained. The crude product is an almost colourless, mobile liquid with a characteristic ketonic odour in contrast with the practically black liquid, contaminated with suspended matter and having a characteristic "hydrocarbon" odour, obtained from either the calcium or the thorium salt.

The mixture of azelaic and suberic acids obtained by the oxidation of ricinoleic acid with nitric acid (Day, Kon, and Stevenson, *loc. cit.*; Baker and Ingold, J., 1923, **123**, 122) also gives a good yield of

suberone, together with a relatively small quantity of a liquid the exact composition of which has not yet been elucidated. This liquid boils at about the same temperature as suberone but can readily be separated from it, as the latter reacts immediately with a saturated aqueous or preferably aqueous-alcoholic sodium bisulphite solution, whereas the former gives no solid derivative.

The formation of suberone by the catalytic decomposition of suberic acid probably takes place in two stages, involving the formation of the anhydride (I) and the subsequent elimination

$$\text{(I.)}\quad \begin{matrix}CH_2\cdot CH_2\cdot CH_2\cdot CO\\ CH_2\cdot CH_2\cdot CH_2\cdot CO\end{matrix}\!\!>\!O \longrightarrow CO_2 + \begin{matrix}CH_2\cdot CH_2\cdot CH_2\\ CH_2\cdot CH_2\cdot CH_2\end{matrix}\!\!>\!CO \quad \text{(II.)}$$

of carbon dioxide (compare Blanc, *Bull. Soc. chim.*, 1908, **3**, 778). Two other mechanisms are possible, one represented by (A) (compare Aschan, *loc. cit.*) and the other involving the intermediate formation of an iron salt.

$$\text{(A.)}\quad \begin{matrix}CH_2\cdot CH_2\cdot CH_2\cdot CO_2H\\ CH_2\cdot CH_2\cdot CH_2\cdot CO_2H\end{matrix} \longrightarrow \begin{matrix}CH_2\cdot CH_2\cdot CH\cdot CO_2H\\ CH_2\cdot CH_2\cdot CH_2\end{matrix}\!\!>\!CO \xrightarrow{-CO_2} \text{(II.)}$$

It is extremely difficult to prepare pure azelaic acid in quantity from the mixed acids obtained by the oxidation of ricinoleic acid with nitric acid; although a product, m. p. 106°, may be obtained by fractional crystallisation from solvents, this contains a considerable quantity of suberic acid, as was shown by analysis and by the production of suberone by its catalytic decomposition. Pure azelaic acid is best prepared by the oxidation of ricinoleic acid with potassium permanganate (Maquenne, *Bull. Soc. chim.*, 1899, **21**, 1061): this melted at 107° and no suberone was obtained by its catalytic decomposition.

Experimental.

Preparation of Suberic Acid.—Castor oil, in lots of 25 kg., was hydrolysed by alcoholic sodium hydroxide to ricinoleic acid, and the latter oxidised by nitric acid to a mixture of azelaic and suberic acids (Baker and Ingold, J., 1923, **123**, 122). The two acids were separated from each other by means of a mixture of benzene and ethyl alcohol in proportion intermediate between those described by Baker and Ingold (*loc. cit.*) and by Day, Kon, and Stevenson (*loc. cit.*); rectified spirit was substituted for absolute ethyl alcohol. The acid which first separated melted at 135—138° and after two crystallisations from water melted sharply at 140°.

Catalytic Decomposition of Suberic Acid.—An intimate mixture of 100 g. of suberic acid (m. p. 140°), 100 g. of iron filings, and 5 g. of finely powdered, crystallised barium hydroxide was placed

2-litre Pyrex distilling-flask fitted with a thermometer, reaching to within 0·5 cm. of the bottom, and connected with a long water-condenser and a receiver. The mixture was slowly heated in an air-bath, the space between the sides of the flask and the bath having been packed with copper turnings. Considerable frothing took place at about 235° and water distilled over: a mobile, slightly coloured liquid with a ketonic odour passed over at 280—290°. The ketone was separated from the water in the distillate, the aqueous layer was extracted twice with ether, and the combined extracts and ketone were washed with alkali and dried with anhydrous potassium carbonate. The ether having been removed through a long fractionating column, the residue was separated under reduced pressure into the following fractions: (1) a small head fraction, b. p. 63—65°/15 mm., $n_D^{18\cdot1°}$ 1·4595, $d_4^{18\cdot1°}$ 0·9378; (2) a main fraction, b. p. 65·5—66°/15 mm., $n_D^{18\cdot3°}$ 1·4611, $d_4^{18\cdot3°}$ 0·9467; (3) a small tail fraction, b. p. 67—70°/15 mm., $n_D^{17\cdot8°}$ 1·4627, $d_4^{17\cdot8°}$ 0·9458. The residue weighed less than 1 g. and the total yield of distillate was 24 g. All the fractions were colourless mobile liquids, and remained so after being kept for 6 months (compare the product from calcium or thorium suberate which rapidly darkens on keeping), and on treatment with aqueous semicarbazide acetate and methyl alcohol gave immediate precipitates of semicarbazones which melted at 162—163°, either alone or when mixed with an authentic specimen of suberone semicarbazone prepared from thorium suberate, after one crystallisation from dilute methyl alcohol. No other semicarbazone could be isolated and it was evident that the ketone was practically pure *cyclo*heptanone. It could be obtained perfectly pure by regeneration from the bisulphite compound.

Preparation of Suberone from Mixtures of Suberic and Azelaic Acids.—The crude mixture of acids must first be recrystallised from benzene. An intimate mixture of 300 g. of the mixed acids, 300 g. of iron filings, and 15 g. of finely ground, crystallised barium hydroxide was distilled from a 4-litre Pyrex distilling flask as described for suberic acid. (The heating must be very gradual, as there is considerable frothing and evolution of fumes in the early part of the reaction—temperature 200—250°. Indeed, this part of the process may be conducted in the open on a large iron plate: the intimate mixture is gently heated until the evolution of steam and ether fumes has ceased, and the cold dark-coloured product is broken up and transferred to the distilling flask.) The rate of heating was such that the liquid distilled at the rate of about one drop per second; the final temperature was 360—400°. The product was isolated as described under suberic acid and distilled, and the fraction, b. p. 62—75°/14 mm., collected; the yield averaged

90 g. from 600 g. of the mixed acids. This fraction was added to a saturated aqueous-alcoholic sodium bisulphite solution, and the crystalline bisulphite compound, which was immediately precipitated, was filtered off, well washed with alcohol and ether, and decomposed with sodium hydroxide, and the ketone isolated by ether extraction. Further small quantities of suberone may be obtained by treating the high-boiling fractions with sodium bisulphite.

The author wishes to thank Professor J. F. Thorpe, F.R.S., for his interest in these experiments and to state that this work is being published during the tenure of a Beit Scientific Research Fellowship.

CCLXIV.—*The Action of Diazo-salts on Aromatic Sulphonamides. Part II. The Mechanism of the Reaction and the Constitution of the Diazo-sulphonamides.*

By ARTHUR KEY and PAVITRA KUMAR DUTT.

THE object of this investigation was to elucidate the mechanism of the reaction

$$R{\cdot}SO_2{\cdot}NH_2 + R'{\cdot}N_2X \longrightarrow R{\cdot}SO_2{\cdot}NH{\cdot}N{:}NR' \longrightarrow R{\cdot}SO_2H + R'N_3 \quad (I.)$$

(Dutt, Whitehead, and Wormall, J., 1921, **119**, 2088; Dutt, J., 1924, **125**, 1463), which takes place with extreme facility in the presence of alkali even at very low temperatures. Several examples of the formation of sulphinic acids under comparable conditions from other sulphonamide derivatives have also been recorded by Forster and Kunz (J., 1914, **105**, 1720) and by Holmes and Ingold (J., 1926, 1305). These reactions are apparently similar in their mechanism, being probably due to the action of hydroxyl ions on the hydrogen which is incipiently ionised because of the strong electron attraction exercised by some neighbouring centre (Holmes and Ingold, *loc. cit.*). For example, in the case of the diazo-sulphonamide (II) such electron attraction actuated by the neighbouring positive charges should induce it to ionise into the complex ion (III) and H^+.

(II.)  (III.) + H^+

After the removal of the proton as water the complex ion (III) should then undergo further change due to the proximity of the positively charged sulphur; the latter would appropriate the two electrons between the sulphur and the nitrogen, resulting in its fission into the sulphinate ion $R{\cdot}SO_2'$ and $R'N_3$. According to this scheme the residue $R'—\overset{\cdot\cdot}{N}=\overset{\cdot\cdot}{N}—\overset{\cdot\cdot}{\underset{\cdot\cdot}{N}}$ should by subsequent movement of electrons be capable of existing in one of the two forms $R'—N=\overset{+}{N}=\overset{-}{N}$ and $R'—\overset{-}{N}—\overset{+}{N}\equiv N$. The distinction of any of these forms from the third possible formula for azoimide, $R'N<\begin{matrix}N\\ \|\\ N\end{matrix}$, may perhaps be elucidated by parachor determination.

The reaction (I) may, on the other hand, be a case of true migration of the hydrogen atom from the nitrogen to the oxygen, followed by fission into the two final products. This hypothesis was tested by heating the pure dry sulphonamide (R = *p*-tolyl and R′ = Ph) both by itself and in solution in a non-ionising solvent, such as pyridine, at a temperature above its decomposition point (87—88°). In the former case a minute quantity of the azoimide was obtained, probably owing to the action of the alkali of the glass or a trace of moisture or both, but none of it was formed in the latter experiment. It is therefore evident that the ionic interpretation offers a plausible explanation of the reaction.

The reaction of the diazo-sulphonamide with an acid hydrolytic agent, forming only $R{\cdot}SO_2{\cdot}NH_2$ and R′OH but no $R'NH_2$, is consistent with formula (II), because, of the two possible tautomeric forms, (II) and $R{\cdot}SO_2{\cdot}N{:}N{\cdot}NHR'$, the proximity of the positive charge on the sulphur should favour the stability of the ion (III) owing to its tendency to neutralise the negative charge on the nearest nitrogen atom. The two lone pairs of electrons on this nitrogen would then appropriate two hydrogen ions, completing the system $R{\cdot}SO_2{\cdot}NH_2$ and leaving a positive ion, $R'—N\equiv N$, which is responsible for the formation of the phenol. In this instance, therefore, the electronic condition is such that the substance ceases to be tautomeric.

The action of acid hydrolytic agents fails to distinguish, as Forster and Garland have pointed out (J., 1909, **95**, 2056), between the tautomeric forms of an aromatic diazoamine, although phenyl-α-naphthyltriazene (Dimroth, Elbe, and Gruhl, *Ber.*, 1907, **40**, 2390) may have the constitution $NHPh{\cdot}N{:}N{\cdot}C_{10}H_7$, because it yields only aniline and no α-naphthylamine when hydrolysed by means of hydrochloric acid in a freezing mixture.

Further, the diazo-sulphonamide is readily methylated in the cold, forming only one monomethyl derivative which, from the evidence

of its reduction products ($R{\cdot}SO_2{\cdot}NH_2$, NH_3, $R'{\cdot}NHMe$, $R'NMe{\cdot}NH_2$, and $R'MeN{\cdot}N{:}N{\cdot}NMeR'$), must be regarded as having the constitution $R{\cdot}SO_2{\cdot}N{:}N{\cdot}NMeR'$ (V). The electronic hypothesis in our opinion offers an explanation of this behaviour. Obviously the methyl derivative cannot have been formed by direct substitution because of the greater stability of the form (II), which should have given the isomeride, $R{\cdot}SO_2{\cdot}NMe{\cdot}N{:}NR'$, and consequently its formation must have been preceded by salt formation with CH_3X at one of the nitrogen atoms. The velocity of methylation is much greater than that of the reaction (I); in other words, it is the substance (II), and not the ion (III), that takes part in this reaction. Now the electron pull due to the positive charges should influence all the nitrogen atoms in the chain, but the farthest one should have its lone pair of electrons comparatively free to take part in any salt formation. This should lead to the formation of the complex (IV), which would subsequently eliminate HX and form (V).

$$\text{(IV.)}\ [R{\cdot}SO_2{-}NH{-}N{=}\overset{\displaystyle CH_3}{\overset{|}{\overset{+}{N}}}{-}R'][\bar{X}] \longrightarrow R{\cdot}SO_2{-}\overset{-}{N}{-}N{=}\overset{\displaystyle CH_3}{\overset{|}{\overset{+}{N}}}{-}R' \longrightarrow R{\cdot}SO_2{-}N{=}N{-}N(CH_3){\cdot}R'\ \text{(V.)}$$

The isomeric methyl derivative, $R{\cdot}SO_2{\cdot}NMe{\cdot}N{:}NR'$, prepared from $R{\cdot}SO_2{\cdot}NHMe$ and $R'{\cdot}N_2Cl$, on reduction yields products ($R'NH_2$ and $R'NH{\cdot}NH_2$) which indicate that it is distinct from the substance (V).

In contrast with the formation of the monomethyl derivative of the diazo-sulphonamide, attention may be directed to the examples containing the system $\cdot CO{\cdot}CH{:}N{\cdot}N{\cdot}R$ described by Auwers (*Annalen*, 1911, 378, 242), which on direct methylation yield two monomethyl derivatives, one an *O*-methyl and the other an *N*-methyl (next to the group R) derivative. In our opinion this difference is due to the fact that the diazo-sulphonamides do not possess the unsaturated centres that are necessary for enolisation previous to *O*-methylation.

Experimental.

Action of Heat on Benzenesulphon-p-tolyldiazoamide (II; R = Ph, R′ = C_7H_7).—The diazo-sulphonamide (10 g., purified as previously described and dried in a vacuum desiccator over phosphoric oxide during several weeks) was heated in a vacuum. At about 80°, slow decomposition took place, producing much tar, and a few drops of an oily liquid distilled which smelt strongly of phenylazoimide (identified in the usual way). It is not advisable to use more of the diazo-sulphonamide for each experiment or heat it to a higher temperature, as it is liable to explode.

The diazo-sulphonamide dissolves readily in cold pyridine and is precipitated unchanged on addition of water. The pure material (5 g.) was dissolved in 50 c.c. of pyridine and heated on the steam-bath for 12—15 hours; the solution was then cooled and poured into sufficient ice-cold dilute sulphuric acid (about 2%) to give an acid solution. Some resinous product separated, but no phenylazoimide.

Action of Glacial Acetic Acid on the Diazo-sulphonamide.—The crude substance (10 g., prepared in very dilute alkaline solution and precipitated by acetic acid) was treated with about 50 c.c. of glacial acetic acid, slowly warmed a few degreesabove the ordinary temperature, and occasionally stirred. It dissolved readily, the colour of the solution, at first light red, gradually darkened, and slow decomposition took place with evolution of gas. From the mixture, diluted with a large volume of water and made alkaline, ether extracted a trace of tar but no aniline. The aqueous solution was acidified and distilled in steam, and phenol identified in the distillate. The residue on cooling gave crystals of *p*-toluenesulphonamide (identified by mixed melting point).

Methylation of the Diazo-sulphonamide.—A solution of 51 g. of *p*-toluenesulphonamide in 3 l. of 2% aqueous sodium hydroxide, cooled in ice and salt, was treated with a diazo-solution (made from 28 g. of aniline dissolved in 90 c.c. of concentrated hydrochloric acid and 120 c.c. of water and diazotised with 22 g. of sodium nitrite dissolved in 70 c.c. of water). To the clear alkaline solution of the diazo-sulphonamide, 80 g. of methyl sulphate were added during one hour, and the agitation continued for 3—4 hours longer. The reddish-brown amorphous mass that separated was collected, washed, and dried in a vacuum desiccator; m. p. 115—118° (decomp.), yield about 75 g. It smelt strongly of phenylazoimide.* After crystallising twice from methyl alcohol (animal charcoal), it was obtained in colourless prismatic needles, m. p. 124—125° (decomp.) (Found: S, 10·9; N, 14·7. $C_{14}H_{15}O_2N_3S$ requires S, 11·1; N, 14·5%).

Reduction of the Methyl Derivative (V).—A suspension of 20 g. of the pure methyl derivative in 300 c.c. of methyl alcohol was reduced with 600 g. of sodium amalgam (2½%). The evolution of ammonia was soon noticed, and as the reaction progressed the ether dissolved and finally a small amount of a crystalline substance separated. The whole mixture was then distilled in steam. The residue in the distilling flask, which contained the crystals (A) referred to above, was filtered off and well washed with water. The filtrate, on

* When the diazo-sulphonamide itself is stirred even for much longer periods with alkali of the strength used in this experiment, very little of the azoimide is formed, showing that the methylation proceeds at a much faster

acidification with hydrochloric acid, gave a colourless solid which was identified as *p*-toluenesulphonamide (mixed m. p.) after recrystallisation. The presence of *p*-toluenesulphonmethylamide could not be detected in this product.

The crystalline residue (A) on recrystallisation from spirit (animal charcoal) separated in almost colourless plates, m. p. 141—142° (decomp.), and proved to be identical with diphenyldimethyltetrazene, NPhMe·N:N·NMePh, prepared by oxidising αα-phenylmethylhydrazine in chloroform solution by means of mercuric oxide (Fisher, *Annalen*, 1877, **190**, 167; Tafel, *Ber.*, 1885, **18**, 1744). The melting point observed by us was, however, 4° higher than that recorded in the literature.

The steam-distillate from the original reduction mixture was acidified with hydrochloric acid and evaporated to dryness. From the dark brown residue (B), hot chloroform extracted monomethylaniline, which was isolated and identified in the form of the hydrochloride, m. p. 125—126° (the material obtained from several experiments was sufficient for the preparation of the acetyl derivative). No other basic substance could be detected in the chloroform extract.

The portion of the residue (B) insoluble in chloroform was extracted with absolute alcohol, which left behind crystals of ammonium chloride. The extracts of the residue from several experiments were collected together and the base was liberated by means of alkali, extracted with ether, dried, and distilled in a vacuum. The pale yellow, oily liquid, b. p. 160°/70 mm., gave an acetyl derivative in hexagonal prisms, m. p. 92—93°, and a crystalline hydrochloride, m. p. 221—222° (decomp.), both identical with those obtained from an authentic specimen of *as*-phenylmethylhydrazine. No trace of methylamine hydrochloride could be detected in the residue insoluble in chloroform.

Action of Benzenediazonium Chloride on p-*Toluenesulphonmethylamide.*—A solution of 5 g. of the methyl ether in dilute aqueous sodium hydroxide was treated in the cold with the diazo-solution made from 5 g. of aniline. The reaction was very slow and a brownish-red viscous mass gradually separated. As this did not show any sign of solidifying, it was washed several times by trituration with water. The gummy residue was soluble in most organic solvents but did not crystallise from any of them.

When its alcoholic solution was reduced by means of sodium amalgam as before, the evolution of ammonia was soon noticed. The mixture after reduction was poured into excess of water and extracted with ether. The ethereal extract on evaporation left a dark oil, soluble in dilute acids, which was apparently

aniline and phenylhydrazine, as it gave the carbylamine reaction, and phenylazoimide and phenol on treatment with nitrous acid. No trace of methylaniline could be detected in the residue.

One of the authors (P.K.D.) desires to thank the Research Fund Committee of the Chemical Society for a grant which has defrayed most of the cost of this investigation.

THE UNIVERSITY, LEEDS. [*Received, May 19th*, 1928.]

CCLXV.—*The Decomposition of Acetyl Peroxide and the Mechanism of Kolbe's Electrosynthesis.*

By OSWALD JAMES WALKER.

THE earlier idea of Schall (*Z. Elektrochem.*, 1896, **3**, 83), that acid peroxides are formed as intermediate products at the anode during the electrolysis of fatty acids, has in recent years been taken up by Fichter (*Trans. Amer. Electrochem. Soc.*, 1924, **45**, 131; *J. Chim. phys.*, 1926, **23**, 493), who has extended the peroxide theory to electrochemical oxidation in general. It is the purpose of this paper to show that the experimental justification for this view is unsound and that there is no necessity to assume that acetyl peroxide is formed during the electrolysis of acetates.

Whatever view we adopt regarding the mechanism of Kolbe's reaction we must assume that free $CH_3 \cdot CO \cdot O$ radicals are present at some stage in the process. If we accept the discharged-ion theory, *i.e.*, that the $CH_3 \cdot CO \cdot O$ radicals result simply from the discharge of acetanions and not from a dehydration of acetic acid by oxygen (compare Fairweather and Walker, J., 1926, 3111 *), the question still arises: Do the $CH_3 \cdot CO \cdot O$ radicals unite to form acetyl peroxide which then decomposes into carbon dioxide and ethane; or do they decompose "unimolecularly," so to speak, into carbon dioxide and free CH_3 radicals, which then unite to form ethane?

The first view may be tested, as Fichter suggested, by preparing the pure acetyl peroxide and causing it to decompose. The application of results of such experiments to the Kolbe reaction at the anode may, however, not be conclusive. For even assuming that acetyl peroxide decomposes on heating entirely into carbon dioxide and ethane, it does not follow that in the anode process, in which

* The values of the anode potential in that paper are through a regrettable error in the calculation all 0·56 volt too high. This in no way affects the reasoning in the paper, which is concerned only with the relative values of the potentials.

these gases are obtained from discharged acetanions, the $CH_3 \cdot CO \cdot O$ radicals must have first united to form a peroxide. On the contrary, one may argue that acetyl peroxide, when heated, breaks up into two $CH_3 \cdot CO \cdot O$ groups, which then react as in the electrical process (compare Wieland and Fischer, *Annalen*, 1925, **446**, 60). It will be seen, however, from the experimental part that a simple decomposition of acetyl peroxide according to the equation $(CH_3 \cdot CO \cdot O \cdot)_2 = C_2H_6 + 2CO_2$ does not take place.

Fichter (*Helv. Chim. Acta*, 1927, **10**, 869) claims to have obtained direct evidence for the peroxide theory, since he has shown that in the electrolysis of a solution of potassium hexoate small quantities of hexoyl peroxide are formed when the temperature is kept very low. This experiment shows that when the conditions are made very favourable the discharged acyl radicals unite to a small extent to form the acid peroxide, but one is not justified in concluding that the Kolbe synthesis, which is the main reaction, has proceeded through the intermediate stage of peroxide. In fact, the difficulty of isolating from the electrochemical products any peroxide at temperatures at which these peroxides are by no means unstable cannot be reconciled with this view. A further difficulty arises when one considers that by electrolysing a solution of an acetate at about 100° considerable quantities of ethane are obtained, although acetyl peroxide decomposes well below this temperature (see experimental part). Also Gibson (*Proc. Roy. Soc. Edin.*, 1924, **44**, 151) has shown that hexachloroethane is formed in the electrolysis of trichloroacetic acid, of which the peroxide is apparently incapable of existence.

The decomposition of acetyl peroxide, on which Fichter largely bases his theory, has really not been studied to any extent (for the previous literature on the subject, see Fichter, *Helv. Chim. Acta*, 1918, **1**, 151). It was decided, therefore, to investigate the nature and composition of the gases obtained by the decomposition of acetyl peroxide under various conditions.

Experimental.

Acetyl peroxide was prepared from acetic anhydride and sodium peroxide by the method of Gambarjan (*Ber.*, 1909, **42**, 4010). The ethereal solution of peroxide was dried over calcium chloride, the ether evaporated at the ordinary temperature, and the crystalline residue of peroxide washed with ether; it was then sufficiently pure; m. p. 26·5° (Nef gives 30°, and Colson 27°). Analysis: A mixture of 0·1—0·2 g. of the peroxide, 50 c.c. of water, 10 c.c. of glacial acetic acid, and 10 c.c. of a 20% solution of potassium iodide was kept for 24 hours (the liberation of iodine takes place

compare Clover and Richmond, *Amer. Chem. J.*, 1903, **29**, 183) and the iodine was then titrated with *N*/10-thiosulphate. Independently prepared samples of the peroxide were found to contain 99·6, 99·8, and 99·4% of $(CH_3\cdot CO\cdot O\cdot)_2$.

In all the experiments that follow, the gases evolved were collected over mercury and analysed in the usual manner in a Bone and Wheeler apparatus containing mercury.

Decomposition of Pure Acetyl Peroxide.—When acetyl peroxide is heated gradually above its melting point the liquid commences to evolve gas at 60—70°, and at 80° the evolution proceeds briskly. The decomposition takes place gently without the violent explosion that occurs when the substance is heated rapidly. The composition of the gas (% vol.) evolved at 80° is: CO_2, 58·7, 61·0; C_2H_4, 1·1, 1·6; O_2, —, 2·3; CO, 1·6, 3·0; CH_4, 34·0, 28·8; C_2H_6, 4·6, 3·4.

The proportion of methane formed is greater than in the explosive decomposition of acetyl peroxide investigated by Fichter (*Helv. Chim. Acta*, 1918, **1**, 152), which did not lead to a simple disintegration according to the equation $CH_3\cdot CO\cdot O\cdot O\cdot OC\cdot CH_3 = C_2H_6 + 2CO_2$. He also found considerable quantities of methane and ascribed its formation to a sort of "cracking" process, due to the violence of the explosion and the high temperature of the decomposition, which he supposes does not occur in the slow molecule-by-molecule decomposition at the anode.

A further experiment, in which the decomposition was carried out quantitatively and as slowly as possible, showed that the absolute yield of ethane, calculated on the weight of peroxide used, is very small. In a small, weighed tube 0·0500 g. of acetyl peroxide was gently heated till decomposition commenced at 61°. The heating was continued, at 65—75°, for about 4 hours, 11·0 c.c. of gas (measured at 13° and 754 mm.) being collected. The residue weighed 0·0257 g., and the amount of undecomposed peroxide in it, estimated by liberation of iodine from potassium iodide, was 0·0170 g. The decomposed peroxide (0·0330 g.) therefore produced 10·4 c.c. of gas (reduced to N.T.P.) having the following percentage composition by volume: CO_2, 58·3; O_2, 0·2; CO, 0·9; CH_4, 38·6; C_2H_6, 1·9. This corresponds to 1·0 molecule of carbon dioxide, 0·65 molecule of methane, and 0·04 molecule of ethane from 1 molecule of peroxide. The formation of ethane is therefore certainly not the main reaction.

Decomposition of Solutions of Acetyl Peroxide.—When a solution (100 g.) of acetyl peroxide (14·4 g.) in water containing acetic acid (27·7 g., to increase the solubility) was gradually warmed, effervescence set in at about 75° and between 80° and 90° there was a brisk

evolution of gas. The gases evolved at about 80° were collected and analysed (expts. *a* and *b*).

Acetyl peroxide dissolved in	CO_2.	C_2H_4.	O_2.	CO.	CH_4.	C_2H_6.
a. Aqueous acetic acid	76·0	1·2	3·1	1·4	16·0	2·3
b. „ „	75·0	—	1·4	1·4	20·8	1·2
c. Ethyl alcohol	50·5	—	—	2·2	45·8	1·5
d. „ „	51·0	—	—	1·7	45·6	1·7

Here again the amount of ethane formed is small compared with that of methane and there is relatively more carbon dioxide.

A solution of 0·15 g. of acetyl peroxide in 0·4 c.c. of alcohol was heated gradually in a water-bath. Gas evolution commenced at about 60°. The gas evolved between 60° and 70° was collected after passing through a cooled tube to condense any alcohol vapour; it consisted mainly of carbon dioxide and methane in nearly equal volumes, with only a very small amount of ethane (see expts. *c* and *d* in the table).

From these experiments, it is evident that the decomposition of acetyl peroxide does not take place to any large extent according to the equation $(CH_3{\cdot}CO{\cdot}O{\cdot})_2 = C_2H_6 + 2CO_2$, and hence there is no reason to suppose that in the electrolysis of acetates, where the gases evolved at the anode are essentially carbon dioxide and ethane, acetyl peroxide has been formed at the anode. It must also be emphasised that methane is not present in the anode gases, although it appears to be one of the necessary products in the decomposition of acetyl peroxide. The only electrolytic formation of methane [illegible] recorded by Baur (*Z. Elektrochem.*, 1923, 29, 105), who used commutated direct current.

There is the possibility that the methane obtained in the above experiments from aqueous solutions of acetyl peroxide may have come from decomposition not of the peroxide itself but of the peracid which is got from it by hydrolysis. It has been shown by Clover and Richmond (*loc. cit.*, p. 184) that a solution of acetyl peroxide kept for 24 hours undergoes the change:

$$CH_3{\cdot}CO{\cdot}O{\cdot}O{\cdot}CO{\cdot}CH_3 + H_2O = CH_3{\cdot}CO{\cdot}O{\cdot}OH + CH_3{\cdot}CO{\cdot}OH.$$

A solution of the peroxide which had been kept for a week liberated almost the whole of the required amount of iodine immediately after the addition of potassium iodide, showing that the change from peroxide to peracid was practically complete (since the former liberates iodine only very slowly). The solution of peracid was heated gradually and at about 40° gas evolution commenced. The gas evolved between 75° and 80° consisted mainly of oxygen, with about 10% of carbon dioxide and no trace of ethane or methane. Hence the decomposition of the peroxide does not proceed through the peracid stage.

In the search for a method whereby acetyl peroxide might be decomposed at lower temperatures than those employed so far, the action of ultra-violet light on the peroxide was investigated: the peroxide decomposed, and larger quantities of ethane were obtained than by any of the previous methods. A solution of acetyl peroxide in aqueous acetic acid was placed in a quartz tube surrounded by a water-cooled quartz condenser and was exposed at a distance of 3 or 4 inches to the light of a mercury vapour lamp. A gas was slowly evolved and after 7 or 8 hours about 5 c.c. had collected. The composition of the gas is shown in the table (expts. *a* and *b*).

Acetyl peroxide.	CO_2.	C_2H_4.	O_2.	CO.	CH_4.	C_2H_6.
a. Dissolved in aqueous acetic acid	75·4	—	1·2	1·4	4·8	17·3
b. „ „ „ „	68·5	—	1·4	1·3	11·8	17·1
c. Solid	66·8	—	1·3	1·2	5·6	25·1
d. „	68·4	2·1	0·7	1·3	3·9	23·6
e. „	67·4	2·0	0·5	1·4	4·4	24·4

In experiments *c*, *d*, and *e*, solid acetyl peroxide was exposed to the ultra-violet light for about 3 hours. The amount of ethane formed was much greater than in the thermal decomposition. Even in this case, however, there is no reason to suppose that the main reaction consists in a simple breaking up of the acetyl peroxide into ethane and carbon dioxide.

Conclusion.

The results of the experiments described in this paper make it appear extremely unlikely that the formation of ethane and carbon dioxide at the anode in the electrolysis of acetates proceeds through the intermediate stage of acetyl peroxide. The view that the discharged acetate ions, which must necessarily be very unstable radicals, react together to give the above-mentioned products still affords the most satisfactory, although perhaps incomplete, explanation of Kolbe's electrosynthesis. In the interaction of these radicals some sort of momentary loose union may well take place prior to a more far-going disruption, but the assumption of the actual formation of the chemically known peroxide is unnecessary and also experimentally unsound. That a small portion of the acetate radicals might unite to form the more stable peroxide would not be surprising, and this possibility is not excluded.

The main arguments against the peroxide theory may be summed up as follows:

(1) The thermal decomposition of acetyl peroxide, both in the pure state and in solution, does not indicate a reaction according to the equation $(CH_3{\cdot}CO{\cdot}O)_2 = C_2H_6 + 2CO_2$.

(2) Methane, which is not found in the anode gases during the

electrolysis of acetates, is always present among the decomposition products of acetyl peroxide, often in large amounts.

(3) Peroxides have not as yet been isolated by electrochemical means, even at low temperatures at which the peroxides are comparatively stable.

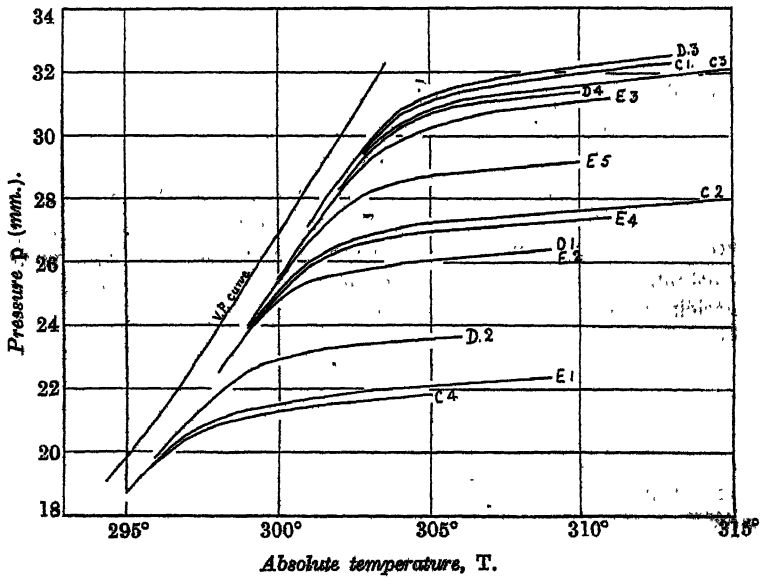
I should like to thank Professor Sir James Walker, F.R.S., for his helpful advice during the course of this work.

UNIVERSITY OF EDINBURGH. [*Received, May 21st,* 1928.]

CCLXVI.—*The Adsorption of Vapours on an Amalgamated Platinum Surface.*

By JOHN WILLIAM SMITH.

THE following experiments are a continuation of those of McHaffie and Lenher (J., 1925, **127**, 1559) and of Lenher (J., 1926, 1785; 1927, 272), who studied the adsorption of water and of benzene vapours on glass, silica, and platinum surfaces at temperatures near the saturation temperature. Assuming the surface to be perfectly plane, they deduced that this adsorption was multimolecular. This hypothesis, however, has been criticised by Fraser, Patrick, and Smith (*J. Physical Chem.*, 1927, **31**, 897) on the ground that the walls of the adsorption vessels employed were not plane, as they had been etched by acid cleaning. This was supported by the observation that the effect was not present in the case of toluene vapour on a freshly-blown glass surface which had not been exposed to moisture. The work here recorded was commenced in the belief that amalgamation of the platinum vessel would produce a perfectly plane surface without the possibility of capillaries in which the adsorbing gas could condense.



EXPERIMENTAL.

The Adsorption of Water Vapour on an Amalgamated Platinum Surface.—The apparatus employed was exactly the type used by McHaffie and Lenher (*loc. cit.*). The platinum vessel, together with a short length of glass tubing, was removed from the U-tube. It was filled with freshly prepared sodium amalgam, the end closed, and the bulb allowed to stand over-night. The amalgam was then removed, and the inside of the vessel washed repeatedly with clean dry mercury. The last traces of the sodium were finally removed by repeated washing with water. The vessel was then replaced in position, care being taken not to heat the platinum vessel so as thereby drive off the mercury from its surface. Blowing

performed through a long tube packed with phosphoric oxide and glass wool so as to prevent the admission of grease. Experiments were then carried out in the manner described by McHaffie and Lenher.

The amalgamated surface was perfectly reproducible, but in no case could a normal vapour-pressure curve be obtained in the amalgamated vessel. The same curve was always reached at the lower temperatures, *viz.*, about 1·3 mm. below the normal vapour pressure. This value was remarkably constant over the temperature range investigated. After thorough cleaning and reamalgamation of the surface, the same curve was always obtained. In each case

FIG. 1.

the vessel was very thoroughly washed for some time after the washings had lost all trace of alkaline reaction. In one case, after a series of readings had been taken, the bulb was disconnected, and again washed about 50 times with water, but exactly the same effect was observed. A selection of the results obtained is given in Table I; T is the absolute temperature, and p the pressure (mm. of mercury at 0°) read at the corresponding temperature. The volume of the platinum bulb was 5·317 c.c. and its internal surface area 15·36 sq. cm.

In Fig. 1, the values of T are plotted as abscissæ against the corresponding pressures p as ordinates. The vapour-pressure curve for water is also given, plotted from the data of Scheel and Heuse

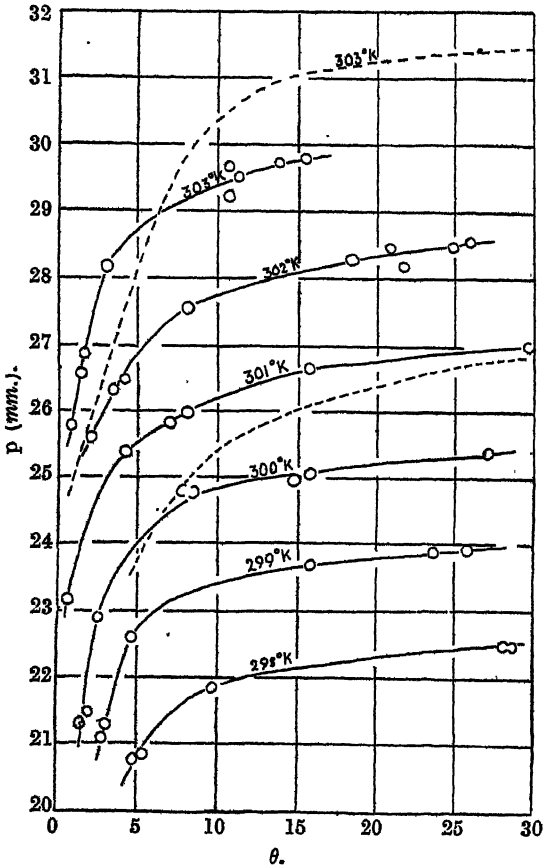
(*Ann. Physik*, 1910, **31**, 715). The series letters C, D, and E refer to different amalgamated surfaces. Between each series the surface was cleaned with nitric acid, washed, and reamalgamated as described above. This treatment did not alter the nature of the platinum surface itself, for the same adsorption curves were obtained before and after treatment.



As in the case of McHaffie and Lenher's experiments, the number of molecules adsorbed per sq. cm. (N/cm.^{2}) is given by

$$N/\text{cm.}^2 = (p/T - p_1/T_1) \times 3{\cdot}359 \times 10^{18},$$

where p is the pressure at some point on the linear portion

experimental curve at the temperature T, and p_1 and T_1 are the corresponding values for the point under consideration. The constant $3{\cdot}359 \times 10^{18}$ is calculated from the dimensions of the platinum vessel. Similarly, the number of molecular layers adsorbed is given by $\theta = (p/T - p_1/T_1) \times 2824$.

FIG. 2.

In Fig. 2, the thickness θ of the adsorbed film is plotted against p, the equilibrium pressure of the film at constant temperature. Small pressure differences become greatly magnified when plotted in this way, and the fact that the results at any one temperature of all three series lie on the same smooth curve attests to the constant nature of the surface. For comparison, two of the isotherms found by McHaffie and Lenher for a platinum surface are also included as broken lines.

The Adsorption of Benzene Vapour on an Amalgamated Platinum Surface.—The adsorption vessel was amalgamated in exactly the same manner as for the previous series of experiments, but in some cases the surface was washed only with dry mercury, whilst in the others it was also washed repeatedly with water. Both surfaces gave the same type of curve, but that washed with water gave the more consistent results. A few of the results obtained with such water-washed surfaces are in Table II.

The number of molecules adsorbed per sq. cm. is given by the same formula as before, and θ is given by $\theta = (p/T - p_1/T_1) \times 1{\cdot}169 \times 10^4$ (Lenher, J., 1927, 276).

FIG. 3.

The adsorption isotherms for a few temperatures are plotted in Fig. 3. In this case, again, the remarkable effect was observed

that the vapour pressure obtained was about 1·6 mm. below the normal value. This was confirmed by introducing benzene till it formed a definite meniscus above the mercury, and then determining the vapour-pressure curve. This followed exactly the curve traced by the lower portions of the other pressure–temperature curves.

Summary.

1. The adsorption of water vapour and of benzene vapour on an amalgamated platinum surface at pressures near the saturation values has been studied.

2. Such a surface is quite permanent in both vapours, but not in the laboratory atmosphere.

3. Both cases show definite effects of the type found by McHaffie and Lenher, and thus support their view that under such conditions multimolecular adsorbed films are produced, in spite of the fact that the surface, being virtually a liquid mercury surface, is presumably incapable of containing capillary cavities of the type postulated by Fraser, Patrick, and Smith.

4. In the amalgamated vessel the vapour pressure of the liquids was always low—to the extent of 1·3 mm. in the case of water and 1·6 mm. with benzene. This was constant throughout the temperature range investigated.

In conclusion, the author desires to express his great indebtedness [redacted] Scientific and Industrial Research for a grant during the tenure of which this research was carried out, and especially to Professor F. G. Donnan, F.R.S., at whose suggestion this work was undertaken, for his kindly advice and criticism during its progress.

THE SIR WILLIAM RAMSAY LABORATORY OF
PHYSICAL AND INORGANIC CHEMISTRY,
UNIVERSITY COLLEGE, LONDON. [*Received, May 15th,* 1928.]

CCLXVII.—*Halogen Derivatives of* o- *and* p-*Azophenol.*

By LOUIS HUNTER and RONALD SIDNEY BARNES.

PREVIOUS attempts to obtain halogen derivatives of *o*- and *p*-azophenol (2 : 2′- and 4 : 4′-dihydroxyazobenzene) have resulted in the isolation of the tetrabromo-compounds (Weselsky and Benedikt, *Annalen*, 1879, **196**, 340) and of a trichloro-*o*-azophenol (Bohn and Heumann, *Ber.*, 1882, **15**, 1499). That the direct [redacted] elementary halogens on these phenols is not entirely [redacted]

substitution is shown by the fact that the latter authors isolated only *s*-trichlorophenol from the action of chlorine upon *p*-azophenol.

The present investigation was originally undertaken with a view to obtaining some of the higher chloro-derivatives of the azophenols, and later as a means of preparation of some substituted aminophenols. So well did these azophenols lend themselves to progressive halogenation that, with the exception of tribromo- and tri-iodo-*o*-azophenol, all the anticipated stages from the mono- to the tetrahalogen substitution products have been obtained, *viz.*, those possessing substituent halogen in positions ortho and para to the hydroxyl groups, although all the possible isomerides were not isolated. The chloroamine method of halogenation (Orton and King, J., 1911, 99, 1185) was used throughout this investigation, toluene-*p*-sulphondichloroamide ("dichloramine-T") being employed (Bradfield, Cooper, and Orton, J., 1927, 2854; Bradfield, Orton, and Roberts, this vol., p. 782). The bromo-compounds described are the first to be prepared by the chloroamine method, thus bringing bromination into line with chlorination and iodination in this respect. The results amply illustrate the extreme delicacy of the chloroamine method.

The positions taken up in the azophenol molecules by the substituent halogen atoms were readily determined by reduction to the corresponding aminophenols, and it was thus found that *p*-azophenol yielded only the 3 : 3′- and not the 3 : 5-dihalogeno-derivative on dihalogenation, and that in the mono-substituted *o*-azophenols the halogen atom occupied the 5-position apparently to the exclusion of the 3-position.

Owing to its structure *p*-azophenol is more liable to oxidation than its *o*-isomeride, and instead of substitution iodinating agents cause partial oxidation to a quinhydrone-like complex,

$$O{:}C_6H_4{:}N{\cdot}N{:}C_6H_4{:}O,HO{\cdot}C_6H_4{\cdot}N{:}N{\cdot}C_6H_4{\cdot}OH,$$

which on further oxidation is transformed into *p*-quinoneazine, $O{:}C_6H_4{:}N{\cdot}N{:}C_6H_4{:}O$. Iodination of *p*-azophenol or of its derivatives by all the usual methods was unsuccessful, though *o*-azophenol was iodinated normally.

The action of more than four equivalents of halogenating agent led in the chlorination of *p*-azophenol to the production of complex chloroquinones of a type similar to *p*-quinoneazine which have not been further investigated, but in all other cases yielded the tetra-substituted compound.

Experimental.

o- and *p*-Azophenols were prepared by Willstätter's modification (*Ber.*, 1906, **39**, 3492) of Weselsky and Benedikt's method (*loc. cit.*). As pointed out by Robertson (J., 1913, **103**, 1472), *p*-azophenol

monohydrate obtained by this method is the *trans*-form; and the compounds described in the present work retain the *trans*-configuration, since tetra-substituted derivatives are readily obtained. Similar arguments apply to *o*-azophenol, although no second modification of this compound has yet been obtained.

In the following account the typical procedure is described in detail for a chlorination, a bromination, and an iodination; all other halogenations are similar unless special precautions are mentioned. In most preparations, and more particularly in iodinations, acetic acid stable to halogens (Orton and Bradfield, J., 1924, **125**, 960) was used as a solvent.

Derivatives of p-*Azophenol* (4 : 4′-*Dihydroxyazobenzene*).—3-*Chloro*-4 : 4′-*dihydroxyazobenzene*. *p*-Azophenol (1·5 g.) was dissolved in glacial acetic acid (600 c.c.) and mixed with a solution of dichloramine-T (0·82 g.) in acetic acid (30 c.c.). A few drops of dilute hydrochloric acid were added, and the mixture was kept in the dark for about ½ hour; chlorination was then complete as shown by the absence of free chlorine. Since dilution with 1 l. of water failed to precipitate the product, caustic soda was added until the mixture was almost neutral. The brown deposit formed was washed, dried, and crystallised from 20% aqueous alcohol, giving fine red granules (1·1 g.), m. p. 184° (Found : Cl, 14·7. $C_{12}H_9O_2N_2Cl$ requires Cl, 14·3%).

The constitution of the compound was fixed by reduction with stannous chloride and hydrochloric acid, and isolation of a mixture of aminophenols; moreover, on further chlorination the substance was transformed into 3 : 3′-dichloro-4 : 4′-dihydroxyazobenzene, the constitution of which has been proved.

3-*Chloro*-4 : 4′-*diacetoxyazobenzene* crystallised from alcohol in fine orange needles, m. p. 160—161°, and the *dibenzoyl* derivative in yellow needles, m. p. 158—159°.

3 : 3′-*Dichloro*-4 : 4′-*dihydroxyazobenzene* formed rust-red needles, m. p. 195°, from alcohol (Found : Cl, 24·7. $C_{12}H_8O_2N_2Cl_2$ requires Cl, 25·0%). Reduction with stannous chloride yielded *o*-chloro-*p*-aminophenol. The *diacetyl* derivative crystallised from alcohol in fine orange needles, m. p. 199°, and the *dibenzoyl* derivative from benzene in bright yellow needles, m. p. 226°.

3 : 5 : 3′-*Trichloro*-4 : 4′-*dihydroxyazobenzene* formed yellow-brown needles, m. p. 172°, from 50% aqueous alcohol (Found : Cl, 33·4. $C_{12}H_7O_2N_2Cl_3$ requires Cl, 33·5%). Reduction with stannous chloride and hydrochloric acid gave a mixture of the hydrochlorides of a mono- and a di-chloro-*p*-aminophenol, and on further chlorination the compound yielded 3 : 5 : 3′ : 5′-tetrachloro-4 : 4′-dihydroxyazobenzene, of known constitution.

The *diacetyl* derivative crystallised from benzene in fine orange needles, m. p. 207—208°, and the *dibenzoyl* derivative in yellow prisms, m. p. 189°.

3 : 5 : 3′ : 5′-*Tetrachloro*-4 : 4′-*dihydroxyazobenzene* was isolated as the hexahydrate, which formed fine yellow needles, m. p. 225°, from aqueous acetic acid (Found: H_2O, 22·9. $C_{12}H_6O_2N_2Cl_4,6H_2O$ requires H_2O, 23·4%). The anhydrous substance had m. p. 240° (Found: Cl, 40·4. $C_{12}H_6O_2N_2Cl_4$ requires Cl, 40·3%). Its product of reduction was 2 : 6-dichloro-4-aminophenol, m. p. 165°. Its *diacetyl* derivative formed yellow needles, m. p. 240°, from alcohol, and the *dibenzoyl* derivative orange needles, m. p. 244°, from benzene.

3-*Bromo*-4 : 4′-*dihydroxyazobenzene*. A solution of *p*-azophenol (2 g.) in stable acetic acid (600 c.c.) was treated with a solution of the brominating agent prepared by mixing solutions of dichloramine-T (1·6 g.) in acetic acid (50 c.c.) and potassium bromide (1·5 g.) in water (20 c.c.). After 30 minutes no free bromine could be detected, and the product was precipitated by partly neutralising the acetic acid and diluting the mixture with water. The product crystallised from aqueous alcohol in yellow needles (2·6 g.), m. p. 153°, which rapidly darkened on exposure to light (Found: Br, 26·9. $C_{12}H_9O_2N_2Br$ requires Br, 27·3%).

Reduction afforded a mixture of *p*-aminophenol and its monobromo-compound, and the constitution of the azophenol was confirmed by further bromination, yielding 3 : 3′-dibromo-4 : 4′-dihydroxyazobenzene (see below).

3-*Bromo*-4 : 4′-*diacetoxyazobenzene* crystallised from benzene in orange needles, m. p. 142°, and the *dibenzoyl* derivative in yellow prisms, m. p. 165—166°.

3 : 3′-*Dibromo*-4 : 4′-*dihydroxyazobenzene* crystallised from alcohol in light brown needles, m. p. 175°, which darkened on exposure (Found: Br, 42·4. $C_{12}H_8O_2N_2Br_2$ requires Br, 43·0%). Reduction yielded *o*-bromo-*p*-aminophenol, m. p. 154°, thus confirming the constitution of the azophenol.

The *diacetyl* derivative crystallised from alcohol in yellow-orange needles, m. p. 161°, and the *dibenzoyl* derivative from benzene in pale yellow needles, m. p. 227°.

3 : 5 : 3′-*Tribromo*-4 : 4′-*dihydroxyazobenzene* crystallised from aqueous alcohol in brown needles, m. p. 184° (Found: Br, 53·1. $C_{12}H_7O_2N_2Br_3$ requires Br, 53·0%). It gave a mixture of mono- and di-bromo-*p*-aminophenols on reduction, and by further bromination, 3 : 5 : 3′ : 5′-tetrabromo-4 : 4′-dihydroxyazobenzene, the constitution of which has been proved.

3 : 5 : 3′-*Tribromo*-4 : 4′-*diacetoxyazobenzene* crystallised from

alcohol in light brown prisms, m. p. 172°, and the *dibenzoyl* derivative from benzene in yellow needles, m. p. 216°.

3 : 5 : 3′ : 5′-Tetrabromo-4 : 4′-dihydroxyazobenzene was obtained as yellow-brown needles, m. p. 252° (decomp.), from acetic acid (Found: Br, 60·4. Calc.: Br, 60·4%), and was identical with the substance described by Weselsky and Benedikt (*loc. cit.*); it yielded 2 : 6-dibromo-4-aminophenol, m. p. 190°, on reduction. The *diacetyl* derivative formed yellow granules, m. p. 240°, from benzene, and the *dibenzoyl* derivative orange needles, m. p. 265°.

3 : 3′-*Dichloro*-5 : 5′-*dibromo*-4 : 4′-*dihydroxyazobenzene*. 3 : 3′-Dichloro-4 : 4′-dihydroxyazobenzene was brominated completely, with 2 equivs. of the brominating agent, in 15 minutes, and a quantity of the product separated; the remainder was obtained by dilution with water. It crystallised from alcohol in fine yellowish-red needles, m. p. 262° (Found: Ag halides/original weight, 151·7. $C_{12}H_6O_2N_2Cl_2Br_2$ requires 150·4%). It reduced to 2-chloro-6-bromo-4-aminophenol, m. p. 177° (decomp.) (compare Raiford, *Amer. Chem. J.*, 1911, 46, 422).

Action of Iodine Chloride on p-*Azophenol*.—Solutions of *p*-azophenol (1 g.) in stable acetic acid (230 c.c.) and of dichloramine-T (0·6 g.) and potassium iodide (0·72 g.) in acetic acid (50 c.c.) were mixed. After 25 minutes the iodine chloride had disappeared and purple granules were deposited (0·8 g.) which crystallised from alcohol in bluish-black needles, m. p. 185° (Found: N, 12·8. Calc.: N, 13·2%). The compound was identified as the quinhydroneazine (Willstätter and Benz, *Ber.*, 1906, 39, 3482) by reduction with sulphur dioxide to *p*-azophenol (m. p. 204°), by stronger reduction to *p*-aminophenol (m. p. 183°), by oxidation in dry ether solution with dry silver oxide to quinoneazine (m. p. 158°), and by a mixed melting-point determination with an authentic specimen prepared by the method of these authors. The same substance was given by the action of excess of the iodinating agent on *p*-azophenol.

Derivatives of o-*Azophenol* (2 : 2′-*Dihydroxyazobenzene*).—5-*Chloro*-2 : 2′-*dihydroxyazobenzene* formed fine brown granules, m. p. 164°, from aqueous alcohol (Found: Cl, 14·4. $C_{12}H_9O_2N_2Cl$ requires Cl, 14·3%). Its constitution was decided by further chlorination to 5 : 5′-dichloro-2 : 2′-dihydroxyazobenzene.

5-*Chloro*-2 : 2′-*diacetoxyazobenzene* crystallised from alcohol in fine orange needles, m. p. 117°, and the *dibenzoyl* derivative in brown prisms, m. p. 119°.

5 : 5′-*Dichloro*-2 : 2′-*dihydroxyazobenzene* was obtained in orange-yellow needles, m. p. 267°, from alcohol (Found: Cl, 25·2. $C_{12}H_8O_2N_2Cl_2$ requires Cl, 25·1%). On reduction with stannous chloride and hydrochloric acid and removal of tin, a hydrochlo-

was obtained which was immediately converted into the acetyl compound by means of acetic anhydride and sodium acetate. The product formed white needles, m. p. 170°, from alcohol, and was proved to be 4-*chloro*-2-*acetamidophenyl acetate* (Found: Cl, 14·5. $C_{10}H_{10}O_3NCl$ requires Cl, 15·6%) by comparison with the compound (m. p. and mixed m. p. 170°) produced by the reduction and subsequent acetylation of *p*-chloro-*o*-nitrophenol.

5 : 5′-*Dichloro*-2 : 2′-*diacetoxyazobenzene* crystallised in orange-red needles, m. p. 199°, from alcohol, and the *dibenzoyl* derivative formed pale brown needles, m. p. 243°.

3 : 5 : 5′-Trichloro-2 : 2′-dihydroxyazobenzene was obtained by the usual method as orange needles, m. p. 235°, from benzene, identical with the product prepared by the method of Bohn and Heumann (*loc. cit.*). Its constitution was proved by its further chlorination to the 3 : 5 : 3′ : 5′-tetrachloro-compound. The *diacetyl* derivative crystallised from alcohol in pale orange prisms, m. p. 189°, and the *dibenzoyl* derivative in yellow-brown granules, m. p. 247°, from benzene.

3 : 5 : 3′ : 5′-*Tetrachloro*-2 : 2′-*dihydroxyazobenzene* formed silky, orange-red needles, m. p. 246—247°, from benzene (Found: Cl, 40·2. $C_{12}H_6O_2N_2Cl_4$ requires Cl, 40·4%). By reduction with stannous chloride a *hydrochloride* (Found: Cl as chloride, 16·2; total Cl, 50·1. $C_6H_5ONCl_2,HCl$ requires Cl as chloride, 16·5; total Cl, 49·6%) was obtained. The corresponding *base*, m. p. 107° (decomp.), was identical with 2 : 4-*dichloro*-6-*aminophenol*, m. p. 109° (decomp.), prepared by the reduction of 2 : 4-dichloro-6-nitrophenol (Fischer, *Annalen*, 1870, Spt. 7, 193). A mixture of the two specimens had m. p. 107°.

3 : 5 : 3′ : 5′-*Tetrachloro*-2 : 2′-*diacetoxyazobenzene* crystallised from alcohol in pink needles, m. p. 195°, and the *dibenzoyl* derivative in yellowish-brown prisms, m. p. 186°.

5-*Bromo*-2 : 2′-*dihydroxyazobenzene* formed a brown, microcrystalline solid, m. p. 154°, from aqueous alcohol (Found: Br, 27·1. $C_{12}H_9O_2N_2Br$ requires Br, 27·3%). Further bromination gave the 5 : 5′-dibromo-compound.

5-*Bromo*-2 : 2′-*diacetoxyazobenzene* formed dark orange needles, m. p. 142°, and 5-*bromo*-2 : 2′-*dibenzoyloxyazobenzene* crystallised from benzene in light brown needles, m. p. 215°.

5 : 5′-*Dibromo*-2 : 2′-*dihydroxyazobenzene* was obtained from alcohol in orange-red needles, m. p. 249° (Found: Br, 42·65. $C_{12}H_8O_2N_2Br_2$ requires Br, 43·0%). On reduction it gave *p*-bromo-*o*-aminophenol hydrochloride (Found: Ag halides/original weight, 146·8. Calc., 147·6%), from which the base was obtained as a white

crystalline solid, m. p. 87° (Schlieper, *Ber.*, 1893, **26**, 2469, records m. p. 88°).

5 : 5′-*Dibromo*-2 : 2′-*diacetoxyazobenzene* crystallised from benzene in orange granules, m. p. 211°, and the *dibenzoyl* derivative in pale brown needles, m. p. 202°.

3 : 3′ : 5 : 5′-Tetrabromo-2 : 2′-dihydroxyazobenzene obtained by the chloroamine method of bromination formed orange-brown needles, m. p. 262°, from benzene (Found : Br, 59·7. Calc. : Br, 60·3%), identical with the substance prepared by Weselsky and Benedikt's method (*loc. cit.*). Its constitution was assumed by these authors, but has now been established by reduction of the compound to 2 : 4-dibromo-6-aminophenol, m. p. 97—98° (Thiele and Eichwede, *Annalen*, 1900, **311**, 373, gave m. p. 98—99°), the hydrochloride of which was analysed for halogen (Found : Ag halides/original weight, 170·5. Calc., 171·2%).

3 : 5 : 3′ : 5′-*Tetrabromo*-2 : 2′-*diacetoxyazobenzene* crystallised from benzene in brown granules, m. p. 210—211°, and the *dibenzoyl* derivative in coarse orange granules, m. p. 214°.

5-*Iodo*-2 : 2′-*dihydroxyazobenzene*. *o*-Azophenol (2 g.) was dissolved in stable acetic acid (200 c.c.), and a solution of 33% excess over one equivalent of iodinating agent added. The latter was generated by adding finely powdered potassium iodide (2·1 g.) slowly with shaking to a solution of dichloramine-T (1·5 g.) in acetic acid (100 c.c.). The mixture was gently warmed on the water-bath, and the course of the reaction was followed by titrating 10 c.c. of the mixture at 10-minute intervals with thiosulphate. When the titre had fallen to one-quarter of the original value, the mixture was cooled and the excess of iodine was destroyed by addition of a solution of sodium sulphite. Dilution with water yielded a brown precipitate which crystallised from alcohol in brown needles (2·2 g.), m. p. 149—150° (Found : I, 37·3. $C_{12}H_9O_2N_2I$ requires I, 37·4%). Further iodination yielded the 5 : 5′-di-iodo-compound.

5-*Iodo*-2 : 2′-*diacetoxyazobenzene* crystallised from benzene in brown prisms, m. p. 138°, and the *dibenzoyl* derivative from alcohol in pale brown needles, m. p. 159°.

5 : 5′-*Di-iodo*-2 : 2′-*dihydroxyazobenzene*, prepared by the treatment of *o*-azophenol with two equivalents of iodinating agent, crystallised from alcohol in brown needles, m. p. 153° (Found : I, 54·2. $C_{12}H_8O_2N_2I_2$ requires I, 54·5%).

Reduction yielded the *hydrochloride* of p-*iodo*-o-*aminophenol* (Found : Ag halides/original weight, 138·8. C_6H_7ONClI requires 139·4%), from which the *base* was obtained in white needles, m. p.

139°; it was identical with the product formed by reducing *p*-iodo-*o*-nitrophenol.

5 : 5′-*Di-iodo*-2 : 2′-*diacetoxyazobenzene* formed dark brown granules, m. p. 145°, from alcohol, and the *dibenzoyl* derivative pale brown needles, m. p. 147°.

3 : 5 : 3′ : 5′-*Tetraiodo*-2 : 2′-*dihydroxyazobenzene* was obtained in the usual way in brown needles, m. p. 98—99°, from benzene (Found: I, 70·65. $C_{12}H_6O_2N_2I_4$ requires I, 70·8%). On reduction it gave the *hydrochloride* of 2 : 4-*di-iodo*-6-*aminophenol* (Found: Ag halides/original weight, 157·1. $C_6H_5ONI_2,HCl$ requires 154·4%), from which the *base* was obtained as white needles, m. p. 120°, identical with the substance obtained by the reduction of 2 : 4-di-iodo-6-nitrophenol; a mixture of the two substances melted at 120·5°.

3 : 5 : 3′ : 5′-*Tetraiodo*-2 : 2′-*dibenzoyloxyazobenzene* formed grey-brown needles, m. p. 241°, from alcohol. The corresponding diacetyl compound was not prepared, since hot acetic anhydride caused decomposition of the azophenol.

Analytical Note.—In this and the following paper mixed halogen analyses were conducted by the Carius method, and expressed either as percentages of each halogen or as a percentage ratio of the weight of the mixed silver halides to the original weight of the substance, according to whether or not the mixed silver halides were converted into silver chloride and reweighed.

CCLXVIII.—*The Preparation of Some Halogenoaminophenols. Part I. Mixed Tetrahalogen Derivatives of o-Azophenol. Part II. Halogen Derivatives of p-Hydroxyazobenzene.*

By LOUIS HUNTER and RONALD SIDNEY BARNES.

Part I. Mixed Tetrahalogen Derivatives of o-Azophenol.

THE method employed for the preparation of substituted aminophenols in this research is based on the ease of reduction of *o*- and *p*-azophenol and their derivatives (see preceding paper). It has been shown (*loc. cit.*) that the primary product of the reaction between two molecules of halogen and one of *o*-azophenol is the 5 : 5′-disubstituted compound, and that further halogenation fills the 3- and 3′-positions. This property allows of the preparation of two isomerides of each of dichlorodibromo-, dichlorodi-iodo-,

and dibromodi-iodo-*o*-azophenol, the reduction of which should give rise to the six theoretically possible mixed 2 : 4-dihalogeno-6-aminophenols; five are described in this paper.

In the preparation of the mixed tetrahalogeno-*o*-azophenols it was not usually necessary to isolate the dihalogen compound from the solvent medium, since, by using the calculated quantity of halogenating agent, substitution of one halogen for hydrogen could be followed by substitution of a second in the same solution. In the case of the 5 : 5'-di-iodo-compounds, however, preliminary isolation of the di-iodo-stage was essential, since it is usual to employ excess of the iodinating agent, the excess being ultimately removed by addition of sodium sulphite. Use of a further quantity of chloroamine in the same solution, whether for chlorination or bromination, would naturally lead to further iodination [illegible]

EXPERIMENTAL.

The same methods of halogenation were used as in the preceding work, although in some cases acetochloroamide was employed instead of dichloramine-T as a source of halogen. The advantage of the former is that its product of hydrolysis (acetamide) is soluble in water, and therefore does not contaminate the halogenated material when this is isolated from acetic acid solution by dilution with water. Analyses are expressed as before (*loc. cit.*, analytical note).

5 : 5'-*Dichloro*-3 : 3'-*dibromo*-2 : 2'-*dihydroxyazobenzene*. — *o*-Azophenol (2 g.) dissolved in stable acetic acid (500 c.c.) was chlorinated to the dichloro-stage by the addition of a solution of dichloramine-T (2·3 g.) in acetic acid (100 c.c.) with the addition of a few drops of dilute hydrochloric acid. When free chlorine could no longer be detected (20 minutes), the solution was reduced to about half its bulk by distillation under reduced pressure. Bromination was then effected by adding to the warmed mixture a solution of dichloramine-T (2·55 g.) in acetic acid (50 c.c.) to which had been added potassium bromide (2·25 g.) in water (10 c.c.). When the mixture was cooled, the *chlorobromo*-compound separated in orange-red prisms. A further quantity was obtained by removing part of the solvent by distillation under diminished pressure. It crystallised from benzene in needles of the same colour, m. p. 259° (decomp.); yield, 3·0 g. (Found: Cl, 15·3; Br, 36·7. $C_{12}H_6O_2N_2Cl_2Br_2$ requires Cl, 16·1; Br, 36·3%).

The *diacetyl* derivative crystallised from alcohol in pale orange needles, m. p. 203°, and the *dibenzoyl* derivative formed fine orange granules, m. p. 212°, from benzene and ligroin.

4-*Chloro*-6-*bromo*-2-*aminophenol*. — The above azophenol was decolorised with a warm mixture of stannous chloride and hydrochloric acid. After removal of tin from the solution with hydrogen sulphide, the residue yielded small white, prismatic crystals of the *aminophenol hydrochloride* (Found: Cl, 27·1; Br, 30·8. $C_6H_5ONClBr,HCl$ requires Cl, 27·4; Br, 30·9%). The *base*, liberated from the hydrochloride by means of aqueous sodium bicarbonate, formed fine white needles, m. p. 89—90°, from aqueous alcohol.

4-*Chloro*-6-*bromo*-2-*acetamidophenyl acetate* formed fine white needles, m. p. 130° (Found: Ag halides/original weight, 107·5. $C_{10}H_9O_3NClBr$ requires 108·1%), and 4-*chloro*-6-*bromo*-2-*benzamidophenyl benzoate* silky white needles, m. p. 180·5° (Found: Ag halides/original weight, 76·38. $C_{20}H_{13}O_3NClBr$ requires 76·98%), from aqueous alcohol.

3 : 3'-*Dichloro*-5 : 5'-*dibromo*-2 : 2'-*dihydroxyazobenzene*, prepared from *o*-azophenol, in a similar manner to its isomeride above, by bromination followed by chlorination, crystallised from benzene in fine orange-red needles, m. p. 263° (Found : Cl, 15·9; Br, 36·4%).

The *diacetyl* derivative crystallised from benzene in silky orange needles, m. p. 199°, and the *dibenzoyl* derivative from benzene and ligroin as an orange powder, m. p. 201°.

6-*Chloro*-4-*bromo*-2-*aminophenol* was obtained as its *hydrochloride* (Found : Cl, 27·4; Br, 31·6%) by reduction of the above azophenol with stannous chloride and hydrochloric acid. The *base* crystallised from aqueous alcohol in white prisms, m. p. 93°.

6-*Chloro*-4-*bromo*-2-*acetamidophenyl acetate* formed white prisms, m. p. 137°, from alcohol (Found : Ag halides/original weight, 108·3%), and 6-*chloro*-4-*bromo*-2-*benzamidophenyl benzoate* crystallised in silky white needles, m. p. 182° (Found : Ag halides/original weight, 76·05%).

5 : 5'-*Dichloro*-3 : 3'-*di-iodo*-2 : 2'-*dihydroxyazobenzene*. — *o*-Azophenol (2 g.) was chlorinated to the dichloro-stage, the solvent acetic acid (600 c.c.) was reduced by distillation to one-third of its bulk, and the dichloro-compound was then iodinated without isolation by the addition of a solution of iodine chloride (2·33 mols.) prepared by dissolving acetochloroamide (2·35 g.) and potassium iodide (4·2 g.) in acetic acid (150 c.c.). The whole solution was made up to 500 c.c. with acetic acid and warmed on a water-bath, specimens of 5 c.c. being withdrawn at 5-minute intervals. After 90 minutes the titre showed that two molecules of iodine chloride had been used, and the solution was cooled and the excess of iodine destroyed by the addition of aqueous sodium sulphite. On removal of the bulk of the solvent by distillation, the dichlorodi-iodo-compound separated as a brown precipitate. A further quantity was obtained by diluting the filtrate with water. It formed orange-yellow needles (4·1 g.) from benzene, which on heating rapidly had m. p. 272° (decomp.) (Found : Cl, 13·1; I, 47·4. $C_{12}H_6O_2N_2Cl_2I_2$ requires Cl, 13·3; I, 47·5%).

The *diacetyl* derivative crystallised from benzene in silky orange needles, m. p. 205°, and the *dibenzoyl* derivative in light brownish needles, m. p. 254°.

4-*Chloro*-6-*iodo*-2-*aminophenol* was obtained, by the reduction of the above azophenol, in the form of its *hydrochloride*, which crystallised from water in small white prisms (Found : Cl, 23·3; I, 40·6. C_6H_5ONClI,HCl requires Cl, 23·2; I, 41·5%). The *base* formed white needles from aqueous alcohol, having no definite melting point but charring at about 90°.

4-*Chloro*-6-*iodo*-2-*acetamidophenyl acetate* formed silky

needles, m. p. 169°, from aqueous alcohol (Found: Ag halides/original weight, 107·9. $C_{10}H_9O_3NClI$ requires 107·1%).

5 : 5'-Dibromo-3 : 3'-di-iodo-2 : 2'-dihydroxyazobenzene was prepared from *o*-azophenol by bromination followed by iodination as in the preceding example. It crystallised from alcohol in light brown needles (yield, 83%), m. p. 255° (decomp.) (Found: Ag halides/original weight, 134·8. $C_{12}H_6O_2N_2Br_2I_2$ requires 135·6%). The *diacetyl* derivative crystallised from benzene and ligroin in pale orange needles, m. p. 186°, and the *dibenzoyl* derivative in pale brown needles, m. p. 252°.

4-Bromo-6-iodo-2-aminophenol hydrochloride, produced by the reduction of the above dibromodi-iodo-compound, formed creamy white flakes (Found: Cl, 10·1; Br, 22·95; I, 35·8. C_6H_5ONBrI,HCl requires Cl, 10·1; Br, 22·8; I, 36·2%). The *base* crystallised from alcohol in fine white needles which decomposed before melting.

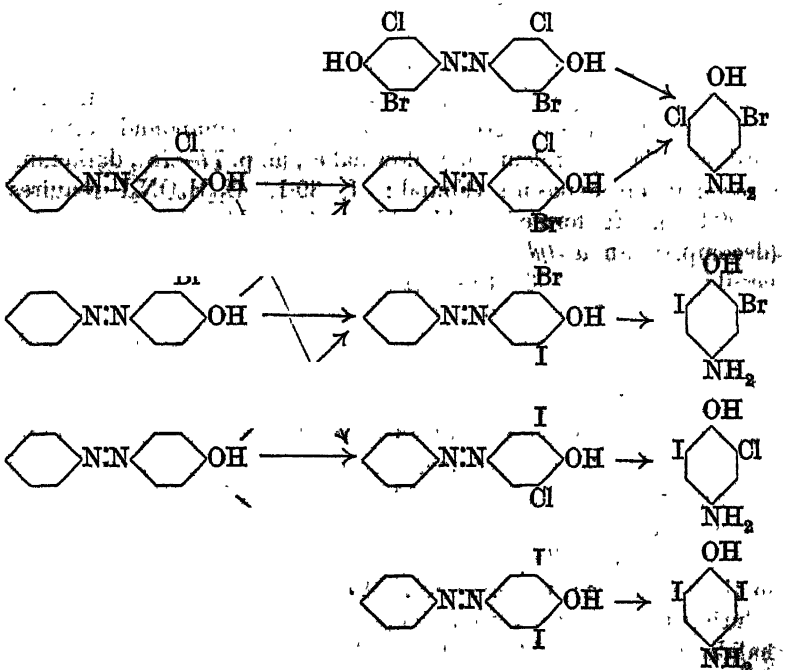
4-Bromo-6-iodo-2-acetamidophenyl acetate crystallised from alcohol in silky white needles, m. p. 190° (decomp.) (Found: Ag halides/original weight, 106·7. $C_{10}H_9O_3NBrI$ requires 106·3%), and *4-bromo-6-iodo-2-benzamidophenyl benzoate* from aqueous alcohol in white prisms, m. p. 185° (Found: Ag halides/original weight, 80·9. $C_{20}H_{13}O_3NBrI$ requires 81·02%).

3 : 3'-Dibromo-5 : 5'-di-iodo-2 : 2'-dihydroxyazobenzene.—5 : 5'-Di-iodo-2 : 2'-dihydroxyazobenzene was isolated as described in the previous paper. It was then brominated with two equivalents of the brominating agent, and the dibromodi-iodo-compound was isolated as orange-red needles, m. p. 256°, after three crystallisations from benzene (Found: Br, 25·9; I, 40·2. $C_{12}H_6O_2N_2Br_2I_2$ requires Br, 25·6; I, 40·7%).

The *diacetyl* derivative crystallised from benzene in golden needles, m. p. 217°, and the *dibenzoyl* derivative in orange-red prisms, m. p. 215°.

6-Bromo-4-iodo-2-aminophenol was obtained by reduction of the above azophenol with stannous chloride and hydrochloric acid, removal of the tin, and decolorisation of the solution by boiling with animal charcoal, as its *hydrochloride* (Found: Ag halides/original weight, 162·9. C_6H_5ONBrI,HCl requires 161·5%), white, crystalline flakes. The *base* formed needles, m. p. 90°, from alcohol.

6-Bromo-4-iodo-2-acetamidophenyl acetate crystallised from aqueous alcohol in pearl-white, silky needles, m. p. 196° (Found: Ag halides/original weight, 106·7. $C_{10}H_9O_3NBrI$ requires 106·3%), and *6-bromo-4-iodo-2-benzamidophenyl benzoate* in fine white needles, m. p. 194—195° (Found: Ag halides/original weight, 80·67. $C_{20}H_{13}O_3NBrI$ requires 81·02%).



3 : 3'-Dichloro-5 : 5'-di-iodo-2 : 2'-dihydroxyazobenzene.—Repeated

attempts to chlorinate 5 : 5′-di-iodo-2 : 2′-dihydroxyazobenzene as described above, with two equivalents of chlorinating agent, yielded a dark brown, amorphous powder which could not be crystallised, and decomposed above 200° without melting. Although its analysis approximated to that calculated for $C_{12}H_6O_2N_2Cl_2I_2$, it was not considered sufficiently pure to be used for the preparation of derivatives, or for reduction to the corresponding aminophenol.

Part II. Halogen Derivatives of p-*Hydroxyazobenzene.*

As iodo-*p*-azophenols could not be prepared (preceding paper), iodine-substituted *p*-aminophenols were obtained by reducing the iodo-derivatives of *p*-hydroxyazobenzene, which are readily accessible; they were separated from the aniline simultaneously formed by means of the difference in solubility of the hydrochlorides.

Direct halogenation of *p*-hydroxyazobenzene gave the 3 : 5-dihalogeno-compounds (compare Hewitt and Aston, J., 1900, 77, 712, 810). The monohalogen derivatives were therefore synthesised by coupling diazotised aniline with the *o*-halogenophenols.

The duplicate methods of preparation of the mixed dihalogen compounds (see scheme) place beyond doubt their constitution, that of the aminophenols derived from them.

Experimental.

The dihalogen derivatives of *p*-hydroxyazobenzene described below were prepared by the chloroamine method.

3-Chloro-4-hydroxyazobenzene was obtained (yield, 70%) by coupling benzenediazonium chloride with *o*-chlorophenol. It crystallised from aqueous alcohol in yellow prisms, m. p. 88·5° (Farmer and Hantzsch, *Ber.*, 1899, **32**, 3089, give m. p. 88°).

3-*Bromo*-4-*hydroxyazobenzene*.—Carefully purified *o*-bromophenol was coupled with the required quantity of diazotised aniline, the mixture being kept strongly alkaline to prevent precipitation of the hydrochloride of the azo-compound. When coupling was complete, the solution was cautiously neutralised by the addition during some hours of dilute acetic acid; rapid neutralisation precipitated the azo-compound as an oil. The solid product crystallised from light petroleum in fine yellow needles, m. p. 80°; yield, 90% (Found: Br, 28·7. $C_{12}H_9ON_2Br$ requires Br, 28·9%). It gave a purple-brown crystalline *hydrochloride*, m. p. 159°. The *acetyl* derivative formed yellow-brown plates, m. p. 98° (Found: Br, 24·9. $C_{14}H_{11}O_2N_2Br$ requires Br, 25·1%), and the *benzoyl* derivative crystallised from aqueous alcohol in brown needles, m. p. 113° (Found: Br, 21·0. $C_{19}H_{13}O_2N_2Br$ requires Br, 21·0%).

3-*Iodo*-4-*hydroxyazobenzene*, prepared (yield, 85%) by a method analogous to that described for the bromo-compound, crystallised from light petroleum as yellow flakes, m. p. 77—78°, darkening somewhat on exposure (Found: I, 39·1. $C_{12}H_9ON_2I$ requires I, 39·2%). It formed a blue-black *hydrochloride*, m. p. 172° (decomp.); an *acetyl* compound, crystallising in slender orange needles, m. p. 103—104° (Found: I, 34·9. $C_{14}H_{11}O_2N_2I$ requires I, 34·7%); and a *benzoyl* derivative, crystallising from alcohol in pale orange needles, m. p. 105° (Found: I, 30·1. $C_{19}H_{13}O_2N_2I$ requires I, 29·7%).

3-*Chloro*-5-*bromo*-4-*hydroxyazobenzene*. — (*a*) 3-Chloro-4-hydroxyazobenzene (1·5 g.) was dissolved in stable acetic acid (40 c.c.) and treated with a solution of acetochloroamide (0·6 g.) in acetic acid (30 c.c.) to which had been added potassium bromide (1·5 g.) in water (10 c.c.). The *chlorobromo*-compound soon began to separate in fine orange needles, which crystallised from aqueous acetic acid in the same form, m. p. 125·5°. A further crop was obtained by diluting the mixture with water; total yield, 1·6 g. (Found: Ag halides/original weight, 105·9. $C_{12}H_8ON_2ClBr$ requires 106·4%).

(*b*) A solution of 5-bromo-4-hydroxyazobenzene (4·0 g.) in acetic acid (35 c.c.) was chlorinated by the addition of a solution of dichloramine-T (1·8 g.) in acetic acid (15 c.c.) and a few drops of dilute hydrochloric acid. Separation of the product commenced

immediately, and chlorination was complete in ½ hour. A further crop was obtained by diluting the solution with an equal volume of water; total yield, 3·5 g., m. p. 125°. A mixture with the substance prepared by method (*a*) had m. p. 125·0°.

The *acetyl* derivative crystallised from aqueous alcohol in orange-brown needles, m. p. 133·5° (Found: Ag halides/original weight, 93·43. $C_{14}H_{10}O_2N_2ClBr$ requires 93·76%), and the *benzoyl* derivative from benzene and ligroin in orange prisms, m. p. 118·5° (Found: Ag halides/original weight, 79·12. $C_{19}H_{12}O_2N_2ClBr$ requires 79·75%).

As a final proof of the constitution of the chlorobromo-*p*-hydroxyazobenzene, specimens reduced with stannous chloride and hydrochloric acid yielded 2-chloro-6-bromo-4-aminophenol, m. p. 177° (decomp.), identical with the substance prepared as described on p. 2055.

2-*Chloro*-6-*bromo*-4-*acetamidophenyl acetate* crystallised from alcohol in fine white needles, m. p. 168·5° (Found: Ag halides/original weight, 107·1. $C_{10}H_9O_3NClBr$ requires 107·9%), and 2-*chloro*-6-*bromo*-4-*benzamidophenyl benzoate* in white platelets, m. p. 111—112° (Found: Ag halides/original weight, 76·65. $C_{20}H_{13}O_3NClBr$ requires 76·81%).

3-*Chloro*-5-*iodo*-4-*hydroxyazobenzene*. — (*a*) The chlorination of 5-iodo-4-hydroxyazobenzene was conducted in the usual way in acetic acid solution, dichloramine-T (1 equiv.) being used in the presence of a few drops of dilute hydrochloric acid. The product (yield, 60%) crystallised from ligroin as a fine brown powder, m. p. 110·5° (Found: Cl, 9·5; I, 35·5. $C_{12}H_8ON_2ClI$ requires Cl, 9·9; I, 35·4%).

(*b*) 3-Chloro-4-hydroxyazobenzene (5 g.) dissolved in acetic acid (150 c.c.) was treated with a solution of iodine chloride (1 mol.) generated by shaking together acetochloroamide (2·75 g.), finely powdered potassium iodide (4 g.), and acetic acid (100 c.c.). The mixture was warmed on the water-bath until the titre had fallen to one-quarter of the original value. The excess of iodine was removed by sodium sulphite, the bulk of the solvent distilled off under diminished pressure, and the residue diluted with water (100 c.c.). The product precipitated crystallised from ligroin in fine brown granules, m. p. 110°; yield, 5·3 g.

A mixture of the two specimens melted at 110°. 3-*Chloro*-5-*iodo*-4-*acetoxyazobenzene* crystallised from alcohol in fine orange-red needles, m. p. 124° (Found: Ag halides/original weight, 94·77. $C_{14}H_{10}O_2N_2ClI$ requires 94·5%), and 3-*chloro*-5-*iodo*-4-*benzoyloxyazobenzene* from benzene in orange prisms, m. p. 115° (Found: Ag halides/original weight, 82·04. $C_{19}H_{12}O_2N_2ClI$ requires 82·[illegible]

2-*Chloro*-6-*iodo*-4-*aminophenol* was obtained together with [illegible]

by the reduction of the above chloroiodo-*p*-hydroxyazobenzene with stannous chloride. On removal of the tin from the resulting mixture, the less soluble *2-chloro-6-iodo-4-aminophenol hydrochloride* (Found: Ag halides/original weight, 170·2. C_6H_5ONClI,HCl requires 170·6%) separated in white needles, from which the base was obtained by treatment with sodium bicarbonate in silky white prisms, m. p. 169° (decomp.).

2-Chloro-6-iodo-4-acetamidophenyl acetate, m. p. 155° (Found: Ag halides/original weight, 106·7. $C_{10}H_9O_3NClI$ requires 107·1%), and *2-chloro-6-iodo-4-benzamidophenyl benzoate*, m. p. 157° (Found: Ag halides/original weight, 80·28. $C_{20}H_{13}O_3NClI$ requires 79·93%), crystallised from aqueous alcohol in needles.

3-Bromo-5-iodo-4-hydroxyazobenzene.—(*a*) 5-Iodo-4-hydroxyazobenzene was treated with one equivalent of the brominating agent prepared by mixing the required quantities of aqueous potassium bromide and an acetic acid solution of dichloramine-T. The halogen soon disappeared, and dilution with water then precipitated the *bromoiodo*-compound, which crystallised from ligroin in orange-brown needles, m. p. 128·5° (Found: Br, 19·8; I, 31·4. $C_{12}H_8ON_2BrI$ requires Br, 19·9; I, 31·5%).

(*b*) A solution of 3-bromo-4-hydroxyazobenzene was treated in acetic acid solution on the water-bath with iodine chloride (1 mol.) prepared as before, until the titre showed that one equivalent of iodinating agent had been used. Dilution of the solution with water, and crystallisation of the amorphous precipitate from alcohol, followed by ligroin, afforded an orange-brown, crystalline material, m. p. 128·5°. Mixed with the specimen obtained above, it melted at 128°.

3-Bromo-5-iodo-4-acetoxyazobenzene crystallised from alcohol in silky, orange needles, m. p. 127—128° (Found: Ag halides/original weight, 95·32. $C_{14}H_{10}O_2N_2BrI$ requires 95·08%), and *3-bromo-5-iodo-4-benzoyloxyazobenzene* in brown prisms, m. p. 85° (Found: Ag halides/original weight, 82·56. $C_{19}H_{12}O_2N_2BrI$ requires 83·43%).

2-Bromo-6-iodo-4-aminophenol.—Loss of iodine resulted on boiling the above bromoiodo-*p*-hydroxyazobenzene with acid stannous chloride, but smooth reduction was achieved by treatment of the azo-compound with an acetic acid solution of stannous chloride prepared by passing dry hydrogen chloride into a mixture of tin and acetic acid until the tin had dissolved. The aminophenol was isolated in the usual way as its *hydrochloride* (Found: Cl, 10·05; Br, 22·8; I, 36·0. C_6H_5ONBrI,HCl requires Cl, 10·1; Br, 22·8; I, 36·2%), from which the base was obtained by the action of sodium bicarbonate in short white prisms, m. p. 185° (decomp.).

2-Bromo-6-iodo-4-acetamidophenyl acetate crystallised from aqueous

alcohol in slender needles, m. p. 186° (Found: Ag halides/original weight, 105·9. $C_{10}H_9O_3NBrI$ requires 106·3%), and *2-bromo-6-iodo-4-benzamidophenyl benzoate* in plates, m. p. 148° (Found: Ag halides/original weight, 80·52. $C_{20}H_{13}O_3NBrI$ requires 81·02%).

3 : 5-*Di-iodo-4-hydroxyazobenzene.*—Attempts to prepare this compound by direct iodination of *p*-hydroxyazobenzene were not successful, oxidation as well as iodination resulting.

To a solution of 3-iodo-4-hydroxyazobenzene (see p. 2064) (4 g.) in acetic acid (65 c.c.) was added a solution of iodine chloride (1 mol.) prepared by mixing together dichloramine-T (2 g.) in acetic acid (35 c.c.) and powdered potassium iodide (2·8 g.). The mixture was heated on the water-bath until the titre showed that one equivalent of iodinating agent had been used (6 minutes). The excess of iodine was then removed by aqueous sodium sulphite, and the product precipitated by the addition of water (100 c.c.). It crystallised from alcohol in brown needles, m. p. 128—129°; yield, 3·1 g. (Found: I, 56·9. $C_{12}H_8ON_2I_2$ requires I, 56·5%).

3 : 5-*Di-iodo-4-acetoxyazobenzene* crystallised from aqueous alcohol in orange-brown prisms, m. p. 162° (Found: I, 51·6. $C_{14}H_{10}O_2N_2I_2$ requires I, 51·6%), and 3 : 5-*di-iodo-4-benzoyloxyazobenzene* from acetic acid in fine, yellow needles, m. p. 137—139° (Found: I, 46·1. $C_{19}H_{12}O_2N_2I_2$ requires I, 45·8%).

Reduction of 3 : 5-*di-iodo-4-hydroxyazobenzene.* Cautious treatment of the azo-compound with an acetic acid solution of stannous chloride and hydrochloric acid afforded *2 : 6-di-iodo-4-aminophenol* hydrochloride, from which the base was obtained by the addition of a saturated solution of sodium bicarbonate. It formed long white needles, m. p. 173°, from alcohol (Found: I, 70·2. Calc.: I, 70·4%). Raiford, Taft, and Lankelma (*J. Amer. Chem. Soc.*, 1924, 46, 2051) give m. p. 169—171°.

3 : 5-*Di-iodo-4-acetamidophenyl acetate* forms silky, white needles, m. p. 209°, from alcohol (Found: I, 57·0. $C_{10}H_9O_3NI_2$ requires I, 57·1%).

Grateful acknowledgment is made to Dr. S. Sugden for a gift of *o*-iodonitrobenzene, to the Department of Scientific and Industrial Research for a grant which enabled one of the authors (R. S. B.) to take part in the work, and especially to Professor K. J. P. Orton, F.R.S., for the facilities he has provided and for the interest he has shown throughout the course of the work set forth in this and the preceding paper.

CCLXIX.—*The Reaction between Acetylene and Sulphur at Temperatures up to 650°.*

By JOHN BUTTERY PEEL and PERCY LUCOCK ROBINSON.

MEYER and SANDMEYER (*Ber.*, 1883, **16**, 2176) obtained material, regarded as thiophen and giving the indophenin reaction, by heating sulphur in acetylene, but it is not stated that the substance was isolated. Capelle (*Bull. Soc. chim.*, 1908, **4**, 150) and de Coninck (*Bull. Acad. roy. Belg.*, 1908, 305) state that only carbon disulphide, thiophten, and a material with a garlic-like odour is present. Recent work (Briscoe and Peel, this vol., p. 1741) has indicated that thiophen is probably produced, and this work sought to determine roughly the composition of the liquid condensed at laboratory temperatures. The main reaction appears to yield carbon disulphide and hydrogen sulphide, but 77% of the sulphur at most is in the condensate, the rest probably converting the acetylene into carbon and hydrogen sulphide. Small quantities of thiophen and thiophten are formed at all the temperatures employed, 500° being the optimum, but benzene and naphthalene are entirely absent.

EXPERIMENTAL.

Preliminary.—Sulphur was heated in an ordinary distillation-flask, clamped horizontally, at the centre of which acetylene was delivered, and the products were passed through the side-limb into a bottle cooled in water and fitted with a reflux condenser. The phenomena observed were similar to those noted by Capelle (*loc. cit.*): the reaction, initiated by a dense yellow flame which deposited carbon, appeared to take place between the vapour and the gas at a temperature below the boiling point of sulphur; later, when there was a sufficiently constant supply of vapour, the acetylene burned steadily. The brown oily liquid from several runs was distilled through a spiral column until no further distillate could be obtained at 150°. The boiling point of the distillate gradually rose to a maximum of about 65°. The residue was distilled under reduced pressure and gave an orange liquid, b. p. 110—115°/20 mm., which on redistillation at the ordinary pressure gave a liquid, b. p. 210—220°, with the reactions of thiophten. The lighter fraction, when fractionated through a bead-filled column 4 feet long, yielded a large head fraction of carbon disulphide, b. p. 46·7°, and a fraction, amounting to 5%, b. p. 84·0°/760·5 mm. This proved to be thiophen, giving the indophenin and other reactions characteristic of that substance (Found: C, 57·1; H, 4·5. Calc.: C, 57·1; H, 4·8%). The carbon disulphide contained a trace of material with a

garlic-like odour which even the careful fractionation employed failed to isolate.

Addition of 5% of iron or 1% of iodine to the sulphur had little effect on the course of the reaction, the proportion of thiophen in the lighter fractions being 6% and 5% respectively.

In order to ascertain the lowest temperature at which the reaction began, the flask was surrounded by a double-walled air-bath, closed at the top with asbestos board, carrying a thermometer, and suitably cut for the neck of the flask. Ignition invariably took place at 275°, but after the first flash, if the temperature continued to be raised, no further flame formation took place even up to 325°. If, however, the flask were cooled below 275° and again raised above that point, flashing was once more observed. Below 300° the rate of reaction was inconveniently slow.

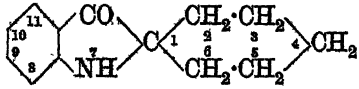
Reaction at about 325°.—Acetylene was led below the surface of the molten sulphur, the object being to obtain material at the lowest temperature (325° ± 5°) at which there was a reasonable rate of reaction. About 38% of the sulphur was converted into a brown oil which yielded CS_2 77%, C_4H_4S 9%, $C_6H_4S_2$ 6%.

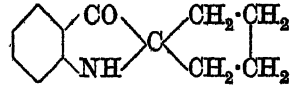
Reaction at about 500°.—A convenient apparatus consisted of a Pyrex tube 22″ × 1·5″ heated to the required temperature in a cylindrical electric furnace 12″ long. The closed end of the tube which protruded 5″ from the furnace was charged with 50 g. of sulphur and a rapid stream of acetylene was delivered about the centre of the heated zone. About 74% of the sulphur was converted into a brown oil containing CS_2 77%, C_4H_4S 12%, $C_6H_4S_2$ 6%.

Reaction at about 650°.—It was clear that a definite change had taken place in the course of the reaction at this temperature, resulting in the production of more carbon which caused constant trouble by choking the end of the tube delivering acetylene. About 77% of sulphur was converted into a liquid containing CS_2 83%, C_4H_4S 5%, $C_6H_4S_2$ 3%.

Previous determinations of the density (Schiff, *Ber.*, 1885, **18**, 1601) and surface tension of thiophen are somewhat old, and these properties have been redetermined on the material (analysed above) after three further fractionations, glass pyknometers of about 10 c.c. capacity and a pair of carefully calibrated capillary tubes being used; $d_4^{20°} = 1{\cdot}0615$ and $\gamma = 32{\cdot}58$ at 20°. These data give a molecular parachor of 189·0, from which may be deduced the parachor of sulphur, 46·5 (value for double bond = 23·2, C = 4·8, H = 17·1, five-membered ring = 8·5). This is in close agreement with the mean value, 46·3, derived from the data for carbon disulphide (Ramsay and Shields, J., 1893, **63**, 1089; Morgan and Thomssen, *J. Amer. Chem. Soc.*, 1911, **33**, 657; Harkins, Cl[illegible]

Roberts, *ibid.*, 1920, **42**, 700) but differs appreciably from the value 50·7 obtained with ethyl mercaptan (Morgan and Chazal, *ibid.*, 1913, **35**, 1821).





The authors desire to thank Mr. H. Smith for assistance in the experimental work, and to acknowledge a grant from the Research Fund Committee of Armstrong College enabling one of them (J. B. P.) to take part in this work.

CCLXX.—*Derivatives of ψ-Indoxyl*spirocyclo*hexane.*

By RAYMOND LIVINGSTON BETTS and SYDNEY GLENN PRESTON PLANT.

IT has recently been shown that *ψ*-indoxyl*spirocyclo*hexane (I) and *ψ*-indoxyl*spirocyclo*pentane (II), although having many reactions in common, differ in some respects (Betts, Muspratt, and Plant, J., 1927, 1310), and it became clear that a study of some of the derivatives of the former would be interesting. By methods similar to those used in the synthesis of (I) we have now prepared 10-*methyl*-,

(I.)  (II.) 

8-*methyl*-, 4-*methyl*-, and 8 : 10-*dimethyl*-*ψ*-*indoxyl*spirocyclo*hexane*, and have examined their reactions. The compounds (I) and (II) are each nitrated, even by dilute nitric acid, with remarkable ease to give a nitro-derivative, which, in the case of (I), is believed to be 10-nitro-*ψ*-indoxyl*spirocyclo*hexane. The methyl derivatives here described can all be nitrated with dilute nitric acid: the nitro-compounds form characteristic sodium derivatives in aqueous sodium hydroxide which are only sparingly soluble in cold water. The positions occupied by these nitro-groups are uncertain, but it seems probable that the 10-position is taken if possible, and the 8- if the former is not vacant. Attempts were made to reduce the nitro-group in some of these compounds with a view ultimately of introducing another substituent to give a substance which might be prepared by methods similar to those used for making *ψ*-indoxyl*spirocyclo*hexane, but the isolation of the corresponding amino-compounds has not been brought about. There can, however, be little doubt that these nitro-groups are in the benzenoid part of the molecule, and this view is supported by the fact that the reactions

of these compounds, especially with aqueous sodium hydroxide, are similar to those of 1-nitro- and 3-nitro-tetrahydroacridone (Perkin and Sedgwick, J., 1924, **125**, 2438).

Although 10-methyl- and 4-methyl-ψ-indoxyl*spirocyclo*hexane can be readily converted by acetic anhydride into the corresponding 7-*acetyl* compounds, acetylation of the 8-methyl and 8 : 10-dimethyl derivatives by this reagent is much more difficult and requires the presence of a little concentrated sulphuric acid. This reluctance can be ascribed to the steric effect of the methyl group in the 8-position.

The alkylated 1-anilino*cyclo*hexane-1-carboxylic acids, from which the ψ-indoxyl*spirocyclo*hexane derivatives described in this paper were obtained by fusion with potassium hydroxide, all dissociate, on distillation, to yield the corresponding alkylated aniline and Δ^1-*cyclo*hexene-1-carboxylic acid, or, in the case of 1-*anilino*-4-*methyl*cyclo*hexane*-1-*carboxylic acid*, aniline and Δ^1-tetrahydro-*p*-toluic acid. This behaviour is similar to that of 1-anilino-*cyclo*hexane-1-carboxylic acid itself, but differs completely from that of the analogous 1-anilino*cyclo*pentane-1-carboxylic acid (Plant and Facer, J., 1925, **127**, 2037).

EXPERIMENTAL.

10-*Methyl*-ψ-*indoxyl*spirocyclo*hexane*.—When a cooled solution of *p*-toluidine (24 g.) and *cyclo*hexanone (20 g.) in glacial acetic acid (100 c.c.) was treated with a concentrated aqueous solution of potassium cyanide (16 g.), 1-*p-toluidino*-1-*cyano*cyclo*hexane* separated in good yield; it was obtained from dilute alcohol in colourless needles, m. p. 76°. A solution of this nitrile (5 g.) in concentrated sulphuric acid (40 c.c.) was kept for 2 days at room temperature, then poured on ice and made alkaline with ammonia; 1-p-*toluidino*-cyclo*hexane*-1-*carboxyamide* separated quantitatively. It crystallised from alcohol in colourless prisms, m. p. 156°. A mixture of the amide (5 g.) and concentrated hydrochloric acid (100 c.c.) was boiled under reflux for 8 hours and then evaporated to dryness. The residue was treated with hot aqueous sodium hydroxide (8%), the solution was filtered, and then acidified with glacial acetic acid. 1-p-*Toluidino*cyclo*hexane*-1-*carboxylic acid* separated in good yield and was obtained from dilute alcohol in colourless needles, m. p. 172° (Found: N, 5·8. $C_{14}H_{19}O_2N$ requires N, 6·0%). When the liquid obtained by distilling this acid from a distillation flask was treated with an excess of dilute hydrochloric acid, Δ^1-*cyclo*hexene-1-carboxylic acid, m. p. 29—31°, remained undissolved; the acid solution, on the addition of ammonia, yielded *p*-toluidine.

A mixture of 1-*p*-toluidino*cyclo*hexane-1-carboxylic acid [illegible]

and potassium hydroxide (65 g.) was heated at 350—360° for ½ hour, allowed to cool, and then treated with an excess of water. The insoluble residue was dried over sulphuric acid in a desiccator and distilled, and the distillate crystallised from petroleum; 10-*methyl-ψ-indoxyl*spirocyclo*hexane* was obtained in colourless prisms, m. p. 164° (Found: N, 6·4. $C_{14}H_{17}ON$ requires N, 6·5%). On boiling its solution in an excess of acetic anhydride for an hour and shaking the cooled product with water, 7-*acetyl*-10-*methyl-ψ-indoxyl*spirocyclo*hexane* was obtained; it crystallised from methyl alcohol in colourless prisms, m. p. 144° (Found: C, 74·6; H, 7·5. $C_{16}H_{19}O_2N$ requires C, 74·7; H, 7·4%). This acetyl derivative is readily hydrolysed to the parent substance by boiling its solution in aqueous-alcoholic potassium hydroxide.

When a mixture of 10-methyl-ψ-indoxyl*spirocyclo*hexane (2 g.), water (40 c.c.), and nitric acid (10 c.c. of *d* 1·4) was boiled for 4 minutes, the solid gradually melted and a red oil appeared. The solution became yellow and, on cooling, the product appeared as a yellow solid. It was crystallised from alcohol, from which (?)8-*nitro*-10-*methyl-ψ-indoxyl*spirocyclo*hexane* separated in yellow prisms, m. p. 158° (Found: N, 10·8. $C_{14}H_{16}O_3N_2$ requires N, 10·8%).

8-*Methyl-ψ-indoxyl*spirocyclo*hexane*.—The preparation of this substance followed the course outlined above for the 10-methyl derivative. 1-o-*Toluidino*-1-*cyano*cyclo*hexane* separated from alcohol in colourless prisms, m. p. 72°, and 1-o-*toluidino*cyclo*hexane*-1-*carboxyamide* from dilute alcohol in colourless prisms, m. p. 143°. It was found advantageous to boil the solution of crude 1-o-*toluidino*-cyclo*hexane*-1-*carboxylic acid* in very dilute aqueous sodium hydroxide for ½ hour with charcoal and then to acidify the filtered solution gradually by adding dilute acetic acid with constant stirring. The acid separated from dilute alcohol in colourless prisms, m. p. 117° (Found: N, 6·0. $C_{14}H_{19}O_2N$ requires N, 6·0%), and, on distillation, it dissociated into *o*-toluidine, identified as aceto-*o*-toluidide, and Δ^1-*cyclo*hexene-1-carboxylic acid. 8-*Methyl-ψ-indoxyl*spirocyclo-*hexane* was obtained from petroleum in colourless prisms, m. p. 197°. On boiling its solution in acetic anhydride, containing a few drops of concentrated sulphuric acid, for several hours and shaking the product with water, 7-*acetyl*-8-*methyl-ψ-indoxyl*spirocyclo*hexane* was obtained as an oily mass, which solidified on being rubbed with ether; after being distilled under reduced pressure, the solid crystallised from methyl alcohol in colourless prisms, m. p. 226° (Found: N, 5·5. $C_{16}H_{19}O_2N$ requires N, 5·4%). (?)10-*Nitro*-8-*methyl-ψ-indoxyl*spirocyclo*hexane* can be obtained by boiling 8-methyl-ψ-indoxyl*spirocyclo*hexane with dilute nitric acid, but a more convenient method is to dissolve the substance in cold, con-

centrated nitric acid and, after 5 minutes, dilute the solution with water. It separates from alcohol in pale yellow prisms, m. p. 273—274° (Found: N, 10·7. $C_{14}H_{16}O_3N_2$ requires N, 10·8%).

8 : 10-*Dimethyl-ψ-indoxyl*spirocyclo*hexane*.—By methods similar to those described for the 8-methyl derivative the following products were isolated: 1-2′ : 4′-*Dimethylanilino*-1-*cyano*cyclo*hexane* from alcohol in colourless prisms, m. p. 115—116°, 1-2′ : 4′-*dimethylanilino*cyclo*hexane*-1-*carboxyamide* from dilute alcohol in colourless prisms, m. p. 133°, 1-2′ : 4′-*dimethylanilino*cyclo*hexane*-1-*carboxylic acid* (which dissociated into 2 : 4-dimethylaniline and Δ¹-*cyclo*hexene-1-carboxylic acid on distillation) from dilute alcohol in colourless prisms, m. p. 125° (Found: N, 5·7. $C_{15}H_{21}O_2N$ requires N, 5·7%), 8 : 10-*dimethyl-ψ-indoxyl*spirocyclo*hexane* from petroleum in colourless prisms, m. p. 190°, and 7-*acetyl*-8 : 10-*dimethyl-ψ-indoxyl*-spirocyclo*hexane* from methyl alcohol in colourless plates, m. p. 96° (Found: N, 5·2. $C_{17}H_{21}O_2N$ requires N, 5·2%). When a mixture of 8 : 10-dimethyl-ψ-indoxyl*spirocyclo*hexane and dilute nitric acid was boiled for ½ hour, a *mononitro*-derivative was produced and this separated from alcohol in pale yellow prisms, m. p. 183—184° (decomp.) (Found: N, 9·9. $C_{15}H_{18}O_3N_2$ requires N, 10·2%).

4-*Methyl-ψ-indoxyl*spirocyclo*hexane*.—From 4-methyl*cyclo*hexanone and aniline by methods similar to those described under 10-methyl-ψ-indoxyl*spirocyclo*hexane the following substances were obtained: 1-*Anilino*-1-*cyano*-4-*methyl*cyclo*hexane* from dilute alcohol in colourless needles, m. p. 107°, 1-*anilino*-4-*methyl*cyclo*hexane*-1-*carboxyamide* from alcohol in colourless prisms, m. p. 161°, 1-*anilino*-4-*methyl*cyclo*hexane*-1-*carboxylic acid* from dilute alcohol in colourless prisms, m. p. 179° (Found: N, 6·2. $C_{14}H_{19}O_2N$ requires N, 6·0%), 4-*methyl-ψ-indoxyl*spirocyclo*hexane* from petroleum in colourless plates, m. p. 189° (Found: N, 6·5. $C_{14}H_{17}ON$ requires N, 6·5%), 7-*acetyl*-4-*methyl-ψ-indoxyl*spirocyclo*hexane* from methyl alcohol in colourless prisms, m. p. 102°, (?)10-*nitro*-4-*methyl-ψ-indoxyl*-spirocyclo*hexane* from dilute alcohol in pale yellow prisms, m. p. 198° (Found: N, 10·9. $C_{14}H_{16}O_3N_2$ requires N, 10·8%), and (?)10-*nitro*-4 : 7-*dimethyl-ψ-indoxyl*spirocyclo*hexane* from dilute alcohol in pale yellow prisms, m. p. 141° (Found: N, 10·3. $C_{15}H_{18}O_3N_2$ requires N, 10·2%). The mixture obtained by distilling 1-anilino-4-methyl*cyclo*hexane-1-carboxylic acid, on treatment with dilute hydrochloric acid, yielded a solid which was readily soluble in aqueous sodium carbonate. This is clearly identical with the Δ¹-tetrahydro-*p*-toluic acid of Einhorn and Willstätter (*Annalen*, 1894, **280**, 163) and of Perkin and Pickles (J., 1905, **87**, 816); it was obtained from dilute acetic acid in colourless needles

134° (Found: C, 68·1; H, 8·4. Calc.: C, 68·6; H, 8·6%). The hydrochloric acid solution yielded aniline, identified as acetanilide, on being made alkaline with ammonia.

1-p-*Aminoanilino*cyclo*hexane*-1-*carboxylic Acid.*—A mixture of *p*-nitroaniline (14 g.), *cyclo*hexanone (12 g.), glacial acetic acid (200 c.c.), and potassium cyanide (10 g. in concentrated aqueous solution) was kept at 40—45° for 2 days, and then poured into dilute hydrochloric acid. 1-p-*Nitroanilino*-1-*cyano*cyclo*hexane*, which separated, was obtained from alcohol in pale yellow prisms, m. p. 134° (Found: N, 17·2. $C_{13}H_{15}O_2N_3$ requires N, 17·1%), and was hydrolysed in the usual way to 1-p-*nitroanilino*cyclo*hexane*-1-*carboxyamide*, isolated from alcohol in yellow prisms, m. p. 217° (Found: N, 16·0. $C_{13}H_{17}O_3N_3$ requires N, 16·0%), and then to 1-p-*nitroanilino*cyclo*hexane*-1-*carboxylic acid*, which separated from dilute alcohol in yellow plates, m. p. 201° (Found: N, 10·3. $C_{13}H_{16}O_4N_2$ requires N, 10·6%). The acid (3 g.), dissolved in dilute aqueous ammonia, was added to a mixture of ferrous sulphate (28 g. in concentrated aqueous solution) and ammonia (25 c.c. of *d* 0·880) at 90—95°, and, after being shaken at that temperature for ½ hour, the solution was filtered and just neutralised with glacial acetic acid. The 1-p-*aminoanilino*cyclo*hexane*-1-*carboxylic acid* which separated was obtained from aqueous pyridine in colourless needles, m. p. 216—217° (Found: N, 12·0. $C_{13}H_{18}O_2N_2$ requires N, 12·0%). The amino-acid decomposed completely on heating with potassium hydroxide alone or admixed with sodium ethoxide.

One of the authors (R. L. B.) wishes to thank the Imperial Order of the Daughters of the Empire (Canada) for a scholarship which enabled him to take part in this research.

CCLXXI.—*The Hydrolysis of Guanidine Carbonate.*

By JAMES BELL.

The hydrolysis of guanidine in aqueous solution (Bell, J., 1926, 1218) at room temperature gives urea: $CN_3H_5 + H_2O = CON_2H_4 + NH_3$. This is also formed on boiling, but some of it is decomposed by the strongly alkaline solution owing to the dissociation of urea to ammonia and cyanic acid at the high temperature (Werner, J., 1918, 113, 84). The cyanic acid is then fixed as guanidine cyanate, which is in turn hydrolysed to guanidine carbonate. The prepar-

ation of guanidine cyanate and a detailed examination of its hydrolysis will be dealt with in a future communication.

It is now shown that guanidine carbonate, when heated in aqueous solution to 100°, undergoes similar changes due to its dissociation into the free base and carbonic acid and hydrolysis of the former. A $N/10$-aqueous solution was unchanged after remaining for 10 weeks at room temperature. When it was boiled under reflux, hydrolysis took place to an appreciable extent; urea was first formed (1) and then decomposition to ammonium carbonate took place to a lesser degree (2).

$$(CN_3H_5)_2,H_2CO_3 + 2H_2O = 2CON_2H_4 + (NH_4)_2CO_3 \quad . \quad (1)$$

$$CON_2H_4 + 2H_2O = (NH_4)_2CO_3 \quad . \quad . \quad . \quad . \quad . \quad (2)$$

No cyanate could be detected among the products of this hydrolysis, even by the delicate copper pyridine test (Werner, J., 1923, **123**, 2577). In this respect, the hydrolysis differed from that of free guanidine, where guanidine cyanate accumulated to a considerable degree. However, it was shown (Bell, *loc. cit.*) that guanidine cyanate is also decomposed on further boiling, and since this salt would be formed at a much slower rate in the hydrolysis of the carbonate, its accumulation would be prevented by the fact that its rate of decomposition exceeds that of its formation.

The results in Table I were obtained after boiling a $N/10$-aqueous solution of guanidine carbonate under reflux for various times.

TABLE I.

	Duration of boiling.			
	1 hr.	3 hrs.	6 hrs.	12 hrs.
Urea present *	25·0	25·2	22·7	20·5
Urea converted into $(NH_4)_2CO_3$ * ...	0·1	11·3	16·5	22·5
Guanidine carbonate unchanged ...	75·0	62·7	60·9	58·0
Total (%)	100·1	99·2	100·1	101·0

* Estimated as percentage of original guanidine carbonate in accordance with equations (1) and (2).

The rate of hydrolysis diminishes very much after 3 hours' boiling and the reaction appears to stop after 12 hours. This retardation is due to the accumulation of ammonium carbonate in the solution (see Table II).

TABLE II.

	Expt. I.	Expt. II.	Expt. III.
Urea present	25·2	5·6	39·5
Urea converted into $(NH_4)_2CO_3$	11·3	0·0	16·5
Guanidine carbonate unchanged ...	62·7	94·7	[illegible]
Total (%)	99·2	100·3	[illegible]

* Estimated by difference.

In Experiment I an $N/10$-solution of guanidine carbonate was boiled for 3 hours under reflux. In Experiment II an $N/10$-solution of guanidine carbonate, to which ammonium carbonate equivalent to 5·2 c.c. of N-acid per 100 c.c. of solution had been added, was treated in the same way. In Experiment III an $N/10$-solution of guanidine carbonate was boiled in an open flask for the same length of time, the volume being maintained constant by the addition of water to replace the loss due to evaporation. Under these conditions, ammonium carbonate volatilised as it was formed. The results of Experiment II show that the presence of ammonium carbonate checks the rate of hydrolysis very considerably, and in Experiment III, where the ammonium carbonate was allowed to escape, the change was much greater than in Experiment I.

Ammonium carbonate in solution dissociates into ammonia and carbonic acid and would therefore diminish the dissociation of guanidine carbonate into free guanidine and carbonic acid. This suggests that the hydrolysis of guanidine carbonate in aqueous solution is due to its dissociation into free guanidine and carbonic acid, the free base being hydrolysed in the manner already described. Salts of guanidine, such as the chloride, which undergo no such dissociation in aqueous solution, remain unchanged on boiling.

The ready hydrolysis of guanidine carbonate should not be overlooked in the use of this substance in the preparation of standard acid solutions.

Experimental.

In each experiment involving boiling, 100 c.c. of solution were used. Ten minutes were required to raise the solution to the boiling point and the burner was always adjusted to secure quiet ebullition only.

Urea was estimated by the xanthhydrol method (Fosse, *Compt. rend.*, 1913, **157**, 948). An aliquot part of the liquid was neutralised and evaporated to dryness, and the residue extracted with glacial acetic acid to which one-fourth its volume of water had been added. An excess of xanthhydrol, dissolved in methyl alcohol, was then added and after 12 hours the precipitate of dixanthylurea was collected, washed with alcohol, dried, and weighed. A small correction was applied for the slight solubility of dixanthylurea in the mixture of acetic acid, water, and methyl alcohol, the value of this correction being determined in preliminary control experiments.

The amount of urea converted into ammonium carbonate was determined by the increase in alkalinity after boiling, equation (2) representing the only reaction producing such an increase. This necessitated the estimation, by absorption in a measured volume of standard acid, of any ammonia which escaped through the reflux

condenser. In Experiment III, however, where this procedure was not possible, the change had to be estimated by difference.

Unchanged guanidine carbonate was estimated by warming gently an aliquot portion of the liquid until all ammonium carbonate was driven off, and then titrating the residue with standard acid. Control experiments showed that guanidine carbonate underwent no change during this procedure.

The author gratefully acknowledges his indebtedness to Professor E. A. Werner for advice received.

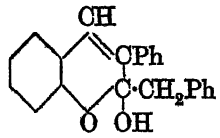
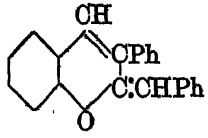
CCLXXII.—*Styrylpyrylium Salts. Part X. Anhydropyrylium Bases and* spiro*Pyrans derived from Dibenzyl Ketone.*

By Robert Dickinson, Isidor Morris Heilbron, and Florence O'Brien.

In Part IX of this series (Dickinson and Heilbron, J., 1927, 1699) mention was made of two compounds obtained by the condensation of dibenzyl ketone with 2-naphthol-1-aldehyde. A full investigation of these substances, together with those obtained from salicylaldehyde with the same ketone, has now been made. Dilthey and Wübken (*Ber.*, 1928, **61**, 963) have also recently prepared the compounds obtained from naphtholaldehyde, without, however, studying the reactions in detail.



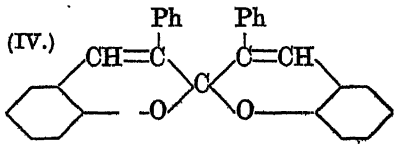
In the presence of piperidine, salicylaldehyde and dibenzyl ketone readily condense to give *2-hydroxy-α-phenylstyryl benzyl ketone*, $HO{\cdot}C_6H_4{\cdot}CH{:}CPh{\cdot}CO{\cdot}CH_2Ph$ (I), the constitution of which has been confirmed by the preparation of its *semicarbazone* and its *methyl ether*.



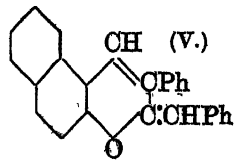
Hertzka (*Monatsh.*, 1905, **26**, 227) has previously attempted the condensation by hydrogen chloride, but failed to obtain any crystalline product. We now find this condensation to be abnormal in that pyrylium salts are only formed with difficulty and are not capable of isolation as the chlorides. From the reaction mixture two crystalline compounds have been obtained. One of these (m. p. 115°) gives analyses in agreement with the formula $C_{22}H_{16}O$ and hence is formed according to the equation :

$$HO{\cdot}C_6H_4{\cdot}CHO + (CH_2Ph)_2CO = C_{22}H_{16}O + 2H_2O,$$

Probably the labile pyrylium chloride hydrolyses to the



base (II), which then loses water, yielding 2-*benzylidene*-3-*phenyl*-Δ^3-*benzopyran* (III).



(II.) 

 (III.)

This view is supported by its ready formation by the action of hydrogen chloride on 2-hydroxy-α-phenylstyryl benzyl ketone (I).

The other substance isolated together with (III), but only obtained in small amount, is 3 : 3′-*diphenyldibenzo*spiro*pyran* (IV). It

(IV.) 

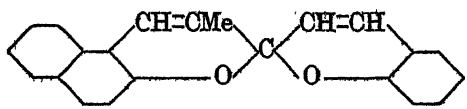
 (V.)

is readily obtained as the sole product by (*a*) condensing two molecules of salicylaldehyde with one of dibenzyl ketone, (*b*) from an equimolecular mixture of salicylaldehyde and 2-hydroxy-α-phenylstyryl benzyl ketone (I), or (*c*) from the benzylidenepyran (III) and salicylaldehyde, all by the action of hydrogen chloride. We have been unable to isolate the corresponding styrylpyrylium chloride which is undoubtedly present in the solution as evidenced by the intense purplish-red colour which develops on standing. Thus dibenzyl ketone to a certain extent resembles dipropyl ketone which, according to Decker and Fellenberg (*Annalen*, 1909, **364**, 30), yields diethyl*spiro*pyran when condensed with salicylaldehyde, although the pyrylium salt may also be obtained. Other examples are 3 : 4-diphenyl-Δ^3-pentenone and 2-indanone, both of which condense with salicylaldehyde and with 2-naphthol-1-aldehyde to give *spiro*pyrans directly (Ruhemann and Levy, J., 1913, **103**, 531).

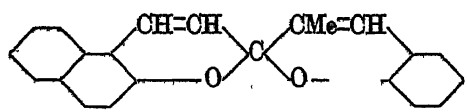
The condensation of dibenzyl ketone with 2-naphthol-1-aldehyde was again abnormal. These compounds in equivalent proportion, when treated with piperidine, failed to yield the anticipated unsaturated ketone analogous to (I), 2-benzylidene-3-phenyl-Δ^3-β-naphthapyran (V) alone being isolated. It thus appears that the naphthalene nucleus has a profound influence on the reaction, facilitating the ring closure from the enolic form of the unsaturated ketone. This compound is formed as main product when hydrogen chloride is employed and has also been prepared by Dilthey and Wübken (*loc. cit.*) by boiling the unstable pyrylium perchlorate with alcohol.

In the above acid condensation a small quantity of 3 : 3′-diphenyldi-β-naphtha*spiro*pyran (VI) is also formed. It is obtained

in better yield by treatment of a mixture of dibenzyl ketone and two molecules of naphtholaldehyde with hydrogen chloride, although the benzylidenepyran is still formed to some extent. As crystallised



(VI.)



from acetone (Dickinson and Heilbron, *loc. cit.*) it gave the analytical results of a *monohydrate* and was not at first recognised as a *spiro*pyran. We have since obtained the anhydrous *spiro*pyran, which agrees in properties with that prepared by Dilthey and Wübken (*loc. cit.*), who employed a similar method.

spiro*Pyrans and Ionisation.*—From a further study of certain *spiro*pyrans, Dilthey and Wübken (*loc. cit.*) draw a parallel between the ease with which these undergo salt formation in the presence of acids (forming styrylpyrylium salts) and the ease with which they change colour on heating in inert solvents. They regard the two changes as analogous. Their arguments are based, however, almost entirely on the behaviour of 3 : 3′-trimethylenedi-β-naphtha-*spiro*pyran. Although, as shown in Part IX, this compound gives no colour in xylene, Dilthey and Wübken find that if it is heated to a sufficiently high temperature (*e.g.*, in diphenyl ether, b. p. 250°) a faint colour is developed. The compound dissolves in glacial acetic acid to a colourless solution (no salt formation), whereas in trichloroacetic acid the colour is violet.

From the above point of view, we have again examined the behaviour of the two compounds 3′- and 3-methylbenzo-β-naphtha-*spiro*pyrans (VII and VIII).

(VII.)

(VIII.)

The former, heated in diphenyl ether, undergoes no colour change, whereas (VIII) develops the usual wine-red colour. On the other hand, both dissolve in glacial acetic acid with salt formation to give respectively bright red and purplish-blue solutions strictly analogous in colour to the corresponding styrylpyrylium chloride solutions. Judged from the intensity of the colour, the extent of salt formation appears to be of the same order of magnitude in each case. On Dilthey and Wübken's view, both would be expected to

colours in diphenyl ether. Their failure to do so shows that the case of formation of the ionic anhydro-base is not strictly comparable with salt formation. We still regard the power to "chelate" as the main factor in the production of the ionised molecule, but certainly do not dispute the possibility of ionisation effects in its absence. Generally, however, the process will require much more drastic energy conditions.

EXPERIMENTAL.

2-Hydroxy-α-phenylstyryl Benzyl Ketone (I).—A solution of dibenzyl ketone (20 g.) and salicylaldehyde (11·6 g.) in alcohol (30 c.c.) was treated with piperidine (25 drops). The yellowish-orange solution was kept at room temperature, a few drops of piperidine being periodically added, until crystallisation commenced. In subsequent preparations the time of reaction was considerably reduced by seeding the mixture. Several successive crops were obtained (total yield, 18 g.). The compound was recrystallised four times from methyl alcohol and formed pale yellow, rhombic crystals, m. p. 177°. Treated with dilute aqueous sodium hydroxide, the crystals are coloured orange-red, and a small portion dissolves to an orange solution. The compound is soluble in concentrated sulphuric acid to an orange-red solution. Although it decolorises bromine, no dibromide could be isolated (Found: C, 84·3; H, 5·9. $C_{22}H_{18}O_2$ requires C, 84·1; H, 5·7%).

The *semicarbazone*, prepared in the usual way, crystallised from alcohol in faintly yellow, glistening, rhombic plates, m. p. 196° (Found: N, 11·1. $C_{23}H_{21}O_2N_3$ requires N, 11·2%).

2-Methoxy-α-phenylstyryl benzyl ketone was readily prepared in good yield by treating an aqueous acetone solution of 2-hydroxy-α-phenylstyryl benzyl ketone with alternate small amounts of aqueous sodium hydroxide and methyl sulphate, the mixture being maintained at about 50° and continuously shaken, until no further orange colour developed with more alkali. After dilution with water, the separated solid was crystallised first from alcohol and then from acetone by addition of water, forming faintly yellow needles, m. p. 140—141° (Found: C, 84·1; H, 6·2. $C_{23}H_{20}O_2$ requires C, 84·1; H, 6·1%).

2-Benzylidene-3-phenyl-Δ³-benzopyran (III).—A solution of an equimolecular mixture of dibenzyl ketone (5 g.) and salicylaldehyde (2·9 g.) in alcohol (50 c.c.) was cooled in a freezing mixture and treated with a slow stream of dry hydrogen chloride until saturated; the colour changed from yellow to dark reddish-brown. After standing over-night at 0°, the mixture was poured into water and treated with aqueous sodium carbonate until faintly alkaline. The

resulting brown precipitate was dried and crystallised first from ether and then twice from alcohol, the pyran separating in glistening golden-yellow needles, m. p. 115° (yield, 5·5 g.). The ethereal mother-liquor yielded a small amount (0·5 g.) of the *spiro*pyran.

The benzylidene-pyran is insoluble in water and alkali, sparingly soluble in cold alcohol, readily in hot, and dissolves in concentrated sulphuric acid to a pale lemon-yellow solution. It decolorises bromine, but no product could be isolated. It is also very resistant to hydrolysis, being recovered unchanged after refluxing for 30 hours with an excess of alcoholic sodium ethoxide [Found: C, 88·9; H, 5·5; *M* (Menzies' method, in chloroform), 317. $C_{22}H_{16}O$ requires C, 89·2; H, 5·4%; *M*, 296]. Alternatively, the benzylidene-pyran may be prepared by saturating a solution of 2-hydroxy-α-phenylstyryl benzyl ketone (1 g.) in alcohol (30 c.c.) with hydrogen chloride.

3 : 3′-*Diphenyldibenzo*spiro*pyran* (IV).—A solution of dibenzyl ketone (5 g.) and salicylaldehyde (5·8 g.; 2 equivs.) in alcohol (50 c.c.) was cooled in ice-water while being saturated with dry hydrogen chloride. After several hours, the separated solid was filtered off. The filtrate, initially reddish-brown, slowly assumed an intense purplish-red colour and deposited more solid. The combined product, obtained in good yield, was crystallised first from alcohol and then twice from acetone, forming colourless needles, m. p. 197°, identical with the substance obtained as a by-product in the preparation of (III). The spiro*pyran* is insoluble in water and aqueous alkali and only sparingly soluble in alcohol. The last solution, treated with dry hydrogen chloride, slowly develops the red pyrylium colour, but from the intensity of the colour only a small amount of salt is present. In concentrated sulphuric acid, the compound dissolves to a deep red solution (Found: C, 86·8; H, 5·1; *M*, 426. $C_{29}H_{20}O_2$ requires C, 87·0; H, 5·0%; *M*, 400). When it is heated in diphenyl ether, no colour develops.

Alternatively, this *spiro*pyran may be obtained in good yield by saturating a mixture of 2-hydroxy-α-phenylstyryl benzyl ketone (1 g.) and salicylaldehyde (0·4 g.) in alcohol (30 c.c.) with hydrogen chloride, and after some hours pouring the product into water and extracting the *spiro*pyran with ether.

2-*Benzylidene*-3-*phenyl*-Δ^3-β-*naphthapyran* (V).—Equimolecular quantities of 2-naphthol-1-aldehyde (2·5 g.) and dibenzyl ketone (3·5 g.), dissolved in alcohol (45 c.c.), were treated with a few drops of piperidine and heated on the water-bath under reflux for 8 hours. After cooling, the crystalline deposit was recrystallised twice from acetone, separating in brilliant reddish-orange needles, m. p.

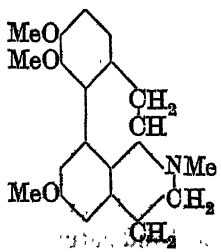
This pyran is insoluble in alkali, but dissolves in concentrated sulphuric acid to a lemon-yellow solution which shows an intense bright green fluorescence (Found: C, 89·6; H, 5·3; *M*, 360. Calc. for $C_{26}H_{18}O$: C, 90·1; H, 5·2%; *M*, 346).

The same compound was obtained in better yield by saturating a solution of dibenzyl ketone (5 g.) and 2-naphthol-1-aldehyde (4·1 g.) in alcohol (40 c.c.) with hydrogen chloride, the mixture being cooled in ice-water. After being kept in the ice-chest for 12 hours, the reddish-brown solution was poured into water and extracted with ether. The extract, dried and concentrated, deposited orange needles (4·5 g.) which, recrystallised from acetone, proved to be identical with the pyran described above (m. p. 145°). The ethereal mother-liquor yielded a small amount of the *spiro*pyran.

On being kept for several days in acetone solution, the benzylidenepyran undergoes a peculiar change; the orange colour disappears and a pale yellow, amorphous solid (m. p. above 200°), which has resisted all attempts at crystallisation, separates. The change does not seem to occur in any solvent other than acetone.

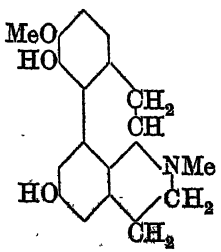
3 : 3′-*Diphenyldi*-β-*naphthas*piro*pyran* (VI).—A mixture of 2-naphthol-1-aldehyde (5 g.) and dibenzyl ketone (3·5 g.) was dissolved in alcohol (40 c.c.), saturated with hydrogen chloride, and kept over-night in the ice-chest. The reddish-brown solution was slowly poured into water, and the resulting curdy brown solid filtered off and well washed. After drying in a vacuum, it was fractionally crystallised from acetone. The main product (2·5 g.) was finally obtained in almost colourless needles, m. p. 248°; the analysis was that of the *monohydrate* of the *spiro*pyran (Found: C, 85·4; H, 5·3. $C_{37}H_{24}O_2,H_2O$ requires C, 85·7; H, 5·0%). The anhydrous compound may be obtained by recrystallisation from benzene with the addition of light petroleum, and has the same m. p. as the hydrate (Found: C, 89·4; H, 5·3. Calc. for $C_{37}H_{24}O_2$: C, 88·8; H, 4·8%).

The *spiro*pyran is practically insoluble in alcohol, only sparingly soluble in acetone, and fairly readily soluble in benzene. It dissolves in concentrated sulphuric acid to a dark red solution, which develops a dark green fluorescence after several hours. No colour develops when it is heated in solvents, such as diphenyl ether.



THE UNIVERSITY, LIVERPOOL. [*Received, June 2nd*, 1928.]

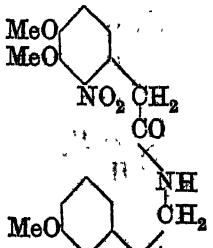
CCLXXIII.—*Synthetical Experiments on the Aporphine Alkaloids. Part IV. A Synthesis of Morphothebaine Dimethyl Ether.*



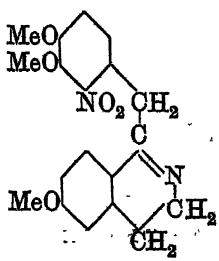
By JOHN MASSON GULLAND and ROBERT DOWNS HAWORTH.

THE method for the preparation of bases of the aporphine group which was described in Part I of this series (this vol., p. 581) has now been extended to the synthesis of 3 : 4 : 6-*trimethoxyaporphine* (I). The lævo-form of this base is identical with morphothebaine dimethyl ether (Klee, *Arch. Pharm.*, 1914, **252**, 242), and thus the structure for morphothebaine (II) advanced by Pschorr and Halle (*Ber.*, 1907, **40**, 2004) is substantiated. Morphothebaine is produced when hot concentrated hydrochloric acid acts on thebaine, and as a phenanthreno*iso*quinoline base, it forms one of the connecting links between the morphine and aporphine groups of alkaloids.

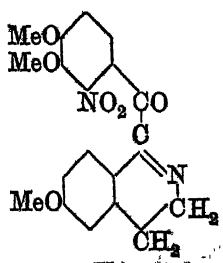
(I.)



(II.)



2′-*Nitro*-3′ : 4′-*dimethoxyphenylaceto*-β-3-*methoxyphenylethylamide* (III), prepared by the interaction of 2-nitro-3 : 4-dimethoxyphenylacetyl chloride and 3-methoxy-β-phenylethylamine (Helfer, *Helv. Chim. Acta*, 1924, **7**, 945), was converted into 2′-*nitro*-6 : 3′ : 4′-*trimethoxy*-1-*benzyl*-3 : 4-*dihydro*isoquinoline (IV) by the action of phosphorus pentachloride. This pale yellow crystalline base, which forms a sparingly soluble *hydrochloride*, *sulphate*, and *methiodide*,

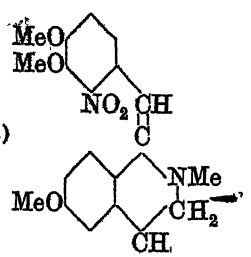


(III.)

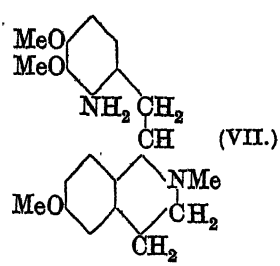
(IV.)

(V.)

is remarkably stable to atmospheric oxidation, but a small quantity of feebly basic 2′-*nitro*-6 : 3′ : 4′-*trimethoxy*-1-*benzyl*-3 :



iso*quinoline* (V) was actually isolated from the mother-liquor of the preparation of the base (IV), and was converted into the amorphous, alkali-soluble *oxime*.



The methiodide of the base (IV), which was abnormal in that it did not appear to undergo alkaline scission but yielded only the crystalline anhydro-base, 2′-*nitro*-6 : 3′ : 4′-*trimethoxy*-1-*benzylidene*-2-*methyltetrahydro*iso*quinoline* (VI), was reduced with zinc dust and hydrochloric acid to 2′-*amino*-6 : 3′ : 4′-*trimethoxy*-1-*benzyl*-2-*methyltetrahydro*iso*quinoline* (VII), an oily base which yielded a crystalline *dihydrochloride* and diazotised readily. The base (VII) was diazotised in a mixture of methyl alcohol and sulphuric acid, and converted by heating into 3 : 4 : 6-*trimethoxyaporphine* (I), an oil from which a crystalline *hydriodide* has been prepared.

This *dl*-base (I) was resolved by means of *d*-tartaric acid, and *l*-morphothebaine dimethyl ether hydrogen *d*-tartrate obtained in crystalline condition. It appeared from its crystalline form, melting point, and rotation, and by a mixed melting-point determination, to be identical with the salt prepared from morphothebaine in the manner described by Klee (*loc. cit.*). The *l*-base was obtained from the hydrogen tartrate as an uncrystallisable oil, which showed the same colour reactions and rotation as a specimen of natural morphothebaine dimethyl ether. Further, the *methiodides* of the two preparations appeared from a comparison of their crystalline form, melting point, and rotations to be similar in every respect, and there can be no doubt that the synthetical and natural products are identical.

d-*Morphothebaine dimethyl ether hydrogen* l-*tartrate* was obtained from the mother-liquor of the resolution by liberating the crude *d*-base and allowing it to combine with *l*-tartaric acid. The *d*-base is an oil which has not crystallised.

(VI.)

(VII.)

EXPERIMENTAL.

2′-*Nitro*-3′ : 4′-*dimethoxyphenylaceto*-β-3-*methoxyphenylethylamide* (III).—2-Nitro-3 : 4-dimethoxyphenylacetyl chloride (from 10 g. of acid) in benzene (50 c.c.) was added gradually to a solution of

3-methoxy-β-phenylethylamine (7 g.) in benzene (50 c.c.). After a short time, the dull yellow precipitate which had separated was mixed with 8% sodium hydroxide solution, and the benzene layer was washed with water and dried. When the solvent had been removed, the residual brown oil solidified; it was then crystallised from methyl alcohol, from which the *amide* separated in colourless needles, m. p. 107—108° (Found: C, 60·7; H, 5·9. $C_{19}H_{22}O_6N_2$ requires C, 61·0; H, 5·9%).

2'-Nitro-6 : 3' : 4'-trimethoxy-1-benzyl-3 : 4-dihydroisoquinoline (IV).—A solution of the amide (III) (10 g.) and phosphorus pentachloride (12 g.) in chloroform (80 c.c.) was kept at room temperature for 36 hours. After the solvent and phosphorus oxychloride had been removed from the mass of felted needles by distillation under reduced pressure, the residue was dissolved in boiling water, and the solution was filtered and cooled. The sparingly soluble *hydrochloride* of the base (IV) which separated was collected (see below for examination of the mother-liquor), suspended in hot water, and decomposed by ammonia. The *base* (IV) thus liberated crystallised from methyl alcohol in faintly yellow, blunt-ended prisms, m. p. 121—123° (7·5 g.) (Found: C, 64·2; H, 5·5. $C_{19}H_{20}O_5N_2$ requires C, 64·0; H, 5·6%).

The *hydrochloride* separated in colourless needles, m. p. 217—218° (decomp.), when a solution of the base in hot dilute hydrochloric acid was cooled (Found: Cl, 9·0. $C_{19}H_{20}O_5N_2,HCl$ requires Cl, 9·0%). It is moderately easily soluble in water and ethyl alcohol, but very sparingly soluble in dilute hydrochloric acid. The *sulphate*, prepared by dissolving the base in dilute sulphuric acid, forms colourless needles, m. p. 237° (decomp.).

The *methiodide* was obtained in a yield exceeding 90% when a mixture of the base and an excess of methyl iodide was heated under reflux on the water-bath for 30 minutes, and the excess of methyl iodide removed. It crystallised from ethyl alcohol in yellow needles, m. p. 220° (decomp.), which were sparingly soluble in water (Found: C, 48·4; H, 4·9. $C_{20}H_{23}O_5N_2I$ requires C, 48·2; H, 4·6%). This substance appeared to be unusually stable to alkaline fission, and attempts to decompose it with sodium hydroxide of various concentrations led only to *2'-nitro-6 : 3' : 4'-trimethoxy-1-benzylidene-2-methyltetrahydroisoquinoline* (VI), which separated as a red oil and was extracted with benzene. When the solution was dried and the solvent removed, the base (VI) solidified; after twice crystallising from benzene–ligroin, it was obtained in prisms, m. p. 108—109°, which appeared as red diamond-shaped tablets or as yellow plates according to the angle from which they were observed. [illegible] in material dried at 100°. C, 66·9; H, 6·0. $C_{19}H_{18}O_5N_2$ [illegible]

C, 64·9; H, 5·9%). By adding sodium iodide to a solution of the base (VI) in dilute hydrochloric acid, the methiodide of the base (IV) was regenerated as an oil which crystallised when rubbed with ethyl alcohol.

2'-*Nitro*-6 : 3' : 4'-*trimethoxy*-1-*benzoyl*-3 : 4-*dihydroisoquinoline* (V).—The acid mother-liquor from which the hydrochloride of the base (IV) had separated (see above) was rendered alkaline with ammonia; the precipitate obtained, when crystallised twice from methyl alcohol, formed faintly yellow prisms, m. p. 164° (decomp.) (Found: C, 61·5; H, 4·9; N, 7·5. $C_{19}H_{18}O_6N_2$ requires C, 61·6; H, 4·9; N, 7·5%). This substance is insoluble in alkali, but dissolves in warm dilute hydrochloric acid and is reprecipitated by sodium acetate. A consideration of its properties leads us to assign to it the constitution (V), and in this connexion it is noteworthy that the colour of a solution of the compound in boiling acetic anhydride is yellow, whereas the non-nitrated 1-benzoyl-3 : 4-dihydro*iso*-quinolines develop a characteristic green coloration under the same conditions (Buck, Haworth, and Perkin, J., 1924, **125**, 2176). The *oxime*, prepared by the action of hydroxylamine hydrochloride and pyridine at 100°, is amorphous and dissolves readily in dilute sodium hydroxide solution.

2'-*Amino*-6 : 3' : 4'-*trimethoxy*-1-*benzyl*-2-*methyltetrahydroiso-quinoline* (VII).—The methiodide (8 g.) of the base (IV), suspended in water (80 c.c.) and concentrated hydrochloric acid (150 c.c.), was heated on the water-bath and reduced by the gradual addition of zinc dust (31 g.). The clear, colourless solution was then cooled, and on several occasions a zinc chloride double salt separated in characteristic, colourless, fan-shaped aggregates of needles. After the addition of an excess of sodium hydroxide solution, the base was isolated by repeated extraction with ether; this extract, when washed with water, dried, and distilled, yielded a pale yellow, unerystallisable oil. This was converted into its *dihydrochloride* by treating an absolute alcoholic solution with dry hydrogen chloride and evaporating the solution to dryness under reduced pressure. The residual oil crystallised from dry chloroform in colourless needles which softened and shrank at 135°, melted at 155°, and retained solvent when dried in a vacuum desiccator (Found in material dried in a vacuum desiccator: Cl, 32·0. $C_{20}H_{26}O_3N_2,2HCl,CHCl_3$ requires Cl, 33·2%). This substance diazotises readily, and the diazonium salts couple with β-naphthol in alkaline solution, yielding a scarlet dye which develops a reddish-purple colour with concentrated sulphuric acid.

dl-3 : 4 : 6-*Trimethoxyaporphine* (I).—A solution of the hydrochloride of the base (VII) (5 g.) in 2*N*-sulphuric acid (30 c.c.) was

boiled in order to free it from chloroform, cooled in ice, and diazotised by the calculated amount of 2*N*-sodium nitrite. After the addition of methyl alcohol (30 c.c.), the orange solution was boiled under reflux for 30 minutes, mixed with concentrated hydrochloric acid (6 c.c.), reduced by zinc dust (2 g.), cooled, filtered, and made alkaline with 30% sodium hydroxide solution. The base (I) was isolated as a pale yellow oil by repeated extraction with ether, followed by the removal of the solvent, and was converted into the *hydriodide* by the addition of sodium iodide to a solution in dilute hydrochloric acid. This salt separated as a gum, but crystallised when rubbed with ethyl alcohol after the mother-liquor had been decanted, and when recrystallised from the same solvent formed almost colourless needles, m. p. 227° (decomp.) (Found in material dried at 100°: C, 53·2; H, 5·2. $C_{20}H_{23}O_3N$,HI requires C, 53·0; H, 5·3%). It is sparingly soluble in water and separates as a granular, non-crystalline mass when a hot solution is cooled.

Resolution of dl-3 : 4 : 6-*Trimethoxyaporphine*. 1-*Morphothebaine Dimethyl Ether*.—The oily *dl*-base (I) was liberated from the hydriodide by sodium carbonate and extracted with ether, and the solvent evaporated. The residue, dissolved in a little 95% ethyl alcohol, was mixed with an alcoholic solution of an equimolecular amount of *d*-tartaric acid; in a few moments, the colourless *l*-morphothebaine dimethyl ether hydrogen *d*-tartrate separated. It crystallised from ethyl alcohol in stellate aggregates of shining needles, m. p. 208—209° (decomp.) (Found in material dried at 100°: C, 60·3; H, 6·3. Calc. for $C_{24}H_{29}O_9N$: C, 60·6; H, 6·1%). In aqueous solution, $c = 1·123$, $l = 1$, $\alpha_D = -0·84°$, whence $[\alpha]_D = -74·8°$. *l*-Morphothebaine was liberated as a colourless oil from the hydrogen tartrate (0·1684 g.) and carefully extracted by successive small quantities of chloroform, and the mixed extracts were dried with a little sodium sulphate and made up to 20 c.c.; $l = 1$, $\alpha_D = -1·00°$, whence $[\alpha]_D = -173·5°$. The colour reactions with Erdmann's and Fröhde's reagents were indistinguishable from those given by the natural *l*-base (see below). The *methiodide* separated in crystalline condition when a solution of the base and methyl iodide in ethyl acetate was warmed for a few minutes on the water-bath; it crystallised from ethyl alcohol in colourless needles which became pasty at 190° and melted at 195° (Found in material dried at 100°: C, 54·0; H, 5·6. $C_{21}H_{26}O_3NI$ requires C, 54·0; H, 5·6%). In aqueous solution, $c = 0·448$, $l = 1$, $\alpha_D = -0·39°$, whence $[\alpha]_D = -87·1°$.

Natural l-*Morphothebaine Dimethyl Ether*.—For comparison, a specimen of natural morphothebaine dimethyl ether was prepared by methylating morphothebaine with diazomethane as descr[illegible]

by Klee (*loc. cit.*). The oil obtained in this way was converted into the hydrogen *d*-tartrate, which crystallised from 95% ethyl alcohol in stellate clusters of shining needles, m. p. 208—209° (decomp.) (Klee gives 205°), and there was no depression of the melting point of a mixture of this material with the synthetical product. In aqueous solution, $c = 1{\cdot}040$, $l = 1$, $\alpha_D = -0{\cdot}78°$, whence $[\alpha]_D = -75{\cdot}0°$ (Klee gives $-74{\cdot}3°$). The oily base, which was liberated by sodium carbonate solution from the hydrogen *d*-tartrate (0·2150 g.), was extracted with chloroform (20 c.c.) as described in the case of the synthetical substance; $l = 1$, $\alpha_D = -1{\cdot}27°$, whence $[\alpha]_D = -172{\cdot}7°$ (Klee gives $-184{\cdot}8°$). With Erdmann's reagent an olive-green colour was immediately developed which changed to a dirty violet-blue and then became red on dilution, and with Fröhde's reagent a deep bluish-green colour was produced which finally became dull violet. The methiodide, prepared as described for the synthetical material, crystallised in needles which became pasty at 190° and melted at 195°, and this melting point was not altered on admixture with the synthetical preparation. In aqueous solution, $c = 0{\cdot}533$, $l = 1$, $\alpha_D = -0{\cdot}47°$, whence $[\alpha]_D = -88{\cdot}2°$.

d-*Morphothebaine Dimethyl Ether*.—The alcoholic mother-liquor from which the *l*-morphothebaine dimethyl ether hydrogen *d*-tartrate had separated (see above) was concentrated, mixed with ammonia, and extracted with ether. The extracts were washed with water, dried, and distilled, and the residue was converted into d-*morphothebaine dimethyl ether hydrogen* l-*tartrate* by mixing an alcoholic solution with an alcoholic solution of the requisite amount of *l*-tartaric acid. This salt separated when the vessel was rubbed, and crystallised from ethyl alcohol in stellate clusters of shining needles, m. p. 208—209° (decomp.) (Found in material dried at 100°: C, 60·6; H, 6·3. $C_{24}H_{29}O_9N$ requires C, 60·6; H, 6·1%). In aqueous solution, $c = 0{\cdot}821$, $l = 1$, $\alpha_D = +0{\cdot}62°$, whence $[\alpha]_D = +75{\cdot}5°$. The colourless oily d-*base*, liberated from the hydrogen l-tartrate (0·1231 g.), was dissolved in chloroform (20 c.c.); $l = 1$, $\alpha_D = +0{\cdot}76°$, whence $[\alpha]_D = +174{\cdot}2°$.

The authors wish to thank the Research Fund Committee of the Chemical Society for grants which have defrayed part of the cost of this investigation.

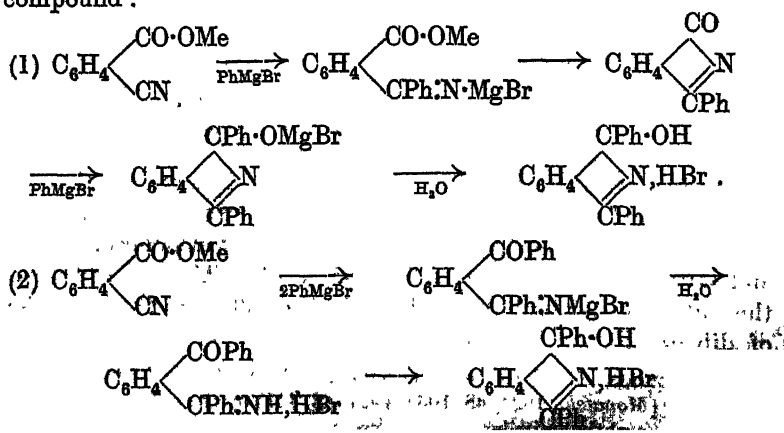
CCLXXIV.—*The Action of Magnesium Phenyl Bromide on Methyl* o-*Cyanobenzoate.* 1 : 3-*Diphenyldihydro-*iso*indole.*

By David Runciman Boyd and Donald Ernest Ladhams.

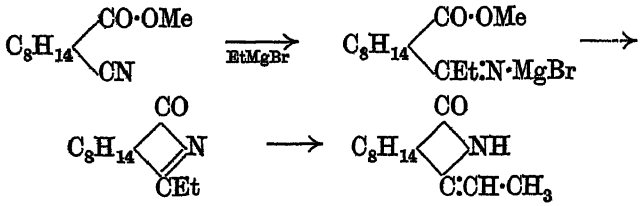
It has been shown by Haller and Legagneur (*Compt. rend.*, 1925, **180**, 1621) that magnesium methyl iodide in ethereal solution reacts with the methyl ester of camphoric acid α-mononitrile to give the corresponding cyano-tertiary alcohol :

$$CN\cdot C_8H_{14}\cdot CO_2Me \longrightarrow CN\cdot C_8H_{14}\cdot CMe_2\cdot OH;$$



in boiling toluene solution, however, the nitrile group also is attacked, the product being the ketonic tertiary alcohol,

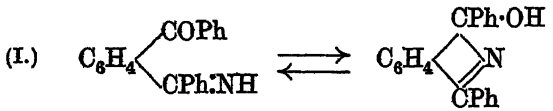
$$COMe\cdot C_8H_{14}\cdot CMe_2\cdot OH.$$



Using magnesium phenyl bromide in ethereal solution, the same authors obtained (*ibid.*, p. 881) the ketimine hydrobromide, $C_8H_{14}(COPh)\cdot CPh{:}NH,HBr$. No observations appear to be on record with regard to the action of a Grignard reagent on an aromatic compound containing both a cyano- and a carbalkyloxy-group. It seemed possible that the cyano-group in such a compound would show a reactivity considerably less than that of the other competing group, and methyl *o*-cyanobenzoate was investigated by us in the hope of obtaining *o*-cyanotriphenylcarbinol.

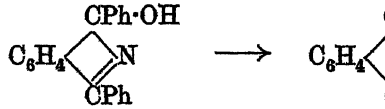
We have found, however, that magnesium phenyl bromide in ethereal solution converts the ester almost quantitatively into the hydrobromide of a base which we consider to be 1-hydroxy-1 : 3-diphenyl*iso*indole. No trace of the isomeric *o*-cyanotriphenylcarbinol could be detected.

Two different routes may be suggested as leading to the *iso*indole compound :



Ring formation by elimination of MeO·MgBr, as in scheme (1), has been postulated by Salmon-Legagneur (*Ann. Chim.*, 1927, **8**, 5) to explain the formation of a nitrogen-ring compound by the action of magnesium ethyl bromide on the methyl ester of camphoric acid α-mononitrile:

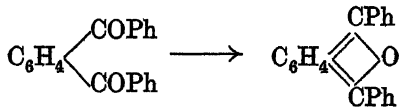
In scheme (2) the *iso*indole derivative is assumed to arise from the ketimine hydrobromide by an intramolecular change.



Although the *iso*indole formula * appears to us the more probable, the isomeric ketimine constitution cannot be definitely excluded. In certain solutions both forms of the compound may be present:

The comparative ease with which hydrolysis to *o*-dibenzoylbenzene takes place on boiling with dilute sulphuric acid may be regarded as evidence of the presence of (I) in the solution. On the other hand, the ring structure is supported by the following considerations:

(1) With concentrated sulphuric acid the base behaves like a tertiary aromatic carbinol, giving a solution of an intense magenta colour. In this solution the compound shows great stability; heating in a water-bath for 2 hours produced little or no alteration.



(2) The base can be reduced to 1 : 3-diphenyldihydro*iso*indole:

The reduction was effected by means of zinc dust and acetic acid, and the yield was small. Most of the base was converted into a yellow solid apparently identical with diphenylbenzfuran (Guyot and Catel, *Bull. Soc. chim.*, 1906, **35**, 1124). The appearance of this substance is attributed to hydrolysis resulting in the formation of dibenzoylbenzene, which is then reduced to the benzfuran.

* Compounds related to *iso*indole have also been obtained by Weiss and co-workers (*Monatsh.*, 1924, **45**, 105; 1927, **48**, 451) by the action of Grignard reagents on *o*-phthalonitrile.

Experiment showed that reduction of dibenzoylbenzene under similar conditions leads to the same yellow product :

Efforts to improve the yield of 1 : 3-diphenyldihydro*iso*indole by the use of other reducing agents were unsuccessful.

1 : 3-Diphenyldihydro*iso*indole appears to be the first example of a 1 : 3-disubstituted dihydro*iso*indole. The parent substance and its 1-methyl derivative were described by Gabriel (*Ber.*, 1893, **26**, 526, 711, 2213), but only *N*-substituted dihydro*iso*indoles have been prepared subsequently. The compound was found to be much more stable than the unsaturated substance from which it was derived, being unattacked by boiling dilute acid or alcoholic potash, and only oxidised extremely slowly by chromic–acetic acid to dibenzoylbenzene. It behaves as a strong secondary base, giving readily crystallised salts and a *nitroso-*, a *monobenzoyl* and a p-*toluene-sulphonyl* derivative (the last alkali-insoluble). From its mode of preparation it might be expected to have the *trans-*, and therefore racemic, configuration, but the material available was not sufficient for experiments on resolution.

The study of the reaction between cyanobenzoic esters and organomagnesium halides is being continued.

Experimental.

Methyl *o*-cyanobenzoate was prepared in 65% yield from methyl anthranilate by Clarke's modification of the Sandmeyer reaction (*J. Amer. Chem. Soc.*, 1924, **46**, 1001). The oily product was distilled under reduced pressure, b. p. 154°/15 mm., and crystallised in the receiver to colourless plates, m. p. 51°.

The Action of Magnesium Phenyl Bromide on Methyl o-Cyanobenzoate.—28·6 G. of the ester (1 mol.) in 300 c.c. of ether were run slowly, with constant stirring, into the ice-cold Grignard reagent prepared from 86 g. of bromobenzene (3 mols.) and 12·2 g. of magnesium (2¾ atoms) in 250 c.c. of ether. Each drop gave a yellow precipitate, so that finally a semi-solid mass was obtained. This was refluxed for an hour, cooled, and decomposed with ice and dilute sulphuric acid. The yellow solid, 1-*hydroxy*-1 : 3-*diphenylisoindole hydrobromide*, was collected and washed with ether, in which it was almost insoluble. Yield, 50 g. (90%). The brown ethereal filtrate gave on evaporation a small amount of gummy material, from which unchanged ester was crystallised by rubbing with alcohol.

hydrobromide was crystallised from chloroform–benzene, but could not be obtained pure. It decomposed above 220°. Attempts to crystallise it from alcohol converted it into *o*-dibenzoylbenzene. The free *base* was obtained by rubbing the hydrobromide with aqueous sodium carbonate, and a little ether to remove gummy matter (some decomposition occurred as shown by the evolution of ammonia). The prismatic crystals obtained from aqueous methyl or ethyl alcohol melted at 192·5° (decomp.) (Found: C, 83·7; H, 5·4; N, 4·9. $C_{20}H_{15}ON$ requires C, 84·1; H, 5·3; N, 4·9%). When boiled in alcoholic potash or dilute sulphuric acid for an hour, the base was quantitatively decomposed into *o*-dibenzoylbenzene, m. p. 145° (Found: C, 83·2; H, 5·1. Calc. for $C_{20}H_{14}O_2$: C, 83·9; H, 4·9%), ammonia also being formed. The *o*-dibenzoylbenzene was identified by conversion into the oxime, m. p. 149—150° after crystallisation from methyl alcohol. The ketone gave a colourless solution with concentrated sulphuric acid. Guyot and Catel (*loc. cit.*) record 146° and 150° as the melting points of the ketone and oxime, and state that the solution of the ketone in sulphuric acid has a pink colour.

The free base dissolved in concentrated, or slightly diluted, sulphuric acid to give a magenta-coloured solution; the hydrobromide gave off hydrogen bromide and bromine. This solution could be boiled for some minutes or heated in the water-bath for 2 hours without any marked decomposition, as shown by cooling, pouring on ice, filtering off any traces of dibenzoylbenzene and neutralising the filtrate. An attempt was made to condense the hydroxy*iso*indole with phenol in the presence of sulphuric acid (Baeyer and Villiger, *Ber.*, 1902, **35**, 3018; Boyd and Hardy, this vol., p. 630). Sulphonation occurred, however, and the product was an amphoteric uncrystallisable substance.

With a view to obtaining evidence as to the constitution of the product arising in the Grignard reaction, experiments on benzoylation were carried out. Before decomposition of the Grignard complex with ice, benzoyl chloride (1 mol.) was run slowly into the well-cooled suspension, which was then refluxed for an hour, cooled, and treated with ice and ammonium chloride. A small quantity of solid remained, insoluble in the ether layer; this was extracted with alcohol, which deposited on dilution a colourless solid, m. p. 220°, containing nitrogen but giving no coloration with concentrated sulphuric acid (Found: C, 84·3; H, 5·6; N, 4·4. $C_{20}H_{15}ON$ requires C, 84·1; H, 5·3; N, 4·9%). On repeating the experiment this substance was not obtained, so that further investigation was not possible. The ethereal solution in each case contained dibenzoylbenzene, benzamide, and tarry matter.

Reduction of 1-*Hydroxy*-1 : 3-*diphenylisoindole*.—An acetic acid solution of the base was kept with excess of zinc dust for 2 days, with occasional warming. The filtrate exhibited a blue fluorescence (destroyed by exposure to light and air), and gave on dilution a deep-yellow solid. This could not be satisfactorily crystallised, but its m. p. of 120—125°, its oxidation by chromic–acetic acid to dibenzoylbenzene, and its behaviour in solution point to its identity with Guyot and Catel's diphenylbenzfuran, m. p. 125°. Dibenzoylbenzene was reduced under the same conditions to the same substance. The diluted acetic acid filtrate gave on neutralisation a white precipitate of 1 : 3-*diphenyldihydroisoindole* in very poor yield. The yield was increased to about 10 to 20% by adding the hydrobromide in small quantities to the boiling suspension of zinc dust in acetic acid. The colourless prisms from alcohol melted at 109° (Found: C, 87·95; H, 6·55; N, 5·1. $C_{20}H_{17}N$ requires C, 88·45; H, 6·3; N, 5·2%). The base is soluble in the usual organic solvents, and in dilute mineral acids; the solution in hot dilute hydrochloric acid gave crystals of the *hydrochloride* on cooling, m. p. 270—280° (decomp.) (Found: Cl, 11·36. $C_{20}H_{17}N,HCl$ requires Cl, 11·53%). The base was slowly oxidised by gradually adding a slight excess of chromic anhydride to an acetic acid solution heated in a water-bath. On cooling, dibenzoylbenzene crystallised.

On adding aqueous sodium nitrite to a dilute sulphuric acid solution of the base, a white precipitate of the *nitroso*-derivative, $C_6H_4(CHPh)_2N{\cdot}NO$, slowly formed. The crystals from alcohol were pinkish, but yellow while in the steam-oven, and melted at 175—175·5° (Found: N, 9·5. $C_{20}H_{16}ON_2$ requires N, 9·3%). This substance was unaffected by alcoholic hydrochloric acid, and could not be reduced to the corresponding hydrazine by zinc dust in acetic acid. On applying Liebermann's test it gave a green solution in the sulphuric acid–phenol mixture. The *benzoyl* derivative (Schotten–Baumann method) gave crystals very sparingly soluble in alcohol, m. p. 236° (Found: N, 3·9. $C_{27}H_{21}ON$ requires N, 3·7%). On treatment with phosphorus pentachloride (v. Braun, *Ber.*, 1904, **37**, 2818) it gave an intractable tarry material. The p-*toluenesulphonyl* derivative melted at about 255° (decomp.). It was insoluble in alkali.

One of us (D. E. L.) wishes to thank the Department of Scientific and Industrial Research for a grant which enabled him to take part in this investigation.

UNIVERSITY COLLEGE, SOUTHAMPTON. [*Received, June 13th, 1924.*]

CCLXXV.—*Striated Photographic Records of Explosion Waves. Part II. An Explanation of the Striæ.*

By Colin Campbell and Arthur Calvert Finch.

It has been shown (J., 1926, 3010; 1927, 1572) that when the explosion-wave in certain gaseous mixtures is photographed by means of a moving-film camera, the records are striated in appearance and the trace of the flame front is marked by regular undulations. The mixtures which showed these phenomena most clearly were those of carbon monoxide and oxygen, with or without the addition of small quantities of hydrogen. The period of the striæ and also of the undulations was approximately proportional to the diameter of the containing tube but independent of its length. In a tube of internal diameter 15 mm. the period was about 1/39,000 sec. and was apparently not affected by the method of ignition of the gases. Several suggestions were put forward as to the cause of these phenomena, such as induced vibrations in the apparatus, a periodic propagation of the explosion-wave, or (as suggested by Mr. E. F. Greig) the flame travelling along a helical path.

The experiments now recorded appear to show that the facts can be accounted for by the last suggestion, and that the vibration of the apparatus or of a column of the gaseous mixture is not responsible for the effect.

Experimental.

The general experimental procedure previously described (J., 1926, 3010) has again been used except that, since only one gaseous mixture was under observation in any one experiment, the diaphragm apparatus was no longer necessary. The explosion apparatus consisted simply of glass and lead tubes of the same internal diameter (usually 12·5 or 15 mm.) rigidly cemented together to form a continuous gallery, usually about 4 m. long, which was placed horizontally in front of a moving-film camera. The explosive mixture was ignited by a break-spark near the closed end of the gallery, the other end (often seen in the photographs) being opened just before firing. The photographs were obtained on Lumière paper, usually 100 mm. wide, which was fastened to a cylindrical drum capable of being rotated at peripheral speeds up to 55 m. per sec. In order to obtain the exact direction of movement of the film as it passed the focus of the camera lens, a small electric lamp, placed near the tube and giving a pin-hole illumination, was lit for several seconds just before the mixture was ignited: this produced the thin black lines seen on many of the photographs.

The "Vibration" Theory.

It was at first imagined that the striæ might have been caused by the vibration of the camera itself, but the fact already mentioned (J., 1927, 1576), that striæ of different periods in two portions of the same tube have been recorded together on the same film, would appear to disprove such an explanation. Further evidence against it can now be given. For example, striæ of gradually increasing periods were obtained when a conical, instead of a cylindrical tube was employed. This is shown in Fig. 1, which was obtained when the internal diameter of the tube increased from 10 mm., on the right, to 25 mm., on the left of the photograph. An *abrupt* change in the internal diameter of the explosion tube has a marked effect on the speed of the flame as well as on its general character (Campbell, J., 1922, **121**, 2483), but the gradual widening of the tube produced no alteration in the speed of the flame in this experiment. In two experiments where the widening was more rapid (the diameter increased from 15 mm. to 28 mm. over a distance of 31 cm.), the character of the flame was altered and its speed reduced.

Vibration of the camera being excluded, that of the explosion tube was next examined. Such vibrations, set up by the explosion itself or transmitted through the bench from the driving motor on the concrete floor, might be either (1) longitudinal vibrations similar to those in a freely supported bar after a sharp knock, or (2) transverse vibrations in the material of the tube (compare vibrations of a bell) causing alternate compression and rarefaction of the hot gases.

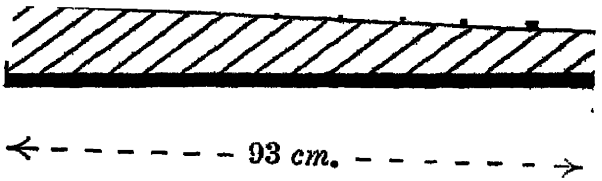
Longitudinal vibrations in a glass tube would have a frequency proportional to its length; they would have the same frequency in all parts of the same tube and would almost certainly show the presence of nodes and anti-nodes at fixed points in it. The striæ, however, have a frequency which is independent of the length of the tube, the frequency is not always the same in different parts of the same tube (*e.g.*, in a conical tube), and the undulations on the trace of the wave-front do not correspond to the same points in the tube in different experiments. Moreover, the frequency of the striæ in one particular tube is about 40,000 per second, whereas the fundamental frequency of the longitudinal vibrations of this tube has been calculated to be about 2,500.

The theory that the striæ are caused by *transverse* vibrations in the material of the tube would appear to gain support from the close relationship which has been found to exist between the frequency of the striæ and the diameter of the tube. On this view, it might be expected that an alteration in the thickness of the wall of the explosion tube would alter the frequency of the striæ.

change has not been observed, but as no method appears to be available for calculating the variation of frequency with wall thickness for bell-vibrations of this type, we are unable to predict whether the effect would be sufficiently great to be apparent. It seemed probable, however, that a change in the elastic properties of the tube wall would alter the frequency of vibration to a much greater extent, and rubber tubes might therefore be expected to give results different from those in glass; but experiments in which a section of the glass explosion tube was replaced by one made of (*a*) thick rubber provided with a thin glass window, and (*b*) very thin semi-transparent rubber, showed striæ of similar frequencies in the glass and rubber sections of the tube.

Since no difference in the striæ could be seen when tubes of rubber and glass were used, an attempt was made to reduce to a minimum any possible transverse vibrations in a glass tube. For this purpose, the glass explosion tube, instead of being clamped, was encased in a large block of cement (reinforced by iron bolts) except for a slit 3 cm. wide extending along the middle 60 cm. of its length. The photograph obtained through this slit showed striæ of the same intensity and frequency as those observed in a tube clamped in the ordinary way.

It would appear, therefore, that vibrations either longitudinal or transverse in the tube itself cannot explain the formation of the striæ.



A train of compression waves in the gaseous mixture, initiated at or near the open end of the tube and moving in a direction opposite to that of the flame motion, might produce striæ, but it has previously been pointed out (J., 1927, 1573) that the slope of the striæ actually observed would require the velocity of such waves to be almost infinitely great. In any case, it seems impossible to believe that the open end of the tube could be a region of high pressure several milliseconds before the flame had arrived there. That the method of ignition also is not concerned in the formation of the striæ is shown by the fact that their frequency is unchanged (*a*) when the frequency of electrical oscillations is altered by increasing the capacity of the secondary circuit, and (*b*) when the mixture is ignited by a taper, the tube, in this experiment, being open at both ends.

The "Helix" Theory.

If a flame is travelling along a helical path in a cylindrical tube, it should appear at two windows separated by an arc of 90° at a time interval which is one fourth of that required for consecutive appearances at the same window. To test this by viewing the flame through

"top" and "front" windows was not satisfactory, because the aspects relative to the camera were not quite similar, one being normal and the other tangential to the tube. Moreover, through a window at the front of the tube, the flame would be visible both at the front and the back of the tube and the consequent doubling of the frequency of the striæ causes a loss of photographic resolution.

Both difficulties were overcome and two tangential views obtained by the use of a plate-glass mirror placed behind the tube and parallel to it. One image on the film record was made directly by the light from the flame as it passed a window near the top of the tube; the other image was produced by the light, after reflexion from the mirror, from the flame as it passed a window at the back. To prevent undesirable reflexions, the tube and the mirror were carefully screened, and in order that both images should be in focus, the aperture of the lens was considerably reduced. In spite of these precautions, a slight confusion on the film was caused by the unavoidable overlapping of the two images. Although this confusion was reduced by using a mixture (*e.g.*, $CH_4 + 6O_2$) which gave clear undulations on the trace of the flame front and very slight luminosity behind it, it was found that such mixtures often gave slightly irregular striations; for this reason carbon monoxide–oxygen mixtures were almost always used. The undulations were further apart and therefore easier to measure when tubes were used, but the area was limited by the [illegible] tubes were 3·5 mm.

In each case the upper trace is the direct image, and the lower that obtained by reflexion from the mirror. The periodic character of the photograph is the result of the flame passing every window the flame is seen. If a line is drawn parallel to the direction of motion of the film through each undulation in the lower trace, it is clear that in (*a*) each undulation in the [illegible] *L* is the distance between [illegible] window) from the next, and in (*b*) the phase difference is [illegible] records can be compared [illegible] the flame has passed [illegible] the top window and [illegible] in (*a*) the direction has been [illegible] the motion is in this case [illegible] has been observed [illegible]

with the tube pointing directly towards the camera. Preliminary experiments had shown that the explosion tube could be placed within 80 cm. of the lens without the latter being damaged or displaced even though the tube itself was completely shattered. The explosion tube was clamped as rigidly as possible, and complete alinement between the axis of the tube and the axis of the lens was secured by the use of a spirit-level and by accurately placed sights similar to those used on a rifle. In order to reduce the amount of extraneous light that reached the camera, the explosion tube was made of copper instead of glass, and on the open end was placed a cap of black paper with an annular aperture (2 mm. wide), the outer edge of which coincided with the inner surface of the tube. With this arrangement, a disc of flame of uniform luminosity moving regularly towards the open end of the tube would produce, on the moving film, a continuous band; any periodic change of the luminosity of the flame—owing to periodicity, chemical or physical, in its propagation—would result in its being recorded as a series of rings. If, however, the foremost actinic portion of the combustion is small in size compared with the diameter of the tube and is rotating regularly about the axis of the latter, it should produce a record which is cycloidal in form. The type of cycloid produced would depend on the *apparent* peripheral rate of rotation of the flame, and this rate would be altered by changing the distance of the tube from the camera, other conditions remaining the same.

Figs. 3, 4, 5, and 6 are reproductions of some of the records obtained by the above method. They are clearly cycloids, and when compared with one another, show the alteration of type as the distance of the tube from the camera is altered. Since different parts of the terminal tube of the explosion gallery could not be at the same distance from the lens, there is a slight variation in type even in a single record, but as the length of the terminal tube was usually short compared with its distance from the camera, the variation is in most cases inappreciable.

The form of cycloids to be expected when the tube is at various positions in front of the camera can be calculated from the known velocity of the explosion-wave (V), the tube radius (r), and the distance L (see above). If the flame is travelling round the circumference of the tube, the arc traversed in time t will subtend an angle α at the centre such that $t = L\alpha/2\pi V$. It has been shown (J., 1927, 1575) that $L = 6r$ (approx.), and therefore $t = 3r\alpha/\pi V$. If the wheel had remained stationary during this period, the position of the flame image would be given by $x = \mu r \cos\alpha$; $y = \mu r \sin\alpha$, where μ is the magnification. But, since the film is moving vertically at a velocity W (the peripheral wheel velocity), each point on it has

moved forward, in time t, a distance $3r\alpha W/\pi V$. The trace of the flame image on the moving film is therefore the cycloid in which the above value of y is replaced by $y = \mu r \sin\alpha + 3r\alpha W/\pi V$. An example illustrates the method employed in plotting the theoretical cycloids:

Experiment 456. Mixture $CH_4 + 5\frac{1}{2}O_2$. Velocity of explosion taken as 1900 m./sec.; $r = 7{\cdot}5$ mm.; $\mu = 1/15$; $W = 53{\cdot}83$ m./sec. Hence the cycloid is $x = 0{\cdot}5\cos\alpha$; $y = 0{\cdot}5\sin\alpha + 0{\cdot}2030\alpha$. By taking different values for α, corresponding values for x and y were obtained. A curve was plotted from these values: it was then photographed and reduced in size for comparison with the record obtained in this experiment. Similar cycloids were plotted for each magnification and tube radius, and the reduced reproductions placed alongside the actual photographic records in Figs. 3—6. In each case, the value of μ taken is that which corresponds with the middle point of the horizontal part of the explosion tube: the theoretical and recorded cycloids, therefore, correspond most closely over the central portions of the latter.

The agreement between the theoretical and the observed results appears to point conclusively to a rotational movement of the flame. That the rotation may be in either direction seems clear from Figs. 5 (*a*) and (*b*), for in (*a*) the cycloid corresponds to a clockwise rotation, whilst in (*b*) it is in the opposite direction.

Helical Traces on the Walls of the Tube.—The "helix" theory is also supported by evidence of a nature quite different from that hitherto described. The inner surface of the terminal glass tube of a gallery of lead and glass sections was found, after several explosions, to be coated with a light deposit of lead dust in which was discernible a very incomplete network of markings apparently consisting of portions of clockwise and counter-clockwise helices. During attempts to repeat this observation and to obtain perfect records of this type, many different incombustible powders were tried as coatings for the interiors of the tubes. A light deposit of French chalk, which adhered fairly readily to the glass surface, was found to be most suitable. Two of the tubes so coated, and used each for one experiment only, have been photographed for us by Messrs. Flatters and Garnett of Manchester and are reproduced in Fig. 7. In both cases the mixture $2CO + O_2$ (containing $0{\cdot}7\%$ H_2) was used. The helical trace is, in each case, clearly marked; in Expt. 467 it is clockwise with respect to the forward movement of the flame, whilst in Expt. 468 it is counter-clockwise.

Both tubes were of 14·7 mm. bore and the average pitch of the helical trace, whose direct measurement is rendered easy by its uniformity and completeness, is very nearly 44 mm. This distance

may, with very small error, be considered identical with that between points in the tube corresponding to successive undulations in the photographic record of the foremost actinic portions of the flame associated with the explosion in a tube of the same diameter. It may be, indeed, that the dust trace shows the actual path traversed by this part of the flame but, on the other hand, it is conceivable that it is due to some invisible disturbance travelling ahead of the flame.

There are several other points of agreement between the photographic records and these helical dust traces. For example, the dust trace produced when the mixture $2CO + O_2$ (containing 1% H_2) was used showed greater regularity than that formed with the mixture $CH_4 + 6O_2$, just as the undulations obtained in the photographs of the flame in the carbon monoxide mixture were more regular than those in the methane mixture. Again, a slow (pre-detonation) flame in the same carbon monoxide mixture was found to give neither striæ in the photographs nor traces in the French chalk, and the well-established explosion-wave in electrolytic gas also gave negative results in both cases.

That the first luminous portion or "head" of the explosion traverses a helical path gives no explanation of the long striæ which are a striking feature of many of the photographs taken on a moving film. Such a luminous "head" to the combustion as it traversed a helical path in a tube provided with only a narrow window would be recorded on the film as a chain of well-marked points or short arcs, whilst the combustion behind the head, if uniformly distributed across the tube section, would produce a uniform background in the photograph. The record, therefore, although probably showing an undulated trace, would be devoid of striæ, and quite unlike any actually obtained.

The production of striæ can, however, be explained by making the further assumption that the most luminous portion of the gas behind the flame front forms a long slender "tail," which lies close to the wall of the tube and rotates with a frequency almost identical with that of the head. Such a rotation of the tail explains the observation that the frequency of the striæ photographed through a middle window is double that recorded through a top window, just as the frequency of the undulations in the photographic record produced by the head was doubled under similar conditions. Through a middle window, the tail is visible twice (at the front and the back of the tube) during each revolution, but with a top window, only once.

Photographs of the Flame in a Vertical Tube.—That this long tail is a reality, and that it rotates in the tube, is evident from the

following experiments. A vertical glass tube, 30 cm. long and of 28 mm. bore (2 mm. wall), was completely covered with black paper except for a 1 mm. horizontal slit round the semi-circumference on the optical axis of the camera lens. The lower end of the tube was rigidly joined, by a conical copper tube (expansion 15—28 mm. over a length of 63 cm.), to a 15 mm.-bore lead tube about 6 m. long. The whole gallery was filled with the mixture $2CO_2 + O_2$ (containing about 1% of H_2) and firing was effected, as usual, by a spark near the closed end of the lead tube. The photograph of the flame, as it passed up the tube, was taken on a film moving at 50 m./sec. Two typical records are shown in Figs. 8 and 9. It is clear that, although the tube was invariably shattered by the explosion, the most luminous part of the burning gases had passed the slit before this occurred.

If the head only of the flame had been rotating, the first recorded portion of the photograph would have been a well-defined point or short line followed by a general greyness of diminishing photographic intensity. The records, however, show a considerable number of well-defined lines of alternate positive and negative slope, and these are evidently produced by the passage of successive portions of a long slender tail first across the front and then across the back of the tube. The regularity of the zig-zag lines also suggests that the whole length of the highly luminous gas is moving round the tube at a velocity which is approximately constant.

The form of the tail. Since the head and the tail of the combustion are rotating in the tube with the same frequency, it seems probable that the tail is the still-luminous track of the head, a very intense local burning near the wall of the tube. The tail, therefore, may occupy the exact position of the path traversed by the head, or its position and form may be modified by the movement of the gases of which it is the most luminous part.

If, during an explosion, the gaseous mixture is, for the moment, assumed to remain at rest, and the head of the flame is traversing a helical path, the luminous tail would, at any instant, be helical in form—like a helical coil of wire lying in the tube. At a narrow horizontal window certain fixed points would be illuminated and should appear as *vertical* bars or striæ in the photographs. It is, however, almost certain that the gaseous mixture is being carried forward in the same direction as the explosion wave, for incandescent dust particles are, in many experiments, apparently carried forward at velocities approaching 1000 m./sec. If this be the case, the helical path of the tail should also be carried forward and produce striæ sloping in the *same* direction as the trace of the flame front. The records, however, show striæ which are never vertical but are either

horizontal or have a slight slope in the opposite direction, and it appears most improbable that a backward movement of the gases, sufficiently rapid to produce striæ of this type and starting from the wave front, could take place. The hypothesis that the tail occupies the helical track of the head in gas which is at rest or moving parallel to the tube axis appears, therefore, to be untenable.

We are inclined to the view that, if the gaseous mixture were at rest or moving only forwards or backwards in the tube, the track of the head would be parallel to and probably near the wall of the tube, and that the tail would be a long narrow pencil of burning gas also parallel, or nearly parallel, to the axis of the tube. This would cause a uniform exposure of the photographic film. If now, the gaseous mixture were set in rotation, the head and tail would both appear intermittently at a horizontal window; the photographic trace of the head of the flame would be undulated, and each appearance of the tail would be recorded as a stria.

If the luminous pencil remained parallel to the axis of the tube whilst the whole mixture was rotating at constant velocity, it should produce horizontal striæ, and these have, in some cases, been observed. The striæ are, however, more frequently slightly inclined to the horizontal, and their slope may be accounted for in one of two ways: either (*a*) the pencil of luminous combustion is inclined to the tube axis, or (*b*) the rates of rotation of different parts of the burning gases are not identical.

Some information on this point may be obtained by comparing the vertical distance on the film between the ends of a single stria with the width of a strip of film which would be affected by a luminous inclined rectilinear tail as it passed once across a narrow window. Each point on a rectilinear tail must, in rotating, pass a window at the same angular velocity as the head of the flame: the time of exposure t is therefore equal to $La/2\pi rV$, where a is the length of arc visible through the window. Using a 3 mm. upper window in a 15 mm. tube, and neglecting the optical effects of the tube wall (which would still further restrict the field of vision), it is safe to assume that not more than one-quarter of the internal circumference is visible. Hence $a/2\pi r < 0{\cdot}25$ and therefore $t < 0{\cdot}25 \times 45/1750 \times 10^{-3}$, *i.e.*, $< 6{\cdot}4 \times 10^{-6}$ sec. During this time a film travelling at 50 m./sec. will be exposed over a vertical distance of $6{\cdot}4 \times 10^{-6} \times 5 \times 10^{4} = 0{\cdot}32$ mm. If, in addition, the tail should, at any moment, appear as a line inclined across the full width of the window, an additional strip of film, whose maximum width is that of the image of the window, will be exposed. In a typical experiment, where $\mu = 0{\cdot}06$ and the window is 3 mm. wide, the additional strip will be 0·18 mm. wide, and the total maximum width of film

Fig

Time axis

2103

affected during the recording of each stria will be 0·32 + 0·18 = 0·50 mm. The vertical distance on the film between the ends of a single stria usually measures 1·2—1·5 mm., and it would therefore appear that, under the conditions of our experiments, a rectilinear tail of any possible slope cannot account for the production of striæ having both great length and appreciable inclination.

An alternative suggestion is that the pencil of luminous gas forming the tail is not rectilinear but is regularly distorted along its length so that it tends to assume the form of a helix. This distortion might be produced by a constantly diminishing speed of rotation of the gaseous medium as its distance from the head increased. Successive portions of this tail, therefore, would not appear at a horizontal window simultaneously but at successive time intervals, and would be recorded as sloping striæ (Fig. 10). The smallness of the slope suggests that the deviation of the tail from a straight-line form is slight, *i.e.*, that the helix is of great pitch. In those mixtures which do not allow of the formation of a long tail, the pitch of the tail helix may be so great that a complete turn may never occur. In other cases, the tail may be long enough for several turns of the helix to be luminous at the same time, and, through a narrow upper window, the corresponding points on each turn of the helix should be visible at any instant. The pitch of the helix, in these cases, may be estimated, therefore, by drawing a horizontal line—representing an instant of time—across one of the records so that it cuts two or more striæ; the length of the line thus intercepted is a measure of the pitch of the helix. Because of the lack of definition of the striæ, the measurement is only approximate, but in one case the pitch so estimated was found to be 46 cm., or about 10 times the pitch of the path of the head of the flame.

Insertion of a Coaxial Rod.—It was thought that some further information on the movements of the gases might result from experiments in which a glass rod was inserted into the tube coaxially with it, so as to offer to gaseous rotation an increased frictional resistance, while having a minimum effect upon any helical motion of flame in a still medium, if a propagation of this type took place.

The tube was 15 mm. in diameter, and the rods were 50—60 cm. long and 5—10 mm. thick. A rod was supported centrally by short, thin copper vanes attached at each end; these vanes offered only a slight resistance to the forward movement of the explosion. The mixture used was, in every case, $2CO + O_2$ (containing about 1% of H_2), and some of the records are reproduced in Figs. 11—14. When a 5 mm. rod was inserted, the forward velocity of the explosion-wave was quite unaffected, but, in the neighbourhood of the rod, the frequency of the striæ was appreciably decreased. Before and

beyond the rod, the undulations and the striæ had the normal frequency. When a rod of 8·3 mm. was used, its effect as an obstacle to the flame became evident, a strong pressure wave being reflected back through the burning gases from the end of the rod first encountered by the explosion wave: the striæ were not so well marked, and the flame velocity was not quite constant. A 9·5 mm. rod accentuated these effects, and the rod was shot from the tube, even though the end of the rod first encountered by the flame had been tapered to a point. A 10 mm. rod appeared to offer an insurmountable obstacle to the normal propagation of the flame. The pressure wave was very intense, and the rod was ejected from the tube: the flame velocity fell to about three-fifths of its former value, and the striæ were hardly visible.

TABLE I.

Effect of an Inserted Rod on the Pitch of the Undulations.
Diameter of Tube (D) = 14·7 mm.

Diameter of rod, mm.	—	5·0	8·3	9·5	10·0
Distance between undulations, *L*, mm.	44	53	55	61	indeterminate
L/*D*	2·99	3·61	3·73	4·16	—

The change in frequency of the striæ at the point where the rod was originally placed is not very abrupt; this may be due, in part at least, to the movement of the rod along the tube, for it was found difficult to make it very secure without using supports which were themselves obstacles to the explosion wave. The frequency of the striæ, however, becomes quite constant within a few centimetres, and is, in each experiment, much smaller in that part of the tube occupied by the glass rod than in the unobstructed portions of the tube. As the thickness of the rod is increased, the frequency of the striæ diminishes and the pitch (*L*) of the undulations undergoes a corresponding increase as shown in Table I. It appears reasonable to suppose that the narrower the annular space the greater will be the retarding effect of the viscous, frictional, or other forces on the speed of rotation of the gases, and the change in pitch of the undulations may indicate that such retardation has taken place.

Effect of Tube Form on the Rotation of the Gases.—It has been shown (J., 1927, 1575) that in uniform cylindrical tubes having diameters of 8—19 mm. the distance between successive undulations is approximately proportional to the tube diameter. This distance, which may be identified with the pitch of the helical path traversed by the head of the combustion, depends on the period of rotation of the gases and on the forward velocity of the flame. For any given mixture the latter is constant, and therefore the period of rotation

of the gases is proportional to the diameter, and hence to the circumference of the tube. That is to say, the *peripheral* velocity of rotation of the gases in the flame front is approximately constant in tubes of different diameters. This explains the gradual decrease in frequency of the undulations observed when a flame travels towards the wider end of a conical tube (Fig. 1).

The head, during each rotation in the wider part of the tube, traverses a longer path than the tail, which is still rotating in the narrower part: it will therefore appear at a horizontal window less frequently than points on the tail, and the end of the latter may become visible before the head passes across the window at a point nearer the wider end. Intermediate points on the tail will be similarly affected to a degree corresponding to the distance from the head, and the photographic records should show striæ sloping in the same direction as the trace of the flame front; such striæ are seen in Fig. 1.

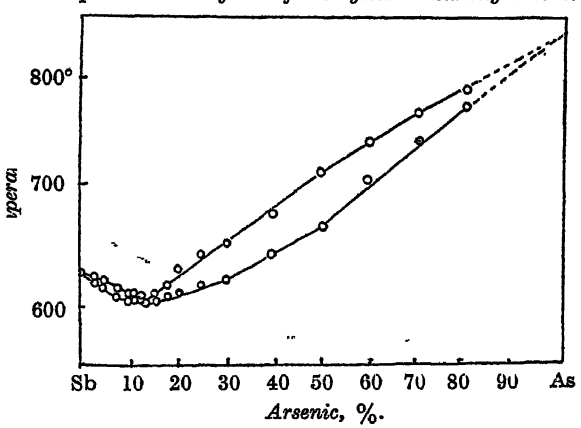
The hypothesis of gaseous rotation may also explain the record (Fig. 7 of the previous paper; J., 1927, 1572) obtained when an explosion wave passes from a wide to a narrow tube. The velocity of the explosion wave remained unchanged, but the period of the undulations very rapidly became that characteristic of the narrow tube. The striæ in the two sections of the tube are not independent, as would be the case if the flame travelled along a helical path in a quiescent medium. If the gases are rotating at constant peripheral velocity in the two sections of the tube, as has been suggested above, the angular velocity of rotation will be greater in the narrow section. The change of velocity at the junction will, of necessity, be a gradual one, and the period of rotation of the tail will therefore be unequal at various points along its length, decreasing towards the flame front. This would account for the great increase in backward slope of the striæ in the first few cm. of the narrow section of the tube.

Although the rotation of the medium would appear to account for the striæ, certain questions still remain unanswered. It is, for instance, not yet clear how such rotation is initiated, what conditions are necessary for its continued existence, and whether the absence of striæ when certain gaseous mixtures are employed is due to the absence of rotation or to the predominant effect of other factors. Such problems as these are at present under investigation.

We should like to record our indebtedness to the Brunner Mond Research Fund, from which some of the apparatus has been purchased, and to the Department of Scientific and Industrial Research for a grant which has enabled one of us (A. C. F.) to devote his whole time to the work.

UNIVERSITY OF MANCHESTER. [*Received, April 11th*, 1928.]

CCLXXVI.- *Equilibrium Diagram of the System Antimony–Arsenic.*



By Qasim Ali Mansuri.

The fact that commercial antimony contains small quantities of arsenic suggested the possibility of the formation of antimony–arsenic alloys, and as no such alloys have been described, the present investigation was undertaken.

Preparation of Materials.—Pure arsenic was prepared as described by the author (*J. Inst. Metals*, 1922, **28**, No. 2); and pure antimony was prepared from the pure trichloride by conversion into oxychloride, which was dissolved in concentrated hydrochloric acid, distilled, reprecipitated, and reduced with sodium carbonate and potassium cyanide.

Alloys.—Accurately weighed quantities of the two metals (40—50 g. together) were placed in hard-glass tubes which were evacuated, sealed, packed in sand in an iron tube, and heated in an electric furnace, thorough mixing being effected by a rocking movement applied to the furnace when the metals were sufficiently mobile.

Equilibrium diagram of the system antimony–arsenic.

6	11	614	607	15	50	716	680
7	12	612	607	16	60	746	710
8	13	605	—	17	70	772	745
9	15	615	607	18	80	792	778

Thermal Analysis.—The temperature of the cooling alloy was recorded by a suspended mirror galvanometer and scale connected with a thermocouple, the hot junction being applied in close contact with the outside of the alloy tubes by means of fireclay. The rate of cooling was about 8° per min. at high temperatures and about 5° per min. below 500°. A cooling curve was always repeated whenever there was any doubt as to its accuracy. Half-minute readings gave the foregoing thermal arrests, from which the equilibrium diagram of the system was constructed.

As none of the arsenic sublimed in the upper part of the glass tube or separated from the alloy, a chemical analysis of the alloys was considered unnecessary, and the composition was based on the weights of the two metals taken. The last alloy (80% As) was rather difficult to prepare, as the temperature required for its formation caused softening of the glass; and higher alloys could not be prepared for this reason.

The alloys freeze over a range of temperature and do not have a single sharp melting point. The first thermal arrest is the beginning of the freezing range and the second is the end.

Micrographic Analysis.—Suitable pieces of the alloy, polished as described previously (*loc. cit.*), were etched with ammonium sulphide and photographed, but owing to rapid oxidation of the surfaces the photographs are not suitable for reproduction. All the alloys proved to consist of a single constituent with a certain amount of coring; in the 80% arsenic alloy, fairly large six-sided crystals were observed.

Summary.

1. Arsenic and antimony alloy in all proportions.
2. They form solid solutions but no chemical compound.
3. The alloy containing 13% of arsenic freezes at the lowest temperature.

CCLXXVII.—*Colloidal Platinum. Part IV. The Existence of Hexahydroxyplatinic Acid in Colloidal Platinum Solutions.*

By STUART W. PENNYCUICK.

IN Part III (this vol., p. 551) it was shown that solutions of colloidal platinum, when prepared by the Bredig method and with extreme precautions, contain a free strong acid which remains in solution

after the platinum has been coagulated. Those results are now confirmed, and evidence is produced that the strong acid is hexahydroxyplatinic acid.

Preparation and Procedure.—The colloidal platinum was made in water of specific conductivity (κ) less than 0·4 gemmho, and with the precautions previously outlined. Only relatively fresh sols were used, *i.e.*, those not more than a week old. After preparation, the sol was boiled for 20 minutes (unless otherwise stated) and then kept in the ice-box to minimise further changes. After 2 days the larger suspended particles appeared to have settled out, for the results outlined in this paper were not appreciably altered when the sols were centrifuged.

The titrations were carried out as described in Part II (J., 1927, 2600). The bases used were exactly 0·001*N*, and were kept in waxed bottles. A simple manipulation allowed of the transfer of the base to the titrating pipette and thence to the cell, without any contamination by atmospheric carbon dioxide.

Isolation of the Free Acid.—The evidence (Part III, *loc. cit.*) clearly indicated that the free acid was a strong acid, comparable in strength with hydrochloric acid. The titration curves (Part II) were, however, not strictly comparable with curves of strong acids, and the author concluded from such titrations that platinum sols were "really unique, and that they cannot strictly be compared either with strong or with weak acids." This apparent contradiction makes it fairly evident that the platinum particles themselves play a disturbing part during neutralisation of the platinic acid by the base.

Now, if the platinum sol is frozen into a solid block (from the outside to the centre), and then re-melted, the whole of the metal is completely precipitated. The solution remaining is not only as clear as water, but after standing or centrifuging, it shows no ultramicroscopic evidence of any remaining suspension. The conductivity of the clear solution is generally about 25% less than that of the original sol. This decrease is probably due to the smaller solubility of the free acid at the lower temperature. The original (and in fact a much higher) conductivity can be obtained by re-boiling the sample containing the coagulated platinum. The higher conductivities so obtained indicate that some of the platinic acid forms part of the colloidal particle. The coagulation by freezing is strictly irreversible.

Sols from which the platinum has been removed by freezing are designated throughout this paper as "coagulated (frozen) sols."

Titration of the Acid in the Coagulated (Frozen) Sol.—The acid being thus isolated, attempts were made to identify it; but owing

to the small quantity present (about 8 mg./l. in an ordinary sample), trustworthy quantitative methods were extremely difficult to apply. Titration of the coagulated (frozen) sol with various bases, however, would definitely test the previous evidence in favour of the acid being a strong acid. This would not only give some indication of the nature of the acid present, but a comparison of the titration curves with those obtained by the titration of the original platinum sol would afford some information as to the action between the added base and the colloidal particles.

Different samples of the coagulated (frozen) sol, of $\kappa = 10$—24 gemmhos, were accordingly titrated at 30° with calcium, barium, sodium, and potassium hydroxides. Since the first two bases gave

similar results, only those for calcium hydroxide are shown; and for a like reason the results of the last two bases are illustrated by sodium hydroxide (see Tables I and II, and Fig. 1, Curves 1 and 2). The two curves are similar in shape and have almost the same minima, the sharpness of which is characteristic of titration curves of strong acids; moreover, weak acids give different types of curves with these two bases (see J., 1927, 2609). The sodium hydroxide curve shows the lower minimum, as would be expected from the

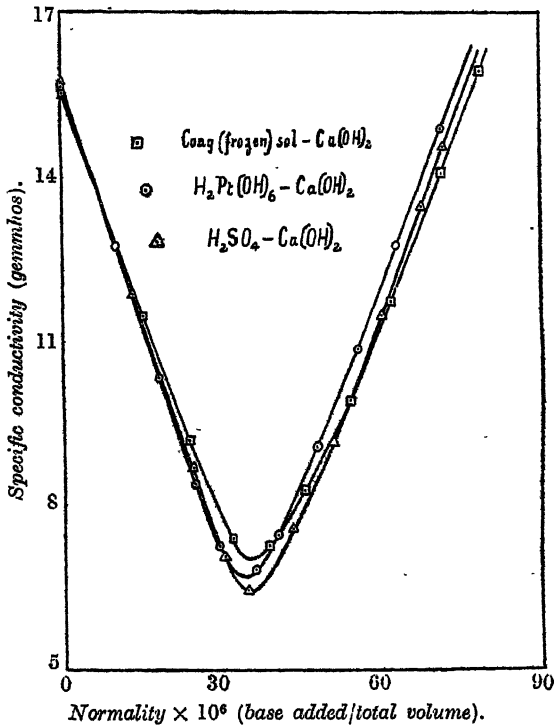
FIG. 1.

mobilities of the sodium and calcium ions, *viz.*, 58·3 and 69·96, respectively (see H. S. Taylor, "A Treatise on Physical Chemistry," 1924, p. 540). In each case the end-points agree satisfactorily with those calculated from the initial conductivities and ionic mobilities.

From this evidence one can conclude quite definitely that the free electrolyte present in platinum sols is a strong acid, and in view of the method of preparation it must be a platinic acid. Now only one such acid is known, *viz.*, hexahydroxyplatinic acid, $H_2Pt(OH)_6$, prepared and investigated by Wöhler (*Z. anorg. Chem.*, 1904, **40**, 423) and by Bellucci (*ibid.*, 1905, **44**, 168). These authors show that it

is a strong dibasic acid, more stable than the corresponding chloroplatinic acid, and that its salts undergo no hydrolysis at 25°. It therefore seemed probable that this was the acid formed during the preparation of platinum sols, but since it is described as being insoluble, an investigation of its solubility limits and its titration curve was necessary in order to strengthen this conclusion.

Preparation and Titration of Hexahydroxyplatinic Acid.—The acid was prepared by boiling chloroplatinic acid with excess of 10% sodium hydroxide solution, diluting the product, and neutralising it with acetic acid in the cold (see Bellucci, *loc. cit.*). The resulting white or yellowish-white precipitate was washed very thoroughly with conductivity water, being warmed with successive additions of 500 c.c. of the water for the final washings. The purified material, when heated to 60° with excess of conductivity water, gave an acid solution having $\kappa_{30^\circ} = 7{\cdot}5$ gemmhos, which increased to 36 gemmhos after 40 minutes' boiling in a borosilicate flask. Platinum sols when boiled for the same time in the same way showed a specific conductivity of about 25 gemmhos. (Various samples of conductivity water were subjected to the same treatment as controls, and always showed $\kappa < 0{\cdot}9$ gemmho.) It is thus evident that the solubility of the hexahydroxy-acid (on boiling) is quite sufficient to account for the conductivity of the platinum sols (also on boiling).



A complication now arises, however. Wöhler (*loc. cit.*) has shown that the white hexahydroxy-acid, which may be formulated as $PtO_2,4H_2O$, loses 1 mol. of water on boiling and gives an ochre-gold trihydrate, which is also probably a strong acid corresponding to $H_2PtO(OH)_4$. On prolonged boiling or on heating in the dry state, it is further dehydrated to the brown $PtO_2,2H_2O$ and then to the monohydrate, but the final molecule of water is very difficult to remove. These changes take place in the insoluble portion of the acid, but it is not known whether they also occur with the dissolved acid; it is certain, however, that the conductivity of the supernatant liquor is increased during these changes in the precipitate.

Owing to the above changes, the solubility product of the hexahydroxy-acid could not be determined. Also, the reason why the sample of hexahydroxy-acid was not boiled during the washing is now apparent.

If the ochre-gold product, or even the brown product, or a mixture of the two, be boiled with conductivity water, some passes very slowly into solution. Different samples of these solutions at widely varying stages of boiling were titrated with sodium and calcium hydroxides, and in every case the shape and position of the curves showed the solution to be that of a strong acid. Only one set of

results is given, *viz.*, that of the once-boiled hexahydroxy-acid * (boiled 25 minutes) when titrated with calcium hydroxide (see Table I and Fig. 2). This curve compares very closely with the corresponding curve for the coagulated (frozen) sol shown in the same figure. It is quite probable that a small and undetected amount of colloidal platinum remains in the coagulated (frozen) sol despite the freezing process. This platinum would cause a slight displacement in the titration curve which would account for the small divergence in the two curves.

FIG. 2.

In order to estimate the experimental error involved in the titration of these acid solutions of such low concentration, a very dilute sulphuric acid solution, stored and handled in exactly the same way as one of the previous solutions, was titrated with calcium hydroxide. The results are in Table I and Fig. 2. The normality

* Although this solution was considered to be the most comparable with the platinum sols (boiled 20 minutes), the boiled solutions of the lower hydrates (*e.g.*, $PtO_2,2H_2O$) showed titration curves whose turning points corresponded very closely indeed to that of the hexahydroxy-acid.

calculated from the initial specific conductivity is 0·000034, and that read from the curve is 0·000035. The conductivity at the turning point is calculated from the mobilities as 5·4 gemmhos, whereas the observed conductivity is 6·4 gemmhos: this difference may be attributed to the unavoidable contamination during boiling and handling.

Titration of the Platinum Sol.—Results for the titration of platinum sols have already been published (J., 1927, 2600), but they were repeated on material prepared in such a way that the curves should be strictly comparable with those obtained from the coagulated (frozen) sols. A sample (800 c.c.) of the pure sol was prepared in the usual manner and divided into halves; one half was frozen, and the subsequent solution formed the coagulated (frozen) sol, whilst the other half was titrated directly with sodium and calcium hydroxides (see Table II and Fig. 1). Comparison of these curves with those for the free electrolyte itself (Curves 1 and 2) shows the part played by the platinum particles when the sol is titrated.

Discussion.

The foregoing experiments afford strong evidence that the free acid present in platinum sols is the strong hexahydroxyplatinic acid, probably in conjunction with some of its lower hydrates. Further, the conclusion that some of the platinic acid forms part of the colloidal particle is strengthened by the following direct evidence. If the sol be siphoned over from the dregs soon after preparation, and then centrifuged, the conductivity on boiling increases markedly —from approximately 6 to 25 gemmhos, or even higher. As has been shown, the whole of this conductivity can be ascribed to the strong acids present, and these must have separated from the colloid particle during boiling. It might be suggested that the acid is really formed during boiling by the oxidation of the finely divided particles, but this is not so, for on continued boiling (without loss of volume) a maximum conductivity of approximately 39 gemmhos is reached after about 8 hours—further boiling gives no further increase but ultimately causes coagulation. Also, if the preparation and the boiling take place in an atmosphere of nitrogen, exactly the same results are obtained. We must conclude, then, that the boiling actually liberates the acid from the colloid particle. Further, if a sol with a specific conductivity of 17 gemmhos is centrifuged, coagulated by freezing, and then boiled for 2 hours, the conductivity increases to about 28 gemmhos, thus leading to the same conclusion. Incidentally, it may be mentioned that if the dregs from the original preparation be washed in the cold, and then boiled with conductivity water, the very small conductivities obtained, about

5 gemmhos, indicate that very little acid is carried down by the dregs.

From the total evidence produced, the author interprets the formation of the colloid particles in the following way. During the sparking process and the atomisation of the platinum, some oxidation occurs, probably at one of the poles, with the formation of molecules of hexahydroxyplatinic acid. The anions of the strong acid condense with platinum atoms to build up aggregates of $Pt–H_2Pt(OH)_6$. Each particle thus acts as a multivalent acid micelle of perhaps very high valency. The acid molecules, or at least those at the surface of the particles, tend to ionise. The ionisation of such a multivalent micelle is still open to investigation, but we can well imagine that such ionisation would be relatively slight owing to the big residual charge that would result. As, however, the bound acid is a strong acid, the tendency to ionise will be particularly great, and the result may be interpreted as a dynamic equilibrium at the surface which gives rise to the so-called double layer.

We are now in a position to discuss the titration curves shown in Fig. 1. The wide divergence between the Pt sol–$Ca(OH)_2$ curve and the corresponding coagulated (frozen) sol–$Ca(OH)_2$ curve is very striking, and indicates that the colloidal platinum particles remove considerable quantities of calcium hydroxide. In the absence of evidence to the contrary, the most satisfactory explanation of the removal of the base appears to be the simplest chemical explanation, *viz.*, that on the gradual addition of calcium hydroxide to the platinum sol, the greater part of the base is neutralised by the free platinic acid, but a small amount is neutralised by the acid at the surface of the colloid particle. This proceeds until the whole of the free acid is neutralised, up to, say, the point B on Curve 3. Any further base is then completely neutralised at the surface of the particles to form the calcium salt of the hexahydroxyplatinic acid which is bound at the surface. The early coagulation of the platinum after the point C indicates that the tendency of the micelle to ionise is not very great, *i.e.*, that the double layer at the surface is disappearing.

At the points E and D, we have the same quantity of calcium hexahydroxyplatinate present—assuming that none has diffused away from the colloid surface in the case of the point D. Further, since the conductivities at these two points are the same, and calcium hydroxide is the only other electrolyte present, it follows that the difference in concentration at E and D represents the amount of base removed by the colloid particles. This difference is 0·000091*N*, and the surface acid neutralised by this excess of base would also be represented by 0·000091*N*, which in the free state would give rise

to a conductivity of 39 gemmhos. When the sol was boiled till it gave a maximum conductivity, the total increase found, due to the liberation of the bound acid, was only 23 gemmhos. The difference of 16 gemmhos may be due to the boiling process not liberating the whole of the acid, or perhaps to the solubility limit of the hexahydroxy-acid, the highest conductivity found for the boiled hexahydroxy-acid being of the order 36 gemmhos.

The Pt sol–NaOH curve (Fig. 1) is essentially different. The relative sharpness of the turning point and the high coagulation concentration indicate that the double layer is more difficult to destroy, and that therefore the sodium salt at the surface of the micelle ionises more freely. Speaking generally, we may say that the greater coagulating power of bivalent bases is due to the formation on the micelle of surface salts, which when so held show a smaller tendency to ionise. This is in keeping with the well-known fact that bivalent bases are less ionised than univalent bases at comparable concentrations.

Two further circumstances may be emphasised. (1) The platinum sol was generally prepared in a stream of carbon dioxide-free air, but this atmospheric oxygen was not responsible for the oxidation of the platinum to the hexahydroxy-acid during sparking, for a preparation carried out in a stream of nitrogen gave strictly comparable conductivities, and on boiling and titration (in a stream of nitrogen) the same set of curves was obtained. (2) If the freezing mixture used during the preparation be dispensed with, and the sol be allowed to become warm, there is always more platinum wastage and a much weaker sol results. This cannot be ascribed to coagulation by heat, for platinum sols can be boiled quite safely for several hours. Now it has been shown that hexahydroxyplatinic acid must be prepared in the cold, and it would therefore appear that the initial preservation of the acid (by the use of a freezing mixture) is essential to the preparation of a strong stable sol.

Summary.

The existence of a strong (free) acid in colloidal platinum sols has been verified by coagulating the platinum by freezing and then titrating the remaining clear solution.

It is believed that there is present either the strong hexahydroxyplatinic acid or a mixture of this acid with some of its dehydrated forms.

Evidence is produced that the hexahydroxy-acid enters into the structure of the colloid particle, and it is suggested that ionisation of the surface acid accounts for the stability of the colloid.

Coagulation of platinum sols by bases is discussed in terms of the neutralisation of this surface acid.

The author is very much indebted to Mr. A. E. Scott, B.Sc., for the preparation of the sample of hexahydroxy-acid used in this work.

THE UNIVERSITY OF ADELAIDE,
SOUTH AUSTRALIA. [*Received, April 30th*, 1928.]

CCLXXVIII.—*The Pectin and Hemicelluloses of the Flax Plant.*

By STANLEY THOMAS HENDERSON.

ON the constitutive problem of the plant pectins the most important papers are those of von Fellenberg (*Biochem. Z.*, 1918, **85**, 118), Ehrlich (*ibid.*, 1926, **168**, 263; **169**, 13), and Nanji, Paton, and Ling (*J. Soc. Chem. Ind.*, 1925, **44**, 253T). Von Fellenberg and Ehrlich extracted their material from plants by water boiling under pressure, whereby products were obtained differing considerably from the "ammonium oxalate pectin" described in the present work.

1. *The Ammonium Oxalate Pectin.*—Flax fibre separated mechanically from the unretted straw was extracted with hot dilute (0·5%) ammonium oxalate solution, and the pectin worked up in the usual way, the characteristic methoxyl groups being removed by alkaline hydrolysis. There remained a substance which from analysis and properties was galactosetetragalacturonic acid, $(C_6H_{10}O_5,4C_6H_8O_6 - H_2O)_n$. This has roughly the same ultimate composition as the hypothetical galacto-arabino-tetragalacturonic acid, $C_{35}H_{50}O_{33}$, considered by Nanji, Paton, and Ling to represent the demethylated form of the pectin complex. But the calculated amounts of carbon dioxide liberated from the "-uronic anhydride" groups by boiling hydrochloric acid (*d* 1·06) are, respectively, 20·7 and 17·6% for these two molecules. Some of Nanji, Paton, and Ling's estimations did, in fact, approach the higher figure, and in the present work it was observed that the yield of carbon dioxide rose steadily to 20·9% with repeated purification of the pectin. Nanji, Paton, and Ling evidently did not complete the separation of the pectin gel from adsorbed carbohydrate produced, presumably, by hydrolysis of the original pectin complex.

It appeared impossible by precipitation methods to render the pectin free from inorganic matter and a small residual methoxyl content. A copper salt was prepared in an attempt to obtain a

more nearly homogeneous product. Determinations of "-uronic anhydride" on the copper salt were, however, very variable, but the quantities of carbon dioxide evolved in the reaction were large enough to rule out the possibility of any non-carboxylated residue in the molecule. This therefore appeared to be

$$3(C_6H_7O_6)_2Cu,2C_6H_8O_6,4H_2O.$$

Hydrolysis of the ammonium oxalate pectin with boiling dilute sulphuric acid gave an almost insoluble polygalacturonic acid, $(C_6H_8O_6)_n$ or $(4C_6H_8O_6,H_2O)_n$. From this reaction were also obtained a small amount of a soluble acid, giving a soluble barium salt, and a syrup containing arabinose, galactose, and a little fermentable hexose of unknown origin. The arabinose in the syrup might arise from adsorbed pentose (see above), or from partial decarboxylation of galacturonic residues.

A better yield of the polygalacturonic acid resulted from hydrolysis with 1% hydrochloric acid. A highly purified specimen (A7) agreed with the formula $(C_6H_8O_6)_n$. Besides this main substance the same barium salt was obtained as in the sulphuric acid hydrolysis.

Ehrlich described two "digalacturonic acids" derived by hydrolysis of the "pectic acid" of sugar beet, namely, insoluble $2C_6H_8O_6,H_2O$ (*a*) and soluble $2C_6H_8O_6$ (*b*). From his flax "pectic acid," only the soluble *b*-acid could be produced. In the present work the main yield closely resembled his *a*-acid in properties. Differences in molecular weight or configuration may be involved. Exception may reasonably be taken to some of Ehrlich's results, for in determining the equivalent of "digalacturonic acid *b*" from flax pectin he recorded titrations differing from the calculated value by 22, 26, and 31% for three separate preparations, although the ash content of the material, to which these discrepancies were attributed, was less than 1% in the single instance where it was determined.*

For simplicity it has been assumed in the above discussion that the carboxylated groups in pectin and its hydrolysis product are entirely galacturonic acid and not glycuronic residues. This has been indirectly demonstrated by the workers already mentioned, although direct quantitative proof is lacking.

2. *Hemicellulose extracted by Water under Pressure.*—When flax fibre or straw, after a preliminary leaching with hot water, was subjected to the action of water under pressure at temperatures between 100° and 145°, various soluble substances were extracted

* In a recent descriptive paper (*Z. angew. Chem.*, 1927, **40**, 1305) Ehrlich has discarded these "digalacturonic acids" in favour of his earlier views on "tetragalacturonic acids."

in the form of calcium-magnesium salts. This was Ehrlich's method of preparing " calcium magnesium pectate " from whole flax straw, but the chemical and genetic relations between the non-gelatinous, easily soluble " pectic acid " so derived and the ammonium oxalate pectin are obscure. It appears desirable, if only for convenience of description, to restrict the term " pectin " to gel-forming substances of high carboxyl content such as the " ammonium oxalate pectin."

Even when purified from adherent tissues, waxes, pectin, and free hemicelluloses, flax fibre still contained carboxylated hemicellulose (CO_2, 5·2%) soluble in water under pressure (Cashmore, J., 1927, 718). The distinction between pectin and non-pectic hemicellulose was evident in this case. The salts and acids resulting from pressure extraction will therefore be referred to as carboxylated hemicellulose, or non-pectic hemicellulose.

On the question of the possible derivation of non-pectic hemicellulose by degradation of pectin, no definite evidence can be given, except that the autoclave treatment for removal of hemicellulose left behind no pectin soluble in ammonium oxalate. On the other hand, purified ammonium oxalate pectin heated with water under similar conditions was converted into a syrup with no recognisable constituents except -uronic residues.

In the present work, two preparations of hemicellulose were made from unretted flax fibre, and one from unretted flax straw. The first two agreed fairly well with the empirical formula $C_6H_{10}O_5$, and yielded 5·6 and 4·3%, respectively, of " -uronic " CO_2.

The extract from whole straw was first purified and analysed as a calcium magnesium salt with 9·7% of -uronic carbon dioxide. Conversion into the free acid lowered this value to 6·04%. Once again, however, the acid corresponded to the formula $C_6H_{10}O_5$. Part of the material obtained by repeated extraction of the straw at higher temperatures gave only 2·74% of carbon dioxide. Ehrlich's so-called " pectic acid " from flax had a higher oxygen content and 13·0 and 13·9% of -uronic carbon dioxide. These varied figures suggest that mixtures of hemicelluloses were produced by pressure extraction. The calcium magnesium salt from straw was a soluble, amorphous powder agreeing closely with the formula $(C_6H_7O_6)_4CaMg,(C_6H_{10}O_5)_6,H_2O$.

3. *Hexopentosan from Flax Straw.*—The yield of calcium magnesium salt was less than 2% on the weight of straw. A more abundant product (5%) was a solid hexopentosan free from -uronic residues. Pentose estimations indicated the presence of equivalent amounts of hexosan and pentosan, and hydrolysis gave galactose, arabinose, and xylose, also a small amount of fermentable hexose.

Note on the Estimation of Pectin.

Since hemicelluloses without the gel-forming characteristics of pectin may contain -uronic groups, it is clearly inadmissible to estimate pectin in flax straw or fibre, or in other tissues containing cellulose, by determining the carbon dioxide evolved on boiling with hydrochloric acid (*d* 1·06). For example, ripe unretted flax fibre separated mechanically from the straw contained 7·0 to 7·8% of -uronic anhydride in several samples, whereas the pectin found by the precipitation method (*Biochem. J.*, 1922, **16**, 60) was only 4·5 to 5%. This fibre, when all adherent tissues had been removed by repeated treatment with hot soap solution, still contained 1·6% of -uronic anhydride in the cleanest sample examined. After ammonium oxalate extraction this value fell to 1·3% (compare Cashmore, *loc. cit.*). A further source of error is the carbon dioxide derived from oxycelluloses under the conditions of estimation.

In Carré's method of estimation (*Ann. Bot.*, 1925, **39**, 811) the pectin is extracted by boiling *M*/75-hydrochloric acid, and precipitated as a calcium salt. This process applied to clean flax fibre lowered the -uronic anhydride content from 1·9% to 0·3%, but the calcium salt amounted to 0·03% only. Further extraction with boiling *M*/100-sodium hydroxide to remove "middle lamella pectic substance" left the -uronic anhydride content unchanged at 0·3%.

EXPERIMENTAL.

1. *Ammonium Oxalate Pectin.*—The straw used was "J. W. S." flax pulled when ripe; the fibre was removed by breaking, scutching, and hackling without retting. Tannins and other soluble substances were removed by one or two extractions with water at 80—90° for a few hours.

One extraction lasting about 7 hours with ammonium oxalate solution (0·5%) at 80—90° was sufficient to remove most of the pectin. 100 G. of fibre, or tow from the hackling, required about 1 l. of liquid. After extraction the filtered liquid was precipitated by an excess of alcohol to give a pale yellow gel. The solid was finally squeezed nearly "dry" in a linen cloth, redissolved in water to not more than 0·5% concentration, reprecipitated by alcohol with a little hydrochloric acid, and so on. Hydrolysis of methoxyl groups was effected by making the aqueous solution of pectin alkaline (*N*/40 in NaOH) and leaving it for about 18 hours at room temperature before adding acid and alcohol. Finally, the gel was macerated with 90% alcohol, then with alcohol and ether, and dried to constant weight in a vacuum over phosphoric oxide. The dried product was pale cream in colour, granular and hard to powder,

and very slowly soluble in cold water. Excess of acid precipitated it from aqueous solutions, and salts of the alkaline earths at once produced colourless gels. Tollens's naphtharesorcinol reagent gave a violet ethereal extract indicating the presence of galacturonic (or glycuronic) groups. Oxidation with nitric acid (*d* 1·15) on the water-bath gave a small yield of mucic acid presumably derived from the galactose residue, for experiments on polygalacturonic acid failed to produce mucic acid except by the slow action of concentrated nitric acid.

Two samples were analysed: (*a*) six times precipitated, and twice hydrolysed in *N*/40-sodium hydroxide: ash, 1·5%; (*b*) ten times precipitated, and five times hydrolysed in *N*/40-sodium hydroxide: ash, 0·9%. Found, on ash-free basis: (*a*) C, 41·8, 42·2, 41·8; H, 5·0, 4·6, 5·0; CO_2 from -uronic anhydride, 19·7, 20·3, 19·7. (*b*) C, 41·4; H, 5·1; CO_2, 20·9; OMe, 0·77; equiv. by back titration with phenolphthalein as indicator, 228·6. $C_6H_{10}O_5,(C_6H_8O_6)_4 - H_2O = C_{30}H_{40}O_{28}$ requires C, 42·4; H, 4·8; CO_2, 20·7%; equiv., 212·1; one methoxyl group per molecule requires OMe, 3·6%. $C_{30}H_{42}O_{29}$ requires C, 41·6; H, 4·9; CO_2, 20·3%; equiv., 216·6. A thrice precipitated sample, not hydrolysed, gave OMe, 2·2; CO_2, 19·3%.

2. *Copper Salt.*—Pectin purified by several precipitations and hydrolyses was dissolved in water at 70—80° to give a solution of about 0·3% concentration, to which was added one-tenth of its volume of *N*-acetic acid, followed by twice this amount of *M*-copper sulphate solution. The mixture was stirred and heated at 80° for an hour, and the gelatinous copper salt was separated, washed free from soluble copper compounds with large quantities of very dilute, hot acetic acid and then with hot water, alcohol, and ether in succession, and dried to constant weight in a vacuum over phosphoric oxide. It formed hard, granular masses of a bright green colour. Not more than about 4 g. could be conveniently prepared in one operation [Found: C, 34·3; H, 4·2; Cu, 11·3 (mean of seven combustions on three different preparations). $(C_6H_7O_6)_8H_2Cu_3,4H_2O$ requires C, 34·6; H, 4·0; Cu, 11·45; CO_2, 21·1%.

$$C_6H_{10}O_5,(C_6H_7O_6)_4Cu_2,3H_2O$$

or $C_{30}H_{36}O_{28}Cu_2,4H_2O$ requires C, 34·5; H, 4·25; Cu, 12·2; CO_2, 16·9%].

The -uronic anhydride estimation gave values for CO_2 varying from 18·0 to 19·8%, and concordant results could not be obtained for any single sample. Taking the elementary analyses and the *maximum* value found for CO_2, it is possible to deduce the formula $C_{32}H_{46}O_{35}Cu_2$, containing *five* -uronic groups. The number of carbon atoms could hardly be explained by the presence of methoxyl

groups, for a determination by Zeisel's method yielded no trace of silver iodide.

3. *Hydrolysis of Pectin by Sulphuric Acid.*—Dry pectin (16 g.) was softened by heating with water and then made up to 900 c.c. of liquid containing 2% of sulphuric acid. After 15 hours' refluxing, the residual gelatinous precipitate (A1) was separated and the hot liquor was treated with excess of barium carbonate and norit, filtered, and concentrated under reduced pressure to a syrup. This syrup was thoroughly extracted with boiling 90% alcohol. Part was insoluble (B, about 0·5 g.) and the extracts were again concentrated to a syrup (C), which was dried (1·7 g.) over sulphuric acid in a vacuum. A1 was purified by three precipitations from dilute soda or ammonia solution by dilute hydrochloric acid with norit treatment. The solid was washed with dilute hydrochloric acid, water, alcohol, and ether, and dried over phosphoric oxide in a vacuum, yielding 1·3 g. of polygalacturonic acid as a colourless powder (see below). Shorter periods of hydrolysis produced greater yields of polygalacturonic acid. Pectin (5 g.) boiled for 2 hours with 500 c.c. of 2% acid gave 0·88 g. (A2), and 10 g. in 600 c.c. of 3% acid gave 2·75 g. in 5 hours (A3).

B, a barium salt, was three times precipitated from aqueous solution by alcohol with a little acetic acid to cause flocculation (Found: "-uronic" CO_2, 12·14%. Compare barium salt from hydrolysis with hydrochloric acid).

C contained arabinose (identified by the diphenylhydrazone, m. p. 196°), and a larger amount of galactose (α-methylphenylhydrazone, m. p. 182°). Melting points were always checked by the "mixed melting point" with an authentic specimen. No xylose could be detected in C by Bertrand's cadmium xylonate test, no ketose by Pinoff's test, and no methyl pentose by Rosenthaler's test.

The syrup, tested in dilute solution for (i) total reducing sugars by Pavy's method and (ii) hexose fermentable by yeast at 35° in Lohnstein's apparatus, showed the presence of 7·4% of fermentable hexose on the total reducing sugars.

4. *Hydrolysis of Pectin by Hydrochloric Acid.*—Dry pectin (10 g.) was dissolved in about 400 c.c. of hot water containing 30 c.c. of *N*-sodium hydroxide to assist solution. Sufficient concentrated hydrochloric acid having been added to make the solution of 1% concentration after neutralisation of the soda, the whole was heated on the water-bath and the gel was separated and purified as before. The yields of dried acid from 10 g. of pectin were: A4, 8 hours' heating, 3·5 g.; A5, 1½ hrs., 2·75 g.; A6, 1 hr., 3·85 g. Part of the solid prepared by hydrolysis with hydrochloric acid was heated for

a further 2 hours in fresh 2% hydrochloric acid, reprecipitated three times, and dried (A7).

Polygalacturonic acid. The samples so prepared were almost colourless, amorphous powders, slightly soluble in hot water but insoluble in cold water and in the usual organic solvents, soluble in caustic alkali or hot ammonium oxalate solution. The substance reduced Fehling's solution on warming and gave a strong positive naphtharesorcinol reaction. Heated with concentrated nitric acid on the water-bath, it gave a small amount of mucic acid, m. p. 211°; this product was not obtained by treatment with dilute nitric acid, or with bromine and 5% hydrobromic acid in a sealed tube at 100°.

The sodium salt, a stiff, colourless gel, or granular powder when dried, was prepared by adding the acid to less than an equivalent amount of *N*/10-soda, filtering the solution, and precipitating the salt three times from an aqueous solution by alcohol.

A sample of A4, carefully washed after five precipitations and dissolved in an excess of *N*/10-sodium hydroxide (0·2343 g. in 20 c.c.), gave $[\alpha]^{15°}_{Hg\ yellow}$ + 334° and $[\alpha]^{15°}_{Hg\ green}$ + 376°.* The highest value recorded by Ehrlich is $[\alpha]^{20°}_{D}$ + 285° (*Z. angew. Chem.*, 1927, **40**, 1305). Found, on ash-free basis:

Sample.	% C.	% H.	%-uronic CO_2.	Equiv.
A4	38·7	4·9	22·9	187
$2C_6H_8O_6,H_2O$ requires ...	38·9	4·9	23·8	185
A2	39·7	4·8	23·7	—
A5 and A6 (mean)	40·0	4·9	24·2, 22·5	194
$4C_6H_8O_6,H_2O$ requires ...	39·9	4·7	24·4	180·5
A1 and A3 (mean).....	40·8	4·6	25·0, 24·5	—
A7 (mean of three)	40·7	4·3	24·8	185
$C_6H_8O_6$ requires	40·9	4·6	25·0	176

The molecular weight of the sodium salt in 2·5% aqueous solution was 292, but the ice separating seemed to be contaminated with gelatinous matter.

In the A5 experiment, a barium salt was isolated as a colourless powder from the mother-liquor by a method similar to that used before [Found: Ba, 19·2; "-uronic" CO_2, 12·04. $C_6H_{12}O_6,(C_6H_9O_7)_2Ba$ requires Ba, 19·5; CO_2, 12·5%].

5. *Extractions by Water under Pressure.*—(1) Unretted flax fibre was repeatedly extracted with water at 50—60° till the washings were colourless. The hemicellulose required was then removed by 6 hours' heating with water (1 l. to 100 g. of fibre) in an autoclave at 30—35 lb. per sq. in. excess pressure, and worked up as described by Cashmore. The substance, dried in a vacuum over phosphoric oxide, was brown, granular, and easily soluble in water to a mobile solution. Yield, about 1·5%. It reduced Fehling's solution slowly

* The author is indebted to Dr. F. G. Mann, of the Cambridge University Laboratories, for these determinations.

on boiling, was stained brown by iodine, and gave a positive naphtharesorcinol reaction (Found, on ash-free basis: C, 44·8, 44·6; H, 6·3, 6·1; "-uronic" CO_2, 5·57; ash, 4·0. $C_6H_{10}O_5$ requires C, 44·4; H, 6·2%).

Another preparation was finally precipitated from water by strongly acid (HCl) alcohol. The ash content fell to 0·6% (Found: C, 45·0; H, 6·3; "-uronic" CO_2, 4·32; OMe, 1·24; equiv., corrected for methoxyl, 1290).

(2) 450 G. of broken, unscutched straw were used in an experiment similar to Ehrlich's. Soluble substances were removed by extraction with water at 50°. There followed five extractions for hemicellulose, first for 2 hours in 5 l. of water at 30—35 lb. per sq. in. excess pressure, then similarly at higher pressures up to 50 lb. per sq. in. From the straw, now considerably darkened, no pectin could be extracted by ammonium oxalate, although cold *N*-caustic soda removed "free hemicelluloses" precipitable by excess of acetic acid.

The aqueous extracts were concentrated to small bulk on the water-bath, and the yellow, flocculent "calcium magnesium pectate" precipitated by alcohol. That from the first pressure extract (P_1) was worked up separately from the less pure material (P_2) arising from later extracts. The aqueous-alcoholic filtrates from P_1 and P_2 were evaporated under reduced pressure, and fractional precipitation then separated a gummy substance, soluble in water but insoluble in alcohol, from the main yield, which was soluble in both solvents. The aqueous-alcoholic solution of the latter was concentrated and freed from a resinous substance soluble in alcohol but insoluble in water. The hexopentosan present in the aqueous solution was finally obtained as a brown, brittle solid (23 g.) by concentration to a syrup and drying in a vacuum over sulphuric acid.

Calcium magnesium salt from whole straw. This, after treatment with norit and precipitation by alcohol, formed a pale yellow or brown powder easily soluble in water or dilute acid. That described above as P_1 (yield, 4·5 g.) gave, after four precipitations, C, 41·1, 41·1; H, 5·4, 5·0; CO_2, 9·7; ash (CaO, MgO), 5·46, 6·13%. The weights of ash, assumed to be CaO and MgO in equivalent quantities, gave (Ca + Mg), 3·64, 4·08%. $(C_6H_7O_6)_4$(Ca + Mg), $6C_6H_{10}O_5,H_2O$ requires C, 41·0; H, 5·2; CO_2, 10·0; (Ca + Mg), 3·67%.

The fraction P_2 (yield, 3·7 g.) was converted into the soluble acid by three precipitations from dilute hydrochloric acid (Found: CO_2, 2·74%). The main yield P_1 was similarly treated (Found: C, 44·4; H, 6·4; CO_2, 6·04. $C_6H_{10}O_5$ requires C, 44·4; H, 6·2%).

Hexopentosan. Oxidation with nitric acid (*d* 1·15) yielded mucic acid, denoting the presence of galactose residues. Bial's orcinol reaction for pentoses gave a positive result, but the tests for methyl pentose and -uronic groups failed (Found, by the Krüger–Tollens–Kröber method: pentosan, calc. as a mixture of arabinose and xylose, from Kröber's tables, 44·0, 40·9. $C_5H_8O_4,C_6H_{10}O_5$ requires pentosan, 44·9%).

The dried solid (5 g.) was hydrolysed by boiling for 4 hours with 250 c.c. of 1% sulphuric acid. Excess of barium carbonate and charcoal were added to the hot liquid, which was filtered, concentrated to a dark brown syrup under reduced pressure, and dried in a vacuum over sulphuric acid. Arabinose was identified in it by the diphenylhydrazone, xylose with difficulty by Bertrand's reaction. Oxidation with nitric acid gave mucic acid as for the unhydrolysed substance. No methyl pentose, ketose, or -uronic groups were distinguished. By the method previously outlined, it was determined that the syrup contained 4·5% of yeast-fermentable hexose calculated on the total reducing sugars.

The author's thanks are due to the Linen Industry Research Association for permission to publish these results; also to Mr. C. R. Nodder and Dr. A. E. Cashmore for helpful advice and criticism.

[*Received, March 9th,* 1928.]

CCLXXIX.—*Resolution of Racemic Chlorobromoacetic Acid.*

By Hilmar Johannes Backer and Hindrik Willem Mook.

The remarkable behaviour of chlorobromomethanesulphonic acid, which according to Read and McMath (J., 1925, **127**, 1572) does not show optical activity in aqueous solution, led us to examine the related carboxylic acid, chlorobromoacetic acid, $CHClBr{\cdot}CO_2H$.

A preliminary study * had already shown the possibility of resolution. In the meantime Read and McMath stated (J., 1926, 2183) that only in some organic solvents might salts of optically active chlorobromoacetic acid be obtained, and in water, in consequence of immediate racemisation, no activity could be observed. A renewed investigation by the same authors (J., 1927, 537) failed to confirm our results.

We have now completed the resolution of this acid, have measured the molecular rotations of acid and salts, and have calculated the

* Communicated to the British Association (Oxford, August 1926) and to the Academy in Amsterdam (June 1926).

rotation of the undissociated acid by means of its dissociation constant. Finally we have examined the rate of racemisation in acid and in alkaline media and in presence of salts.

Experimental.

Chlorobromoacetic acid is readily prepared from commercial trichloroethylene by the method of Crompton and his collaborators (J., 1920, **117**, 691; 1921, **119**, 1874; 1923, **123**, 1226).

The addition product of dichlorovinyl ether and bromine splits for the greater part into chlorobromoacetyl chloride and ethyl bromide (J., 1921, **119**, 1874) and also to a smaller extent into chlorobromoacetyl bromide and ethyl chloride:

$$CHClBr\cdot CClBr\cdot O\cdot C_2H_5 = CHClBr\cdot COBr + C_2H_5Cl.$$

Chlorobromoacetyl bromide distilled at 158—160°/normal pressure and at 47—49°/15 mm. (Found: Cl + Br, 82·5. Calc. for $C_2HOClBr_2$: Cl + Br, 82·65%). It was identified with the product obtained by heating chlorobromoacetic acid with phosphorus tribromide in chloroform solution on a water-bath (Found: Cl + Br, 82·45%).

The chlorobromoacetic acid obtained from the mixture of chloride and bromide, either by direct hydrolysis or by hydrolysis of the ester, distilled at 103—104°/11 mm. (Found: Cl + Br, 66·6; *M*, 173·4, 173·3. Calc. for $C_2H_2O_2ClBr$: Cl + Br, 66·5%; *M*, 173·4). Under normal pressure it boiled at 214·5—215° with slight decomposition, the distillate containing a little hydrogen halide. It melted at 31·5°. Vanderstichele (J., 1923, **123**, 1227) found 25°, Read and McMath (*loc. cit.*) 38°.

When the acid is neutralised with a concentrated potassium hydroxide solution (*e.g.*, 4*N*), and the same quantity of acid added, the *acid potassium chlorobromoacetate* crystallises (Found: K, 10·2; equiv., 386·8. $C_2HO_2ClBrK,C_2H_2O_2ClBr$ requires K, 10·2%; equiv., 384·9).

The *normal potassium* salt is more soluble. It separates in anhydrous crystals from an aqueous solution on evaporation in a vacuum (Found: K, 18·65. C_2HO_2ClBrK requires K, 18·5%).

Electrical Conductivity of Chlorobromoacetic Acid.—This was measured at 25° (± 0·02°).

Conc., c (g.-mol./l.).	Mol. cond., μ.	μ^2c.	Conc., c (g.-mol./l.).	Mol. cond., μ.	μ^2c.
1 × 0·2724	139·7 × 10^{-3}	5·32 × 10^{-3}	$\frac{1}{32}$ × 0·2724	337·2 × 10^{-3}	0·97 : 10^{-3}
$\frac{1}{2}$ × „	180·5	4·44	$\frac{1}{64}$ × „	359·8	0·55
$\frac{1}{4}$ × „	225·3	3·46	$\frac{1}{128}$ × „	371·6	0·29
$\frac{1}{8}$ × „	267·7	2·44	$\frac{1}{256}$ × „	379·0	0·15
$\frac{1}{16}$ × „	305·3	1·59			

$$\mu^2c = -K\mu_\infty\mu + K\mu_\infty^2.$$

μ^2c plotted as a function of μ gives a straight line intersecting the ordinate axis at the value $K\mu_\infty^2$ and making with the axis of abscissæ an angle whose tangent is $K\mu_\infty$.

By this graphical method we found $K\mu_\infty^2 = 8{\cdot}38 \times 10^{-3}$ and $K\mu_\infty = 8{\cdot}38 \times 10^{-3}/382 \times 10^{-3} = 2{\cdot}19 \times 10^{-2}$. Therefore $K = (2{\cdot}19 \times 10^{-2})^2/(8{\cdot}38 \times 10^{-3}) = 0{\cdot}057$, that is, $K_{25°} = 5{\cdot}7 \times 10^{-2}$.

Resolution of Chlorobromoacetic Acid.—In our preliminary study (*loc. cit.*) the dextrorotatory acid was isolated in the form of its quinine salt. The lævorotatory acid has now been obtained by means of the *brucine* salt, which separates when a solution of sodium chlorobromoacetate (0·1 mol.) and brucine acetate (0·1 mol.) in a total volume of 1 litre are mixed.

The alkaloidal salts may be purified by "cold crystallisation" (*Proc. K. Akad. Wetensch. Amsterdam*, 1925, **28**, 64). This precaution, however, is not necessary, since the tendency to racemisation is not very strong; a careful crystallisation from warm water is sufficient. The solution must not be heated long because of the instability of chlorobromoacetic acid in hot water.

The brucine salt, therefore, is shaken with 2 parts of water at room temperature and mixed with 20 parts of boiling water. The clear solution, obtained within a minute, is quickly cooled until crystallisation sets in. After about five such crystallisations, the brucine salt is optically pure. It crystallises with 2 or 3 molecules of water, which are given off at 110° and in a vacuum over phosphoric oxide (*a*. Found: H_2O, 6·3; calc. for $2H_2O$, 6·0%. *b*. Found: H_2O, 8·5; calc. for $3H_2O$, 8·7%. *c*. Found in salt dried in a vacuum: Cl + Br, 20·4. $C_2H_2O_2ClBr, C_{23}H_{26}O_4N_2$ requires Cl + Br, 20·4%).

In our first experiments the alkaloidal salts were converted into the ammonium salt, whose concentration was estimated by evaporation of its solution. More trustworthy results were obtained by decomposing 2 or 3 g. of the brucine salt with 15 c.c. of water and sodium hydroxide in excess, extracting the brucine with pure chloroform, and titrating the excess of alkali with sulphuric acid (0·2*N*) and phenolphthalein. The solution of the sodium salt (about 20 c.c.), the molecular concentration of which was thus known, was examined in a polarimeter.

In one experiment 200 g. of the brucine salt were recrystallised from 25 times its weight of water. The crystallisation was repeated four times, a sample being used after each crystallisation for polarimetric examination. The brucine salt then weighed only 14 g. and showed no rise of rotatory power.

About 2 g. were decomposed with 15 c.c. of water and 3·47 c.c. of sodium hydroxide (1·035*N*). The solution, after being extracted with chloroform and neutralised with 1·20 c.c. of sulphuric acid

(0·198*N*), showed $\alpha_D = +0{\cdot}21°$ ($l = 2$). The rotation of the sodium salt was thus $[M]_D = +6{\cdot}3°$.

The rotatory power of the free acid in aqueous solution is greater than that of the sodium salt and of opposite sign; it depends on the concentration and is raised by addition of strong acids. The reason is that chlorobromoacetic acid is a fairly strong acid which dissociates to a considerable extent in solution, giving an anion of opposite rotation.

The rotation of the undissociated acid cannot be measured by addition of sulphuric acid in excess, because the dissociation is not sufficiently reduced. Therefore the rotation of the pure acid was measured in different concentrations at 17°, and also the degree of dissociation was calculated from the dissociation constant by means of the equation $K = \alpha^2 c/(1 - \alpha)$. The value of $K_{17°}$ was found to be $8{\cdot}1 \times 10^{-2}$.

The active acid was prepared by decomposing the brucine salt with sulphuric acid, extracting the chlorobromoacetic acid with ether, drying the solution with fused sodium sulphate, and evaporating the ether in a current of dry air at the ordinary temperature. The pure active acid was dissolved in water, and its concentration determined by titration.

If the molecular rotation observed for the mixture acid–ion is represented by M_m, the unknown rotation of the acid by M_a, and the rotation of the ion by M_i ($= 6{\cdot}3°$), we have $M_m = \alpha M_i + (1 - \alpha)M_a$ or $M_a = (M_m - 6{\cdot}3\alpha)/(1 - \alpha)$.

c (g.-mol./l.).	$\alpha_D$obs. ($l=2$).	M_m.	α.	M_a.
0·150	−0·335°	−11·2°	0·50	−28·6°
0·208	−0·525	−12·6	0·44	−27·5
0·250	−0·695	−13·9	0·42	−29·0
0·347	−1·14	−16·4	0·37	−26·0

The average value of $[M]_D$ for the undissociated acid is − 28°.

The rotations of the salt and of the acid were measured for different wave-lengths in order to determine the rotatory dispersion:

λ ($\mu\mu$)	656	589	546	516	486
Anion (sodium salt): $[M]$ ...	+4·8°	+6·3°	+7·4°	+8·3°	+9·1°
Undissociated acid: $[M]$ ...	−22°	−28°	−36°	−42°	−50°

Racemisation of Active Chlorobromoacetic Acid.—An aqueous solution of the free acid does not show any tendency to racemise at the ordinary temperature. The salts racemise, but very slowly.

Only in presence of an excess of a strong base is the velocity of racemisation appreciable. Under these conditions, accurate measurements of the velocity coefficient are difficult, because the acid hydrolyses when it is kept for a long time in alkaline solution;

hydrogen halide is formed and the quantity of free alkali diminishes. The experiments were therefore stopped when the solutions gave a turbidity with nitric acid and silver nitrate. The velocity coefficient was calculated by aid of the formula $k = (\log \alpha_1 - \log \alpha_2)/t$. For a larger number of observations (*e.g.*, 4), Schmid's method (*Z. physikal. Chem.*, 1926, **119**, 8) was used,

$k = (\log \alpha_1 + \log \alpha_2 - \log \alpha_3 - \log \alpha_4)/(t_3 + t_4 - t_1 - t_2)$.

Time was expressed in hours and Briggsian logarithms were used. The rotations were measured for the D and E lines in a tube of 2 dm. and their sum, $\alpha_D + \alpha_E$, was substituted for α in the formula.

1. *Acid solution.* Chlorobromoacetic acid (0·08 g.-mol./l.) in presence of sulphuric acid (1·38 equivs.) at 25°. The rotation, 0·65°, did not change in 77 hours and therefore there was no racemisation.

2. *Acid solution.* The same acid solution as in experiment 1 was examined at 100°. Titration of the acid, 1·46 equivs. per litre. The rotation was 0·665° and fell in $3\frac{3}{4}$ hours to 0·445°. The concentration of the acid titrated had not changed. Racemisation constant $k_{100°} = 4{\cdot}5 \times 10^{-2}$. After $16\frac{3}{4}$ hours the solution was red and the quantity of acid had increased to 1·54.

3. *Neutral solution.* A solution of the ammonium salt with the rotation — 0·14° was kept at the ordinary temperature. After 90 days the rotation was —0·11° and after 570 days —0·07°. The racemisation of the salts in neutral solution is therefore negligible.

4. *Chloroform solution of a salt.* The racemisation of the brucine salt was studied in chloroform solution, because according to Read and McMath (J., 1926, 2184) salts of active chlorobromoacetic acid are stable in this solvent. A solution of 2 g. of the brucine salt in 25 c.c. of chloroform and 5 c.c. of methyl alcohol was examined at 25°; the lævorotation increased gradually owing to racemisation of the dextrorotating component.

t (hours)	0	96	321	417	489	652
$\alpha_D + \alpha_E$	−1·04°	−1·09°	−1·29°	−1·42°	−1·55°	−1·68°

This racemisation, therefore, is not slower, but much faster than the racemisation of the neutral salts in water.

5. *Alkaline solution.* 0·15 G.-mol. of sodium chlorobromoacetate and 0·049 g.-mol. of sodium hydroxide per litre. Temperature 25°. The rotation observed was 0·325° * and after 4 hours 0·145°. The final titration indicated the presence of 0·047 g.-mol. of base, so that the hydrolysis was negligible. Racemisation constant $k_{25°} = 9 \times 10^{-2}$.

* For the pure active salt this value ($\alpha_D + \alpha_E$) should be 0·43°. The salt was thus one quarter racemic, which does not affect the calculation of the velocity coefficient.

6. *Alkaline solution.* 0·18 G.-mol. of sodium chlorobromoacetate and 0·031 g.-mol. of sodium hydroxide per litre. Temperature 25°. The rotation was 0·38° and after 5½ hours 0·225°. Final titration, 0·029 g.-mol. of base. Racemisation constant $k_{25°} = 4·2 \times 10^{-2}$. The racemisation, therefore, is slower than in experiment 5, where the concentration of hydroxyl ions was greater.

7. *Alkaline solution with potassium nitrate.* (*a*) 0·0168 G.-mol. of sodium chlorobromoacetate and 0·0075 g.-mol. of sodium hydroxide per litre at 25°.

t	0	5¾	12¼	
a	0·42°	0·335°	0·255°,	$k_{25°} = 17 \times 10^{-3}$.

(*b*) 0·0168 G.-mol. of sodium chlorobromoacetate, 0·0072 g.-mol. of sodium hydroxide, and 0·2 g.-mol. of potassium nitrate per litre at 25°.

t	0	3¼	12¼	
a	0·42°	0·335°	0·23°.	$k_{25°} = 26 \times 10^{-3}$.

The presence of potassium nitrate, therefore, accelerates the racemisation in alkaline solution.

8. *Alkaline solution with calcium nitrate.* (*a*) 0·0168 G.-mol. of sodium chlorobromoacetate and 0·0039 g.-mol. of sodium hydroxide per litre at 25°.

t	0	18½	29½	42½	
a	0·42°	0·34°	0·31°	0·26°.	$k_{25°} = 4·7 \times 10^{-3}$.

(*b*) 0·0168 G.-mol. of sodium chlorobromoacetate, 0·0030 g.-mol. of sodium hydroxide, and 0·2 equiv. (0·1 mol.) of calcium nitrate.

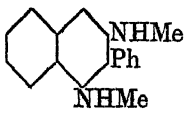
t	0	18	29½	
a	0·42°	0·18°	0·11°.	$k_{25°} = 20 \times 10^{-3}$.

The calcium nitrate causes a greater acceleration of the velocity than potassium nitrate in equivalent concentration.

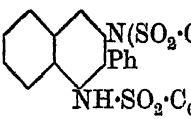
Conclusions.

1. Active chlorobromoacetic acid is stable at the ordinary temperature; the rotation of its aqueous solution does not change in several days.

2. The activity of the salts is not permanent in presence of strong bases. Hydroxyl ions catalyse the racemisation.



3. The racemising action of hydroxyl ions on the chlorobromoacetic anion is accelerated by salts, especially those with kations of higher valency.



ORGANIC CHEMICAL LABORATORY OF THE STATE UNIVERSITY,
GRONINGEN. [*Received, May 15th*, 1928.]

CCLXXX.—N-*Methyl Derivatives of 2-Phenylnaphthylene*-1 : 3-*diamine*.

By CHARLES STANLEY GIBSON, WILLIAM SIMPSON KENTISH, and JOHN LIONEL SIMONSEN.

IT was observed by Lees and Thorpe (J., 1907, **91**, 1296) that when 2-phenylnaphthylene-1 : 3-diamine is methylated two isomeric dimethyl derivatives (I) are obtained, the particular isomeride formed depending on the conditions of methylation. Since these two methylated bases, being di-secondary amines, could not be structurally different, the nature of the isomerism remained unexplained at the time. With the kind permission and encouragement of Professor J. F. Thorpe, we have attempted the elucidation of this problem.

(I.) 

(II.)

We have confirmed in almost all particulars the work of Lees and Thorpe; we have been successful in elaborating somewhat more convenient methods for the preparation of the two bases, more especially of the β-base, and we have also succeeded, although indirectly, in converting the α-base into the β-base. The α-base, which is dimorphic, is formed when the diamine is treated with methyl sulphate in the presence of alkali (see p. 2136) and, by a slight modification of the original method, we have greatly increased the yield of the base. At the same time, a not inconsiderable amount of the tetramethyldiamine is produced together with a small quantity of the trimethyldiamine.

Lees and Thorpe prepared the β-base by heating the parent diamine with an excess of methyl sulphate, but the base is not readily obtained pure by this method and the yield varies considerably with small changes in the temperature of heating. When the reaction is carried out at 94° the β-dimethyldiamine and the trimethyldiamine are produced in approximately equal quantities, and the best yield of the former substance is obtained at 90°. The β-dimethyldiamine is, however, best obtained in a state of purity by the following method in which the formation of higher methylated products is avoided.

Di-p-toluenesulphonyl-2-phenylnaphthylene-1 : 3-*diamine* is very readily prepared by the action of *p*-toluenesulphonyl chloride on the original diamine in pyridine solution. The products of this reaction have been exhaustively examined, since it was of interest to determine whether isomeric di-substitution products are also

formed in this case. The main product of the reaction is a substance, *α-di-*p-*toluenesulphonyl-2-phenylnaphthylene-*1 : 3-*diamine*, which is soluble in alkali and, like the α-dimethyldiamine, is dimorphic, the two forms having m. p. 188—189° and 203—205°, respectively. The lower-melting form, which has been designated α_1-, is obtained when the sulphonamide is precipitated from alkaline solution by acidification or when it is recrystallised from ethyl alcohol in such strength that crystallisation does not take place until the ordinary temperature is reached. When the lower-melting form is melted in a capillary tube and allowed to resolidify, it undergoes conversion into the higher-melting form. The α-, or stable, form of the disulphonamide separates when crystallisation takes place from a hot solution. Both forms crystallise in prisms and the dimorphic relationship was confirmed by Sidgwick's method (J., 1915, **107**, 672).

The alcoholic mother-liquor from which the α-disulphonamide had been removed contained a second disulphonamide, which, after repeated crystallisation from methyl alcohol, was obtained in soft needles, m. p. 173—175°. This substance was only obtained in sufficient quantity for analysis, but in all probability it is *β-di-*p-*toluenesulphonyl-2-phenylnaphthylene-*1 : 3-*diamine* corresponding to the β-form of the dimethyl base.

In addition to the α- and β-disulphonamides, which are soluble in alkali, two other substances were isolated from this reaction. One of these, having m. p. about 213°, was not obtained crystalline and therefore was not analysed. Since, however, it gave the original diamine on hydrolysis, it was probably the tetrasulphonyl derivative. The other crystallised from methyl alcohol in needles, m. p. 153—154°, and proved to be a *trisulphonyl* derivative, probably having the constitution (II).

The α-disulphonamide is readily methylated by methyl sulphate in the presence of alkali, yielding NN'-*dimethyldi-*p-*toluenesulphonyl-2-phenylnaphthylene-*1 : 3-*diamine*, which, on hydrolysis, yields the β-dimethyldiamine in theoretical amount. This is the most convenient method for preparing the pure β-base in quantity.

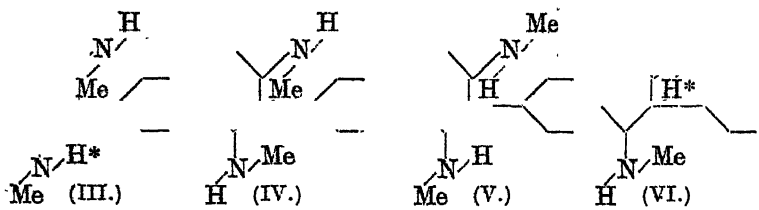
The important investigations by Kenner and his collaborators (J., 1922, **121**, 614 and subsequent papers) on the resolution of substituted diphenylcarboxylic acids have shown that, whilst the molecular asymmetry necessitates the impossibility of free rotation of the two benzene nuclei, the formula suggested by Kaufler to account for certain supposed cases of isomerism is unnecessary (compare Le Fèvre and Turner, J., 1926, 2476). It is significant that molecular asymmetry has been realised only in diphenyl derivatives which have at least three of the four positions

(2 : 2′ : 6 : 6′) substituted and it appears that the substituents should be large (*e.g.*, Cl, NO_2, CO_2H). An adequate explanation of this has been suggested by Mills (*Chem. and Ind.*, 1926, **45**, 883, 905) on a purely mechanical basis (compare Turner and Le Fèvre, *ibid.*, p. 831).

From formula (I), it is clear that in the two *NN′*-dimethyl derivatives of 2-phenylnaphthylene-1 : 3-diamine we have substituted derivatives of diphenyl each with all the substituents in one nucleus. It was found on preparing a model, using ordinary atomic diameters as indicated by Mills (*loc. cit.*), that free rotation of the unsubstituted phenyl group in the dimethyl base is prevented owing to interlocking if all the nuclei and the substituent groups are co-planar. In the light of Mills's suggestion, therefore, it seemed not improbable that one or both forms of this base should be resolvable into optically active forms.

The salts of both α- and β-*NN′*-dimethyl-2-phenylnaphthylene-1 : 3-diamine with optically active acids did not prove satisfactory for the purpose and no evidence of resolution of either of the bases was obtained. We therefore investigated the methylenecamphor derivatives prepared by condensation of each of the two bases with *d*-hydroxymethylenecamphor—a method which, in the hands of Pope and his collaborators (Pope and Read, J., 1913, **103**, 1516; Kipping and Pope, J., 1926, 494), has proved of great value for the optical resolution of primary and secondary amines.

The α-base, when treated with *d*-hydroxymethylenecamphor, gave a quantitative yield of α-NN′-*dimethyl-2-phenylnaphthylene*-1 : 3-*diaminomono*-d-*methylenecamphor*, only one of the secondary amino-groups reacting. This substance, which crystallised well, was perfectly homogeneous and there was no sign of the formation of optical isomerides. The remaining secondary amino-group is singularly unreactive and cannot be acetylated by acetic anhydride. This abnormal behaviour of the α-dimethyldiamine is exhibited in other reactions, since it only yields a *monoacetyl* and a *mono*-p-*toluenesulphonyl* derivative.



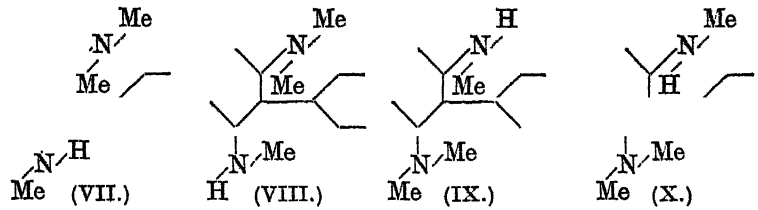
Similar interaction of the β-base with *d*-hydroxymethylenecamphor resulted in the formation of a very sparingly soluble *dimethylenecamphor* derivative, which, like the mono-derivative of the α-base, showed no signs of heterogeneity. The difference in reactivity of the α- and β-bases was further exemplified by the β-base readily yielding a diacetyl derivative and the disulphonamide (m. p. 305°) referred to above.

Although the possibility of the resolvability of the α- and β-dimethyldiamines (compare Gibson and Simonsen, J., 1915, **107**, 115) is not excluded, the facts so far established are adequately explained

by assuming *cis-trans* isomerism of the two bases. This being so, the conversion of the one form into the other should be possible. We have succeeded in converting the α-form into the β-form by an indirect method.

Lees and Thorpe showed that both bases yielded dinitrosoamines on treatment with nitrous acid, the formation taking place very slowly from the α-base (*loc. cit.*, p. 1286) and immediately from the β-base. According to these authors (pp. 1298, 1299) the dinitrosoamine prepared from the α-base has m. p. 174—175°, that from the β-base, m. p. 179°; we have now found that these two dinitrosoamines are identical and, when carefully purified, both have m. p. 180—181°. This identity was confirmed by the method of Sidgwick. When the dinitrosoamine prepared from either of the bases is reduced with tin and hydrochloric acid, it gives a quantitative yield of the β-dimethyldiamine, and it follows, therefore, that it is the dinitrosoamine of the β-base. This explains the retarded separation of the dinitrosoamine when prepared from the α-base, the course of the change probably being the conversion of the mononitrosoamine of the α-base, which is obviously the first product of the reaction, into the mononitrosoamine of the β-base, followed by formation of the dinitrosoamine. This is in complete accord with the facts that the α-base only yields monoacetyl, mono-*p*-toluenesulphonyl, and monomethylenecamphor derivatives.

The conversion of the α-dimethyldiamine into the β-dimethyldiamine by the nitrosoamine reaction strongly supports the view that these two bases are *cis-trans*-isomerides of a type not previously observed. There would appear to be four possible formulæ (partly represented by III—VI) for these bases on the assumption that the rings and nitrogen atoms with attached groups are co-planar.



There can be little doubt that the β-dimethyldiamine must be represented by the *trans*-form (IV), since both the hydrogen atoms of the secondary amino-groups are highly reactive. It is further clear that (V) cannot represent the α-dimethyldiamine, since in it both hydrogen atoms might be expected to be subject to steric hindrance. We have no means of distinguishing between the formulæ (III) and (VI), in each of which one of the hydrogen atoms,

H*, would appear to be likely to be affected by steric hindrance; but we prefer (III), since the base is more reactive than would be anticipated if the hydrogen were in the 1-position in the naphthalene nucleus.

Pending further investigation of related compounds, the suggested uniplanar configuration of the two *NN'*-dimethyldiamines adequately explains their *cis-trans* isomerism. The evidence so far accumulated lends additional support to the generally accepted view that the valencies of a tervalent nitrogen atom lie in one plane.

Lees and Thorpe (*loc. cit.*, p. 1299) described a trimethyldiamine, and we have obtained this base in a somewhat higher state of purity (see p. 2139). It can obviously be represented by partial formulæ (VII—X).

Since this base can be acetylated readily and is also formed by the direct methylation of the β-dimethyldiamine, we consider that it is most probably represented by (VIII). We had hoped to prepare one of the other possible trimethyl bases by the methylation of the α-dimethyldiamine or its *p*-toluenesulphonyl derivative, but in this we were not successful. In alkaline solution the diamine is not methylated, and it is converted into the tetramethyl base by methyl sulphate at 110°. The *p*-toluenesulphonyl derivative was very resistant and was not attacked by methyl sulphate at 145°; above this temperature sulphur dioxide was evolved and decomposition commenced.

EXPERIMENTAL.

2-Phenylnaphthylene-1 : 3-diamine was prepared by the method of Lees and Thorpe (*loc. cit.*, p. 1287). We found it advantageous to interrupt the steam distillation as soon as the xylene had passed over, the excess of nitrile being allowed to remain in the distillation flask. The yield of the base was approximately 50% and after crystallising six times from alcohol and once from light petroleum it had m. p. 113·5° (Lees and Thorpe give 116°). The acetyl acetate, prepared by boiling the base with acetic anhydride containing a trace of pyridine, crystallised from alcohol in prisms, m. p. 175°. The m. p. 185° given by Atkinson and Thorpe (J., 1906, **89**, 1935) is possibly a misprint (Found: C, 71·3; H, 5·8. Calc.: C, 71·4; H, 5·9%).

α-NN'-*Dimethyl*-2-*phenylnaphthylene*-1 : 3-*diamine*.—The yield of the methylated base was somewhat improved by the following modification of Lees and Thorpe's method. The base (15 g.) was dissolved in methyl alcohol (200 c.c.) and after the addition of methyl sulphate (150 g.) potassium hydroxide solution (600 c.c.; 25%) was added gradually, the temperature being kept below 5° and the mixture mechanically stirred. The crude granular methylation product was dried and boiled with methyl alcohol (50 c.c.), which dissolved the bulk of the impurities. The residue after two crystallisations from light petroleum (b. p. 80—100°) had m. p. 168° (yield, 30%).

As shown by Lees and Thorpe, the base is dimorphic, being obtained either in needles or in prisms according to the conditions of crystallisation. The long needles are obtained most readily if either an alcoholic or light petroleum solution of the base be allowed to crystallise at 30°. If such a solution is allowed to crystallise in the ice-chest, the prism form separates. At 17° the colourless needles become yellow and opaque and are seen under the microscope to be pseudomorphs composed of minute prisms. These gradually pass into large yellow prisms. Both forms have m. p. 170°.

The methyl alcoholic and light petroleum solutions from which the α-base had been obtained gave on removal of the solvents a somewhat gummy residue. This was repeatedly crystallised from alcohol and large colourless prisms were ultimately obtained, m. p. 122° (yield, 35%). This substance was identified as the tetramethyl derivative of the diamine by analysis (Found: N, 9·7. Calc.: N, 9·6%), by the method of mixed m. p., and by conversion into the nitroso-derivative, m. p. 135°.

In another experiment the solid from the mother-liquor was dissolved in hydrochloric acid and treated with sodium nitrite solution. A portion of the nitrosoamines formed was soluble in acid and was identified as the nitrosoamine of the trimethyldiamine (yield, 6%). The crude insoluble nitrosoamine, on reduction with tin and hydrochloric acid, gave, in addition to a resin which was insoluble in acids, a quantity of β-*NN'*-dimethyl-2-phenylnaphthylene-1 : 3-diamine. This was best purified by distillation in superheated steam (yield, 25%).

Methylation of α-NN'-*Dimethyl*-2-*phenylnaphthylene*-1 : 3-*diamine*.—When the α-base was heated for 1 hour at 100° or 115° with an excess of freshly distilled methyl sulphate, the mixture gradually became solid and yielded the tetramethyldiamine, m. p. 122°, in a theoretical yield. The diamine could not be further methylated by treatment with methyl sulphate in alkaline solution.

Monoacetyl-α-NN'-*dimethyl*-2-*phenylnaphthylene*-1 : 3-*diamine* was

obtained when the α-base was digested for some hours with acetic anhydride. It crystallised from alcohol in iridescent prisms, m. p. 203° (Found : N, 9·3. $C_{20}H_{22}ON_2$ requires N, 9·2%).

p-*Toluenesulphonyl*-α-NN'-*dimethyl*-2-*phenylnaphthylene*-1 : 3-*diamine*.—A solution of the base (2 g.) and *p*-toluenesulphonyl chloride (5 g.) in pyridine (15 c.c.) was heated on the water-bath for 4 hours, and poured into water. The white solid (3·2 g.) obtained crystallised from alcohol, in which it was somewhat sparingly soluble, in needles, m. p. 219—220° (Found : C, 72·2; H, 5·8. $C_{25}H_{24}O_2N_2S$ requires C, 72·2; H, 5·8%). The *monosulphonamide* was soluble in concentrated hydrochloric acid, and when hydrolysed with a mixture of acetic and sulphuric acids the original α-base was regenerated. It could not be acetylated or methylated, being unaffected by methyl sulphate at 145°.

α-NN'-*Dimethyl*-2-*phenylnaphthylene*-1 : 3-*diaminomono*-d-*methylenecamphor*.—The α-base (2·6 g.) was dissolved in a mixture of alcohol (140 c.c.) and acetic acid (25 c.c.) and after the addition of *d*-hydroxymethylenecamphor (5·4 g.) in alcohol (15 c.c.) the mixture was heated on the water-bath for 30 minutes. On cooling and dilution with water a crystalline solid (2·7 g.), m. p. 168°, separated and a further quantity (1·7 g.) was obtained from the mother-liquor after treatment with alkali to remove the excess of *d*-hydroxymethylenecamphor. The product, which was quite homogeneous, crystallised from methyl alcohol, in which it was somewhat readily soluble, in colourless prisms, m. p. 167—168°. It depressed the m. p. of the original α-base (Found : N, 6·7. $C_{29}H_{32}ON_2$ requires N, 6·6%*). In alcohol at 20° ($c = 0·2484$, $l = 4$), it gave $\alpha_{5461} = +4·04°$, whence $[\alpha]_{5461} = +406·5°$.

Attempts to prepare an acetyl derivative by treatment with acetic anhydride were unsuccessful.

The salt which formed when equivalent quantities of α-*NN'*-dimethyl-2-phenylnaphthylene-1 : 3-diamine and *d*-camphor-10-sulphonic acid were mixed in hot aqueous alcohol and the mixture allowed to cool separated in glistening prisms and was homogeneous.

The α-base (3·5 g.) was added to a hot solution of *d*-α-bromocamphor-π-sulphonic acid (8·52 g.) in water (445 c.c.), and alcohol (30 c.c.) added to give a clear solution. A voluminous mass of fine needles separated and after 2 days changed to yellow prisms of the α-base, which were optically inactive. The filtrate, on evaporation to dryness in a vacuum over sulphuric acid, gave a deep red resin which slowly crystallised in nodules on being kept in acetone–ethyl

* We are indebted to Mr. A. Bennett, of the Microanalytical Laboratory, University of Manchester, for the microanalyses of this compound and of the dimethylenecamphor compound described on p. 2140.

acetate. The salt, which appeared to be homogeneous, could not be recrystallised, since it was insoluble in acetone, ethyl acetate, benzene, and light petroleum. It was readily soluble in water or alcohol but underwent hydrolysis in these solvents.

β-NN'-*Dimethyl*-2-*phenylnaphthylene*-1 : 3-*diamine*.—(1) The base (10 g.), heated with methyl sulphate (65 g.) at 100° for 2 hours, gave a solid which had m. p. 93° after crystallisation from alcohol and was evidently a mixture. When the reaction was carried out at 115—120°, an almost theoretical yield of the tetramethyldiamine, m. p. 122°, was obtained and this was characterised by conversion into the nitroso-derivative, m. p. 136°. A series of experiments was carried out at temperatures between 90° and 100°, since it was found that below 90° the product contained much unchanged primary amine. At 90°, the dimethyl derivative was the main product. It was found possible to estimate fairly accurately the percentages of dimethyl and trimethyl derivatives in the product by treatment with nitrous acid, since the mononitrosoamine of the trimethyl base was soluble in mineral acids, and the dinitrosoamine of the dimethyl base insoluble. The results are in the following table, 2 g. of the crude methylation product being used in each case.

Temp. of methylation.	Dinitroso-amine.	Mononitroso-amine.	% Me_2.	% Me_3.
90°	2·12 g.	0·24 g.	87	11
94	1·20	1·11	49	50
100	0·73	1·55	30	70

(2) The β-base was prepared in quantity by the methylation of *di*-p-*toluenesulphonyl*-2-*phenylnaphthylene*-1 : 3-*diamine*, followed by hydrolysis. A solution of the diamine (50 g.) and *p*-toluenesulphonyl chloride (150 g.) in pyridine (400 c.c.) was heated on the water-bath for 4 hours and poured into water. The thick brown oil obtained was washed with dilute hydrochloric acid to remove pyridine and heated on the water-bath for 30 minutes with sodium carbonate solution to remove the excess of acid chloride; the remainder solidified on cooling and then had m. p. 175—183° (yield, 114 g.). It was best purified by solution in sodium hydroxide (10%), which left undissolved a small quantity of a red solid (*A*). When the filtrate was acidified the sulphonamide was deposited as an almost colourless, crystalline powder. It was recrystallised from alcohol, α-*di*-p-*toluenesulphonyl*-2-*phenylnaphthylene*-1 : 3-*diamine* being obtained pure; the mother-liquor contained a small quantity of a second substance (see below).

The sulphonamide was dimorphic. When crystallised from methyl alcohol, the α-form separated in fine glistening prisms, m. p. 203—205°, and the same form resulted if the amide was allowed to

separate from a *hot* solution in either alcohol or acetic acid. If this form was crystallised from a dilute solution in alcohol, so that deposition took place in the cold, prisms were also obtained which had, however, m. p. 188—189°, rapidly resolidified, and then melted at 203—205°. This low-melting α_1-form was also obtained when an alkaline solution of the sulphonamide was acidified (Found: for α, C, 66·4; H, 4·9; for α_1, S, 12·0. $C_{30}H_{26}O_4N_2S_2$ requires C, 66·4; H, 4·8; S, 11·8%). The sulphonamide was somewhat sparingly soluble in alcohol, benzene, and acetic acid and insoluble in water and light petroleum. The dimorphic relationship of these two forms was established by Sidgwick's method (*loc. cit.*) with benzene as the solvent, the following depressions being observed:

Depression of f. p. by α_1 alone	0·086°
,, ,, ,, ,, α ,,	0·025
,, ,, ,, ,, $\alpha + \alpha_1$	0·029

The original mother-liquor from the first crystallisation of the sulphonamide contained a small quantity of a second substance which, after repeated crystallisation from methyl alcohol, in which it was somewhat readily soluble, was obtained in soft needles, m. p. 173—175°. It is possible that this m. p. is not quite accurate, since the amount of material available for purification was small (Found: C, 66·8; H, 4·9. $C_{30}H_{26}O_4N_2S_2$ requires C, 66·4; H, 4·8%). *β-Di-p-toluenesulphonyl-2-phenylnaphthylene-1 : 3-diamine* is much more readily soluble in the ordinary organic solvents than either of the α-forms and when mixed with these causes a marked depression in m. p.

The solid (*A*) (see above), which was insoluble in alkali, dissolved in hot alcohol, yielding a deep red solution from which a brown amorphous solid, m. p. about 213°, was slowly deposited. This product could not be obtained pure enough for analysis, but was probably the tetrasulphonyl derivative of the diamine, since on hydrolysis with a mixture of acetic and sulphuric acids it gave the original base. The deep red mother-liquor on concentration yielded a small quantity of a crystalline solid, which after repeated crystallisation from methyl alcohol was obtained in fine, colourless needles, m. p. 153—154°. Analysis showed this to be *tri-p-toluenesulphonyl-2-phenylnaphthylene-1 : 3-diamine* (II) (Found: C, 63·7; H, 4·6. $C_{37}H_{32}O_6N_2S_3$ requires C, 63·8; H, 4·6%).

Di-p-toluenesulphonyl-NN'-dimethyl-2-phenylnaphthylene-1 : 3-diamine.—The α-disulphonamide (50 g.) was dissolved in sodium hydroxide solution (270 c.c.; 10%) and methyl sulphate (200 c.c.) was added gradually with constant agitation, the solution being kept alkaline. An oil separated which rapidly solidified (53 g.); it

crystallised from pyridine in small plates, m. p. 305° (Found: C, 67·5; H, 5·3. $C_{32}H_{30}O_4N_2S_2$ requires C, 67·3; H, 5·3%). The methyl derivative was very sparingly soluble in all the ordinary organic solvents.

*Hydrolysis of Di-*p*-toluenesulphonyl-*NN'*-dimethyl-2-phenylnaphthylene-*1 : 3*-diamine.*—The amide (100 g.) was dissolved in a mixture of acetic acid (100 c.c.) and sulphuric acid (200 c.c.) and heated on the water-bath for 2 hours. The clear brown solution was poured on ice and made alkaline with ammonia. An oil separated which rapidly solidified (yield, 46 g.); after crystallisation from alcohol it had m. p. 159—160° and was pure β-*NN'*-dimethyl-2-phenylnaphthylene-1 : 3-diamine. When this base was treated with *p*-toluenesulphonyl chloride in pyridine solution, it was reconverted into the above-mentioned sulphonamide, m. p. 305°. On treatment with methyl sulphate at 100° it was converted quantitatively into the tetramethyl base, m. p. 122°, and in alkaline solution it was partly converted into the trimethyldiamine, which was identified by the preparation of the nitrosoamine.

*Diacetyl-*β*-NN'-dimethyl-2-phenylnaphthylene-*1 : 3*-diamine.*—The β-base was boiled for 2 hours with acetic anhydride, and after removal of the excess of the anhydride by evaporation with alcohol the *acetyl* derivative was recrystallised from dilute methyl alcohol or benzene and obtained in rosettes of small prisms, m. p. 207—208° (Found: N, 8·2. $C_{22}H_{22}O_2N_2$ requires N, 8·1%).

β-*NN'-Dimethyl-2-phenylnaphthylene-*1 : 3*-diaminodi-*d*-methylenecamphor.*—The β-base (2·6 g.) was dissolved in a mixture of alcohol (75 c.c.) and acetic acid (20 c.c.; 50%) and after the addition of *d*-hydroxymethylenecamphor (5·4 g.) in alcohol (15 c.c.) the mixture was heated on the water-bath for 30 minutes. On cooling in the ice-chest over-night, a hard, crystalline cake (4·25 g.), m. p. 274—277°, had separated. By evaporation of the filtrate and removal of the excess of *d*-hydroxymethylenecamphor with alkali a further quantity (1·6 g.) was obtained. It crystallised from alcohol in nodules of colourless prisms, m. p. 277—279° (Found: N, 5·2. $C_{40}H_{46}O_2N_2$ requires N, 4·8%). In alcohol at 20° ($c = 0·2142$, $l = 4$), it gave $\alpha_{5461} = +5·57°$, whence $[\alpha]_{5461} = +650·1°$.

The β-base (2 g.) was added to a hot solution of *d*-camphor-10-sulphonic acid (3·54 g.) in water (7 c.c.). On cooling, the viscid, red solution deposited a mass of fine needles. This salt dissolved in its own water of crystallisation at 105° and was very readily soluble in water, acetone, and alcohol, less soluble in ethyl acetate. The salt and the mother-liquor were separately made alkaline; the base recovered was in each case optically inactive.

The β-base (2 g.), when added to a hot solution of *d*-β-bromo-

camphor-π-sulphonic acid (4·74 g.) in water (25 c.c.), slowly dissolved, giving a reddish-brown solution which deposited an oil on stirring. On cooling, the oil redissolved, but there was no separation of crystals. The solvent was evaporated in a vacuum and the residual resin, which was readily soluble in acetone, crystallised slowly from a solution in ethyl acetate. It was recrystallised from acetone–ethyl acetate, from which it was deposited in nodules. The bases recovered from the crystalline salt and from the mother-liquor were inactive.

The Dinitrosoamines of α- *and* β-NN'-*Dimethyl*-2-*phenylnaphthylene*-1 : 3-*diamines.*—α-*Base.* The dinitrosoamine was prepared as described by Lees and Thorpe (*loc. cit.*, p. 1297) and obtained in a yield of 85%. After recrystallisation from alcohol and then from benzene, it was obtained in clusters of yellow needles, m. p. 180°.

β-*Base.* The dinitrosoamine was obtained from the β-base in a somewhat better yield (95%). The final crystallisation was from benzene. It had m. p. 180—181°.

These two dinitrosoamines were found to be identical. They have the same m. p. and mixtures in all proportions melt at this temperature. The identity was confirmed by the application of Sidgwick's method (*loc. cit.*), benzene being used as the solvent. The following depressions were observed :

Depression of f. p. with				β-form alone, 0·759°
,,	,,	,,	,,	β- + α-forms, 0·764
,,	,,	,,	,,	α-form alone, 0·750
,,	,,	,,	,,	α- + β-forms, 0·761

NN'-*Trimethyl*-2-*phenylnaphthylene*-1 : 3-*diamine.*—The crude nitrosoamine of the trimethyl base obtained by the action of methyl sulphate on the diamine (see p. 2136) crystallised from alcohol in buff-coloured needles, m. p. 151°. These (5 g.) were dissolved in acetic acid (25 c.c.) and, after the addition of an excess of tin and hydrochloric acid, heated on the water-bath for ½ hour, the red solution rapidly becoming colourless. The solution was made alkaline with sodium hydroxide, boiled to decompose tin salts, and extracted with benzene. The dried benzene solution was evaporated, leaving the colourless base, which crystallised from alcohol in needles, m. p. 104—105° (Lees and Thorpe, *loc. cit.*, give 98—99°) (yield, 4·4 g.) (Found : C, 82·8; H, 7·3. Calc. : C, 82·6; H, 7·2%).

The *acetyl* derivative, prepared by means of acetic anhydride, crystallised from alcohol in needles, m. p. 178° (Found : N, 9·0. $C_{21}H_{22}ON_2$ requires N, 8·8%).

One of us (W. S. K.) is indebted to the Department of Scientific and Industrial Research for a maintenance grant which has enabled

him to take part in the work. We wish to express our thanks to the Government Grant Committee of the Royal Society for a grant which has defrayed the greater part of the cost of this investigation.

CCLXXXI.—*The Interaction of Cuprous Chloride and the Chromates of Potassium in a Solution of Sodium Chloride.*

By HUBERT JOHN PATRIDGE VENN and VERNON EDGE.

ROSENFELD (*Ber.*, 1879, **12**, 958) obtained a green precipitate on adding cuprous chloride, dissolved in a concentrated solution of sodium chloride, to an excess of a solution of potassium chromate. Similar experiments are now described, and, in addition, the dichromate was used, and the order in which the reagents were mixed was sometimes reversed. Complex precipitates were obtained, differing in colour and constitution according to the method of preparation. The reaction is shown to consist essentially in the oxidation of the cuprous salt and reduction of the chromate or dichromate, with formation of basic compounds, but owing to their instability to washing, these compounds do not always give trustworthy analytical results.

EXPERIMENTAL.

Materials.—Cuprous chloride, prepared by the method of Wöhler (*Ann. Chem. Pharm.*, 1864, **130**, 373), was stored in the dark in a vacuum desiccator, and remained quite white indefinitely (Found: Cu, by iodometric method, 64·11, 64·06; by electrolysis, 64·08. Calc.: Cu, 64·10%). The other reagents were of A.R. quality; the chromate and dichromate were recrystallised twice and thoroughly dried. All solutions were made up free from dissolved air and stored under hydrogen, and all the experiments were carried out in an atmosphere of the same gas.

Apparatus.—This consisted of a wide-necked bottle, of about 1 l. capacity, fitted with a rubber stopper carrying a motor-driven stirrer, an inlet tube for hydrogen, and a burette.

The reactions were all carried out at room temperature, except in Case II, and the theoretical values in the tables are based on equations (1)—(4) on p. 2145.

Case I. When a dilute solution of potassium dichromate is slowly added to cuprous chloride dissolved in concentrated sodium

chloride solution, a green precipitate is continuously formed until the whole of the chloride is oxidised. If the dichromate is added too rapidly, some of it reacts with the basic products, which then become contaminated with a basic chromate. If this side reaction is avoided, reaction takes place in the molecular ratio $Cu_2Cl_2 : K_2Cr_2O_7 = 3 : 1$, for when known amounts of each reagent were used, complete analyses of the precipitates and filtrates gave the following values for this ratio: 2·96, 3·02, 2·99, 2·99.

Known weights of cuprous chloride were oxidised by the addition during 5 hours of the calculated volumes of a 1% solution of potassium dichromate; cupric chloride was estimated in the filtrate, the amounts of copper thus found being given below as a percentage of the cuprous chloride taken.

G. of Cu_2Cl_2 taken (approx.).	Conc. of sodium chloride solution used. 15%.	20%.	25%.
1	5·64% Cu	5·30% Cu	5·67% Cu
2·5	—	5·79	—
5	5·84	5·45	5·33

Average 5·57% Cu; theory requires 5·35% Cu.

The washed precipitates were dried to constant weight at 97°, and their analyses are given in Table I.

TABLE I.

	1.	2.	3.	4.	5.	6.	Mean.	Calc.	Atomic ratios, found.	Atomic ratios, theory.
Cu, %	43·00	42·92	42·80	42·85	42·82	42·85	42·87	42·38	11	11
Cr, %	12·85	—	—	—	12·83	12·83	12·84	12·61	4·03	4
Cl, %	—	12·90	—	13·04	—	13·05				
Cl, % (corr.)*		12·50		12·55		12·50	12·52	12·89	5·77	6
H_2O, %	18·80	—	—	18·70	—	—	18·75	18·57		

* The correction is due to the deduction of chlorine present in the precipitate as sodium chloride.

Case II. When an attempt was made to oxidise cuprous chloride with potassium chromate in the same way, the reaction did not go to completion, although different conditions of concentration, time of stirring, and temperature (up to 60°) were tried. In two cases the partial precipitates were filtered off, washed, dried at 97°, and analysed:

Cl, %	10·30	—	2·25	—	2

Case III. Known quantities (1·0—1·5 g.) of cuprous chloride were dissolved in 500 c.c. of 20% sodium chloride solution and added

more or less rapidly to excess of potassium dichromate solution; brown precipitates were immediately produced, and the filtrates contained cupric chloride (Found: Cu, as % of Cu_2Cl_2 taken, 10·84, 10·80. Calc.: Cu, 10·70%). The precipitates were washed, and dried at 97°. They contained the chromate radical, but no chlorine. The analyses are given in Table II.

TABLE II.

	1.	2.	3.	Mean.	Calc.	Atomic ratios, found.	theory.
Cu, %	36·30	36·42	36·44	36·38	36·30	5	5
Cr, %	11·60	11·70	11·75	11·68	11·87	1·96	2
CrO_4 as % Cr	11·71	11·78	11·76	11·75	11·87	1·97	2
H_2O, %	14·58	14·50	—	14·54	14·40		

Although the precipitate obtained in Case I reacts with potassium dichromate, we have satisfied ourselves that, even on digestion with 1% potassium dichromate solution for 2—5 days, it cannot be made to yield a precipitate of the same composition as that obtained in Case III, for under such conditions the average composition of the final product, dried at 97°, was Cu, 37·86; Cr, 13·12; Cr, present as CrO_4, 8·15; Cl, 10·25%. It will be seen that although a large percentage of chromate radical is now present, very little change has taken place in the ratio Cu : Cl.

Case IV. These experiments were carried out in the same way as those in Case III, potassium chromate being used instead of the dichromate. This was a repetition of Rosenfeld's (*loc. cit.*) experiment, as far as could be gathered from the available details. The washed precipitates were dried at 110°, as in his experiments, and the results are shown in Table III. Our figures are in better agreement, among themselves, than Rosenfeld's, and the atomic ratios agree better with equation (4) than do those obtained from his results.

Discussion.

It is noteworthy that, in spite of variations in the concentration of the sodium chloride solution and of casual alterations in the time and other conditions, the analytical results are so constant for each set of experiments. Another point of interest is the fact that the reagents are not used up in every case in the proportions given by

the simplest equations by which the reactions can be expressed, *viz.*, (5) and (6). The results of the analyses show that further reactions have taken place, and we give below equations for these secondary reactions. Equations (1), (2), (3), and (4) express, for the respective cases, the sum of all the reactions, and it is from these equations that the theoretical values in the tables have been calculated.

For Case I.

$$2(3Cu_2Cl_2 + K_2Cr_2O_7 + 7H_2O) = 2[2KCl + 2CuCl_2 + 4Cu(OH)_2 + 2Cr(OH)_3]. \quad (5a)$$

$$CuCl_2 + 2Cu(OH)_2 + H_2O = 2CuO,CuCl_2,3H_2O.$$

$$2CuCl_2 + 6Cu(OH)_2 + 2H_2O = 2(3CuO,CuCl_2,4H_2O)$$

or $$6Cu_2Cl_2 + 2K_2Cr_2O_7 + 17H_2O = 4KCl + CuCl_2 + 2CuO,CuCl_2,3H_2O + 2(3CuO,CuCl_2,4H_2O) + 4Cr(OH)_3 \quad (1)$$

For Case II.

$$3Cu_2Cl_2 + 2K_2CrO_4 + 8H_2O = 4KCl + CuCl_2 + 5Cu(OH)_2 + 2Cr(OH)_3 \quad (6)$$

$$CuCl_2 + 3Cu(OH)_2 = 3CuO,CuCl_2,3H_2O$$

or $$3Cu_2Cl_2 + 2K_2CrO_4 + 8H_2O = 4KCl + 3CuO,CuCl_2,3H_2O + 2Cu(OH)_2 + 2Cr(OH)_3 \quad (2)$$

For Case III.

$$3Cu_2Cl_2 + K_2Cr_2O_7 + 7H_2O = 2KCl + 2CuCl_2 + 4Cu(OH)_2 + 2Cr(OH)_3 \quad (5)$$

$$Cu(OH)_2 + K_2Cr_2O_7 = CuCrO_4 + K_2CrO_4 + H_2O$$

$$K_2CrO_4 + CuCl_2 = CuCrO_4 + 2KCl$$

$$2CuCrO_4 + 3Cu(OH)_2 + H_2O = 3CuO,2CuCrO_4,4H_2O$$

or $$3Cu_2Cl_2 + 2K_2Cr_2O_7 + 7H_2O = 4KCl + CuCl_2 + 3CuO,2CuCrO_4,4H_2O + 2Cr(OH)_3 \quad (3)$$

For Case IV.

$$3Cu_2Cl_2 + 2K_2CrO_4 + 8H_2O = 4KCl + CuCl_2 + 5Cu(OH)_2 + 2Cr(OH)_3 \quad (6)$$

$$CuCl_2 + K_2CrO_4 = 2KCl + CuCrO_4$$

$$CuCrO_4 + 2Cu(OH)_2 = 2CuO,CuCrO_4,2H_2O$$

or $$3Cu_2Cl_2 + 3K_2CrO_4 + 8H_2O = 6KCl + 2CuO,CuCrO_4,2H_2O + 3Cu(OH)_2 + 2Cr(OH)_3 \quad (4)$$

Chromates of chromium have been intentionally ignored, on account of the doubt as to their existence in presence of water. The basic chlorides and chromates of copper given above are all known, except $3CuO,2CuCrO_4,4H_2O$; Rosenfeld (*Ber.*, 1880, **13**, 1470), however, has described the compound $5CuO,2CuCrO_4,5H_2O$.

The compound $3CuO,CuCl_2,4H_2O$ has been characterised by Britton (J., 1925, **127**, 2803).

In the equations for the secondary reactions, cupric hydroxide is imagined as behaving at the moment of formation like an electrolyte, and this supposition explains the interesting fact that the reaction proportions and products vary with the manner of mixing the reactants.

Summary.

(1) The interactions of cuprous chloride, dissolved in a solution of sodium chloride, with potassium chromate and dichromate have been studied.

(2) The colour and composition of the precipitates formed depend on the chromate used and on the manner of precipitation.

(3) The precipitates have been analysed, and equations involving basic copper salts have been proposed, according to which the formation of these basic salts is ascribed to secondary reactions.

THE ROYAL TECHNICAL COLLEGE,
SALFORD.

CCLXXXII.—*Acid and Salt Effects in Catalysed Reactions. Part XV. The Catalytic Activity of Hydrochloric Acid in the Hydrolysis of Ethyl Acetate.*

By HARRY MEDFORTH DAWSON and WILLIAM LOWSON.

THE experiments to be described in this paper represent an attempt to measure as accurately as possible the catalytic effect produced by hydrochloric acid of widely varying concentration in the hydrolysis of ethyl acetate.

If the active mass of the hydrolyte is constant and the catalytic effect is assumed to be due to the hydrogen ion, then according to the classical theory the reaction velocity should be given by the equation $v = kc_H$. On the other hand, the equation for the velocity according to the activity theory is $v = k'a_H = k'f_H . c_H$ in which the activity coefficient f_H varies with the hydrogen-ion concentration, or, more generally, with the ionic concentration of the reaction medium.

According to Brönsted (*Z. physikal. Chem.*, 1922, **102**, 169; 1925, **115**, 337), these equations are particular forms of a more general equation, for the applicability of which a substantial amount of experimental evidence has been brought forward. In terms of this equation, the influence of the ionic environment which is

expressed by f_H depends on the nature of the primary reaction. If this involves the interaction of the hydrogen ion with a neutral molecule, the reaction velocity should not be greatly affected by the ionic concentration of the reaction medium, but the converse would be true if the primary change involves the interaction of the hydrogen ion with a negatively charged entity.

For certain reactions, it may not be difficult to identify with some degree of certainty the constituents which are involved in the primary change, but this is by no means generally the case. In such circumstances it cannot be definitely stated whether a given reaction will or will not be markedly affected by variations in the ionic environment. This, indeed, is a matter for experiment, and in the consideration of the data yielded by experiments on acid-catalysed reactions it is of the first importance to ascertain whether the observed catalytic effect is simple or composite. This necessitates the consideration of the effects which may be produced by neutral molecules and negative ions, as well as those which are due to the "hydrogen" or other similar positive ions. Unless due regard is paid to the possibility of such simultaneous catalytic effects, it is scarcely feasible to discuss the question whether the catalytic activity of the hydrogen ion is proportional to its concentration, or whether it is dependent on a factor which varies very appreciably with the ionic concentration of the reaction medium. Furthermore, since the ionisation constants of weak acids are changed by the addition of catalytically inert salts, it is obvious that any attempt to discriminate between concentration and "activity" as the factor which determines the catalysing power of the hydrogen ion requires a careful choice of the experimental conditions. These should be such that the observed catalytic effect can with reasonable certainty be ascribed entirely to the hydrogen ion, and it should further be possible to measure the reaction velocity over a wide range of hydrogen-ion concentrations, for which range the corresponding variations in the thermodynamic activity should be known with some degree of certainty.

These considerations suggested hydrochloric acid as a suitable catalyst for investigation, for, on the one hand, there is good reason to suppose that this acid is almost completely ionised in dilute solution and that the catalytic effects produced by it may be ascribed entirely to the hydrogen ion, and, on the other, the dependence of the thermodynamic activity of hydrochloric acid on its concentration has been determined with considerable precision by various methods.

In selecting the hydrolysis of ethyl acetate as an acid-catalysed reaction for which the requisite conditions would appear to be

satisfied, we were also influenced by the circumstance that this reaction had been previously studied with results which were said to support the view that the catalytic effects produced by hydrochloric acid are related to the thermodynamic activity of the hydrogen ion.

The data recorded by Harned and Pfanstiel (*J. Amer. Chem. Soc.*, 1922, **44**, 2193) suggest that the specific catalytic activity of hydrochloric acid passes through a minimum at a concentration of 0·07—0·08 mol. per litre. This minimum is supposed to be connected with a minimum in the activity coefficient of the hydrogen ion, which according to these authors occurs at an acid concentration of 0·15—0·18 mol. per litre.

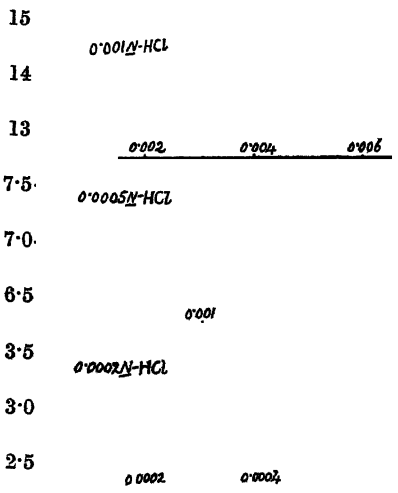
From a study of the effects produced by the addition of chlorides to a 0·05*N*-hydrochloric acid solution, Åkerlöf (*Z. physikal. Chem.*, 1921, **98**, 260) draws the conclusion that the catalytic activity of the acid is proportional to the cube root of the activity of the hydrogen ion. Such a relation can scarcely be regarded as other than empirical. For other reactions, *e.g.*, the inversion of sucrose (compare Jones and Lewis, J., 1920, **117**, 1120; Moran and Lewis, *ibid.*, 1922, **121**, 1613; Scatchard, *J. Amer. Chem. Soc.*, 1921, **43**, 2387), where the experimental results have been interpreted in terms of the activity of the hydrogen ion, the proof of the alleged relation between reaction velocity and hydrogen-ion activity appears to be equally inconclusive. The conversion of *N*-chloroacetanilide into *p*-chloroacetanilide in presence of hydrochloric acid (compare Harned and Seltz, *J. Amer. Chem. Soc.*, 1922, **44**, 1475; Soper and Pryde, J., 1927, 2761) is not catalysed by hydrogen ions and will not therefore be discussed here.

The evidence for the view that the rate of hydrolysis of ethyl acetate with hydrochloric acid as catalyst is determined by the thermodynamic activity of the hydrogen ion did not seem to us to be acceptable, and for this reason new measurements have been undertaken which extend the previous lower limit for the concentration of the hydrochloric acid from 0·01*N* (compare Taylor, *Medd. K. Vetenskapsakad. Nobel.-Inst.*, 1913, **2**, No. 34; Harned and Pfanstiel, *loc. cit.*) to the much lower value 0·0002*N*.

When the concentration of the hydrochloric acid is less than 0·01*N*, the course of the reaction is markedly affected by the acetic acid produced. This autocatalytic influence of the acetic acid, which increases as the concentration of the hydrochloric acid diminishes, precludes the use of any simple integration formula in the co-ordination of the experimental data. We have therefore attempted to measure directly the velocity of the reaction in the early stages of hydrolysis. These measurements were made at

25° with a fixed concentration of ethyl acetate ($e = 0{\cdot}206$ mol. per litre) in presence of hydrochloric acid varying in concentration from $c = 0{\cdot}0002$ to $c = 0{\cdot}002$ mol. per litre. Carefully selected, chemically inert flasks were used as containers.

In these experiments, the reaction was allowed to proceed until a small proportion (0·5—3%) of the ester was hydrolysed. If Δx denotes the concentration of the acetic acid formed during the interval t, then $\bar{v} = \Delta x/t$ represents the mean velocity for this period, and $x = \Delta x/2$ is the mean concentration of the acetic acid. For the attainment of the primary object of these experiments it was soon realised that the values of x which determine the magnitude of the autocatalytic effect must be kept as small as possible, and this necessitated the carrying out of the observations on a large scale which may be illustrated by reference to the detailed procedure followed in an experiment with 0·0005*N*-hydrochloric acid. The requisite amount of a 0·01*N*-hydrochloric acid solution was weighed into a 250 c.c. flask, and freshly distilled water was added to give about 240 c.c. of solution. When the temperature had reached 25°, 5·00 c.c. of ester were added and the volume was made up to 250 c.c. After a suitable interval (about 4 days) the entire contents of the flask were titrated with 0·1*N*-sodium hydroxide solution. The initial acidity was derived from the immediate titration of a similarly prepared parallel solution. For $t = 5864$ minutes, the titration difference thus obtained was 10·83 c.c., which represents 2·1% hydrolysis and corresponds with $\Delta x = 0{\cdot}00433$, $x = 0{\cdot}00216$, and $\bar{v} = 7{\cdot}38 \times 10^{-7}$ mol. per litre per minute.



If for small values of x, the magnitude of which depends on the concentration (c) of the hydrochloric acid, the observed mean reaction velocities ($\bar{v}$) are plotted against the corresponding mean acetic acid concentrations (x), a straight line is obtained. By extrapolation to $x = 0$, the autocatalytic effect may be eliminated, and the initial velocity v_0 due to the undisturbed action of the hydrochloric acid may be derived. Since the mean ester concentration ($e - x$) falls slightly as x increases, more strictly comparable velocities are those given by $\bar{v}' = \bar{v}e/(e - x)$, but as a matter of fact the substitution of $\bar{v}'$ for $\bar{v}$ makes no appreciable difference to the value of the extrapolated initial velocity. The graphs of $\bar{v}$ against x are shown in Fig. 1, and the initial velocities derived from these are $v_0 = 13{\cdot}40 \times 10^{-7}$, $6{\cdot}70 \times 10^{-7}$, and $2{\cdot}65 \times 10^{-7}$ respectively for $c = 0{\cdot}001$, $0{\cdot}0005$, and $0{\cdot}0002$ mol. per litre. From these initial velocities, the values of the catalytic coefficient k are then given by $k = v_0/ce$.

As the concentration of the hydrochloric acid increases, the autocatalytic influence of the acetic acid diminishes rapidly. For

0·002*N*-hydrochloric acid, the autocatalytic effect is almost exactly counterbalanced by the effect of the fall in the ester concentration, with the result that the observed mean velocity in the early stages of hydrolysis is practically identical with the initial velocity.

In hydrochloric acid solutions more concentrated than 0·01*N*, the autocatalytic effect may be almost entirely neglected in comparison with the change in the velocity which is due to the fall in the ester concentration, and for these solutions the velocity coefficient has been derived from the formula $k = 1/ct \,.\, \log e/(e - \Delta x)$, having

FIG. 1.

Plot of mean reaction velocity ($\bar{v}$) *against mean acetic acid concentration* (x) *for* 0·001N-, 0·0005N-, *and* 0·0002N-*hydrochloric acid as catalyst.*

due regard for the range over which this is applicable without appreciable interference from the reverse reaction (compare Dawson and Lowson, J., 1927, 2107).

The values of k obtained by the above methods are in Table I.

TABLE I.

	0·0002	0·0005	0·001	0·002	0·01	0·02	0·04	0·1	0·5
$k \,.\, 10^3$	6·43	6·50	6·50	6·49	6·54	6·45	6·50	6·48	6·76

In the consideration of these figures, it may be noted that $c =$ 0·0002 represents the lowest concentration of hydrochloric acid for which it is possible in practice to make use of the linear extrapolation method. At greater dilutions, the autocatalytic effect

plays too large a part. For the interval $c = 0{\cdot}0002$—$0{\cdot}2$, the constancy of k, within the limits of experimental error, signifies that the catalytic activity of the hydrochloric acid is proportional to its concentration. Over this range the activity coefficient falls from 0·994 to 0·783 (Lewis and Randall, "Thermodynamics") and the mean activity coefficient from 0·997 to 0·884. According to Harned (*J. Amer. Chem. Soc.*, 1920, **42**, 1818), the fall in the individual activity coefficient of the hydrogen ion is less than this, but the argument on which this conclusion is based seems doubtful. In the circumstances, the mean activity coefficient would seem to afford the only data for comparing the activity and the concentration of the hydrogen ion, and as is evident from the constancy of k in the above table, there is no apparent connexion between the catalytic activity and the thermodynamic activity.

The fact that k increases with c at higher concentrations (compare, *e.g.*, Harned and Pfanstiel, *loc. cit.*) may be due to the action of undissociated hydrochloric acid, which is in all probability a very active catalyst. Ionic effects of the kind associated with catalytically inert salts (compare Dawson and Key, this vol., p. 1239) may also play a part, and it does not yet seem possible to attempt the interpretation of the observations which have been made on the action of hydrochloric acid in concentrated solutions.

The mean reaction velocities used in the above-described method for the elimination of the autocatalytic effect represent only a part of the observations made with dilute hydrochloric acid solutions. Other measurements were made in which the proportion of acetic acid was greater, and prior to the consideration of the experimental data, the catalytic process may be subjected to closer analysis.

In accordance with previous results, the equation for the reaction velocity may be written

$$\begin{aligned} v &= v_h + v_{OH} + v_a + v_w + v_m \\ &= \{k_h[H^+] + k_{OH}[OH^-] + k_a[A^-] + k_w[H_2O] + \\ &\qquad k_m[HA]\}.[\text{ester}][\text{water}] \quad . \quad (1) \end{aligned}$$

Since $k_{OH}/k_h = 10^3$, it follows that the v_{OH} term may be neglected if the hydrogen-ion concentration is greater than 10^{-4}. This was actually the case in all experiments. From the ratios $k_a/k_h = 3{\cdot}3 \times 10^{-5}$ and $k_m/k_h = 2{\cdot}4 \times 10^{-4}$ (Dawson and Lowson, J., 1927, 2444) it is also apparent that v_a and v_m may be neglected in comparison with v_h. The term v_w is probably extremely small, evidence for this view being afforded by the reaction-velocity data for mixtures of the series $0{\cdot}1CH_3{\cdot}CO_2H + xCH_3{\cdot}CO_2Na$, which can be satisfactorily interpreted without the introduction of such a term. It would therefore appear that the velocity of hydrolysis under the

conditions of these experiments is determined by the concentration of the hydrogen ion. We may therefore write

$$v = k_h[H^+][\text{ester}][\text{water}] = k[H^+][\text{ester}] \quad . \quad . \quad (2)$$

Furthermore, since $[H^+] = [Cl^-] + [A^-] = c + [A^-]$

and $$[A^-] = K(x - [A^-])/(c + [A^-])$$

we derive $$[H^+] = c + \tfrac{1}{2}\{\sqrt{(K+c)^2 + 4Kx} - (K+c)\} \quad (3)$$

For such small differences in the concentration of the acetic acid as are involved in the determination of $\bar{v}$, the hydrogen-ion concentration given by (3) and the corresponding reaction velocity given by (2) are linear functions of x. It follows that the observed mean reaction velocity $\bar{v} = \Delta x/t$ should be very nearly identical with the actual velocity due to the catalytic action of the mixture $c\text{HCl} + x\text{CH}_3\cdot\text{CO}_2\text{H}$, where x is the mean concentration of the acetic acid for the interval t. Equation (2) may therefore be written in the form

$$k = \Delta x/[H^+](e - \tfrac{1}{2}\Delta x)t \quad . \quad . \quad . \quad . \quad . \quad (4)$$

When the values of $[H^+]$ derived from (3) by the introduction of $K = 1{\cdot}85 \times 10^{-5}$ are used to calculate k from (4), it is found that k diminishes slowly as the concentration of the acetic acid increases. This suggests that the ionisation constant of the acetic acid in the ester solution is less than the value for pure aqueous solutions. In view of the fact that the hydrogen-ion concentration of aqueous solutions of weak acids is very appreciably reduced on the addition of substances such as ethyl alcohol, acetone, etc., it may indeed be expected that ethyl acetate, as a substance of low dielectric capacity, will produce a similar and even greater effect. Evidence of this reduction is afforded by the data obtained in the experiments of Dawson and Lowson (*loc. cit.*) on the rate of ester hydrolysis with acetic acid as catalyst, from which the value derived for $k\sqrt{K}$ is $2{\cdot}61 \times 10^{-5}$. Combining this with $k = 6{\cdot}5 \times 10^{-3}$, we obtain $K = 1{\cdot}6 \times 10^{-5}$ for the ionisation constant of acetic acid in a 0·4-molar solution of ethyl acetate.

In qualitative agreement with this result, it has been found that the conductivity (κ) at 25° of a 0·1*N*-solution of acetic acid in the above solvent (40 c.c. of ester per litre) is only $4{\cdot}57 \times 10^{-4}$ mho as compared with $\kappa = 5{\cdot}30 \times 10^{-4}$ mho when the solvent is pure water. This difference may be due in part to a change in the ionic mobilities, but there can be little doubt that the presence of the ester reduces the ionisation of the acetic acid. In the presence of hydrochloric acid the reduction may be counteracted to some extent as a result of the increase in the ionic concentration in the environment of the dissociable acetic acid molecules, but since the hydro-

chloric acid concentrations concerned are very small, this effect is probably not of much importance. A detailed investigation of the relations in question might enable us to express the ionisation constant as a function of the concentrations of the ester and of the hydrochloric acid, but the necessary data are not available. In these circumstances the ionisation constant has tentatively been given the value $K = 1{\cdot}6 \times 10^{-5}$, in terms of which it is possible, as will be shown, to give a satisfactory account of the observed reaction velocities.

The results are summarised in Table II. Col. 1 gives the time intervals in minutes; Col. 2 the quantities of ester in mols. per litre hydrolysed during these intervals; Col. 3 the mean reaction velocities $\Delta x/t \cdot 10^7$; Col. 4 the mean ester concentrations $(e - \Delta x/2)$; Col. 5 the mean acetic acid concentrations $(x \cdot 10^3)$; Col. 6 the mean hydrogen-ion concentrations $[H^+] \cdot 10^3$; and Col. 7 the velocity coefficients $(k \cdot 10^3)$ derived from equation (4). It is apparent that

† Initial addition of acetic acid to give a 0·01*N*-solution.

the measured reaction velocities can be satisfactorily interpreted in terms of equation (4), for the variations in the tabulated values of k are within the limits which are attributable to experimental error.

With reference to the magnitude of the autocatalytic effects which are involved, it may be noted that the observed velocity increases by about 25% in the experiments with 0·0002*N*-hydrochloric acid, and by about 40% in those with 0·0005*N*-hydrochloric acid. The maximum velocity ($\bar{v} = 10{\cdot}06 \times 10^{-7}$) in the latter series corresponds with a solution in which the mean concentration of the acetic acid is nearly thirty times as great as the concentration of the hydrochloric acid. These figures serve to indicate the range of the variations which are associated with the measurements recorded in the table.

The results afford additional support for the contention that the rate of hydrolysis of ethyl acetate is determined by the hydrogen-ion concentration of the solutions. Considered in the light of Brönsted's "intermediate complex" theory, they would seem to indicate that the primary stage of the reaction consists in the interaction of the hydrogen ion with the electrically neutral ethyl acetate molecule.

Summary.

The catalytic effects produced by hydrochloric acid in the hydrolysis of ethyl acetate have been examined over a wide range of acid concentrations.

A method for the elimination of autocatalytic effects and for the determination of initial velocities is described.

For concentrations of hydrochloric acid between 0·0002 and 0·2 mol. per litre, the initial velocity is proportional to the concentration of the acid.

At all stages the velocity is determined by the hydrogen-ion concentration of the solution.

The catalytic activity of the hydrogen ion would thus appear to be determined by its concentration and not by its thermodynamic activity.

THE UNIVERSITY, LEEDS. [*Received, May 19th*, 1928.]

CCLXXXIII.—*Acid and Salt Effects in Catalysed Reactions. Part XVI. Catalytic Effects in the Iodination of Mesityl Oxide.*

By HARRY MEDFORTH DAWSON and ARTHUR KEY.

THE experiments now to be described originated in the observation that an old sample of acetone sodium bisulphite reacted abnormally quickly with iodine. It was suspected that the presence of con-

densation products might be the cause of this enhanced reactivity, and preliminary experiments with mesityl oxide showed that this substance in dilute aqueous solution reacts very rapidly with iodine and that the change is similar to that which occurs with acetone—the reaction is catalysed by acids, and for a given hydrogen-ion concentration the velocity is proportional to the concentration of the mesityl oxide and independent of the concentration of the iodine. It follows that the rate of disappearance of the iodine is determined by a preliminary change in the mesityl oxide, and that the iodine reacts immediately with the product of this transformation.

For the same concentration of ketone, and with dilute hydrochloric acid (*e.g.*, 0·01*N*) as catalyst, the mesityl oxide reaction takes place more than 200 times as rapidly as the acetone reaction, and this high speed suggested that a study of the autocatalytic change would provide a convenient starting point in the investigation of the factors which determine the velocity of the reaction.

Early experiments of this kind showed that the course of the autocatalysed reaction is similar to the corresponding reaction with acetone. In its later stages, the velocity can be represented fairly satisfactorily by the simple autocatalytic equation $dx/dt = kmx$, in which m represents the concentration of the mesityl oxide, and x the concentration of the catalytically active hydrogen ion in the form of hydriodic acid, which is measured by the fall in the concentration of the iodine in accordance with the equation $C_6H_{10}O + I_2 \longrightarrow C_6H_9IO + HI$. Integration of the differential equation gives $\log x = kmt +$ constant, and in agreement with this it was found that the plot of $\log x$ against t for the later stages of the reaction gave approximately a straight line. Very considerable deviations from the straight line were always found, however, in the initial period, and these deviations were such as to show clearly that the velocity of the reaction in its early stages is much greater than can be accounted for by the above equation. We were at first inclined to seek an interpretation of these oft-repeated observations in the joint catalytic action of the hydrogen and hydroxyl ions, but later experiments showed quite definitely that the combined action of these ions does not account for the facts, which, indeed, can only be explained by the further assumption that catalytic effects of considerable magnitude are to be attributed to the undissociated water molecules.

Attention may first be directed to some of the difficulties which were encountered in the earlier experiments on the autocatalysed reaction. These showed large differences in the behaviour in the initial stages of the reaction when different samples of mesityl

oxide were employed. Some of the latter were obtained by repeated fractional distillation of commercial specimens, and others were prepared by us from acetone by conversion into diacetone-alcohol which was separated and subsequently converted into mesityl oxide by distillation with a very small quantity of iodine (Hibbert, *J. Amer. Chem. Soc.*, 1915, **37**, 1748). With such samples of mesityl oxide, which were almost identical in density and refractive index, the times required for the autocatalysed change to proceed to the same point under precisely the same conditions varied very widely. With a concentration of 4 c.c. of mesityl oxide and 0·001 mol. of iodine per litre, the time occupied by the disappearance of the iodine ranged from 40 to 200 minutes, although the course of the reaction in the later stages was the same in each case within narrow limits.

These results directed our attention to observations recorded by Harries (*Ber.*, 1899, **32**, 1329; *Annalen*, 1904, **330**, 189), who found that a specimen of mesityl oxide could not be entirely dissolved in a 40% solution of sodium bisulphite. The insoluble fraction, amounting to 30%, differed but little in density and refractive index from the original and gave the same *cis*- and *trans*-oximes. Since the mesityl oxide recovered from the bisulphite solution dissolved completely on renewed treatment with this reagent, Harries came to the conclusion that mesityl oxide is not chemically homogeneous and that a new type of isomerism is involved. In similar experiments, Morton (J., 1926, 719) failed to detect any such abnormality in the behaviour of mesityl oxide, and inferred that some unrecorded factor was involved in the work of Harries. Our own observations would suggest that the mesityl oxide examined by the latter was impure, for we have found that the miscibility of mesityl oxide with water is very greatly reduced by the impurities which are usually present in the ordinary preparations.

In partial explanation of the inconsistencies in the behaviour of different samples of mesityl oxide in the autocatalysed reaction with iodine, it was found that these contained varying amounts of an acidic substance which is not removed by distillation, but which can be separated by treatment with a dilute solution of alkali, or even by repeated extraction with water. After such treatment, the various samples showed much closer agreement in their behaviour under the conditions afforded by autocatalysis. When, however, these acid-free specimens were examined with reference to the velocity of iodination in acetate buffers of p_H 5—5·5, they exhibited marked differences, and this suggested the presence of a non-acid impurity. The removal of this was eventually effected by crystallising the mesityl oxide from a solution of the acid-free samples in

light petroleum. By the use of liquid air to obtain the necessary low temperature, the crystals were separated by filtration and freed from solvent by distillation. The mesityl oxide was then examined by measuring the velocity of iodination in an acetate buffer of p_H 5·2. The results obtained after one, two, and three crystallisations were:

Mesityl oxide (acid-free).	M. p.	Velocity of iodination.
Purified by distillation	−44·0°	2·0
Once crystallised	−42·5	1·2
Twice crystallised	−41·5	0·91
Thrice crystallised	−41·5	0·87

From the above data it would appear that the product obtained in the second crystallisation is very nearly pure, and this is the material which has been used in our final experiments. These, it may be noted, have not disclosed any factor which was not already indicated in the earlier experiments with less pure samples of mesityl oxide.

Under the conditions of the experiments which we have made with mesityl oxide, there is a close similarity in the behaviour of this substance and of acetone towards iodine, but it should be noted that marked differences are shown in the reactivity of the respective iodo-substitution products. The iodomesityl oxide would appear to undergo hydrolysis very readily, for when the solution in which the reaction has proceeded to completion is titrated with standard alkali and phenolphthalein as indicator, the consumption of alkali is nearly twice that required by the hydriodic acid formed in the primary reaction. The iodomesityl oxide also reacts readily with sodium thiosulphate, and the reactivity disclosed by these observations restricts to some extent the range of the conditions which are suitable for measurements of the velocity of iodination. There are, however, substantial grounds for the belief that the essential factors associated with this reaction have been identified and evaluated. The measurements to be described include observations on the catalytic activity of hydrochloric and acetic acids, on the velocity in buffer solutions, and on the course of the autocatalysed reaction. On account of the limited solubility of (impure) mesityl oxide in water, the solvent used at first contained 5% (vol.) of alcohol, and since this solvent facilitated the addition of small quantities of mesityl oxide in the form of an alcoholic solution, it was employed in all the experiments. The standard concentration of the mesityl oxide was 4·00 c.c. per litre (0·035M), and as a rule iodine was added to give a 0·001M-solution. The temperature was 25°.

Hydrochloric Acid as Catalyst.—In consequence of the high speed

of the reaction in dilute hydrochloric acid solution, the progress of the change could not be followed by the customary method of titration with standard thiosulphate, and the following method was therefore adopted. At a given instant the reaction was started by the addition of a measured quantity of iodine to the solution containing the mesityl oxide and hydrochloric acid, and when the reaction was nearly completed a little starch paste was added and the time noted at which the blue colour disappeared. This method has also been used in some of the experiments with acetic acid as catalyst. Such experiments give the mean reaction velocity $\bar{v}$, and from a series in which the quantity of added iodine is varied, it is possible to determine the initial velocity of the reaction. Table I gives the results for such experiments with 0·0101*N*-hydrochloric and with 0·05*N*-acetic acid.

TABLE I.

0·0005	3·20	1·56	0·0005	30·9	0·162
0·0010	6·27	1·60	0·0010	54·5	0·183
0·0015	9·16	1·64	0·0015	72·8	0·206

In each series, the mean velocity increases with the iodine concentration. This is connected with the increasing catalytic effect of the hydriodic acid produced, although the influence of the latter is to some extent counteracted by a fall in the concentration of the mesityl oxide. It is sufficient to note that the mean velocity is a linear function of the original iodine concentration and therefore that it is possible to derive the initial velocities for each series. The values so obtained are $1·52 \times 10^{-4}$ for 0·0101*N*-hydrochloric acid and $0·141 \times 10^{-4}$ for 0·05*N*-acetic acid.

From similar series of experiments with hydrochloric acid solutions of varying concentration, it has been found that the initial velocity (v_0) is almost exactly proportional to the concentration (c). On the assumption that the catalytic effect under these conditions is attributable to the hydrogen ion, these experiments give for $k_h = v_0/c$ the value 0·015. Other observations suggest a somewhat lower value, *viz.*, $k_h = 0·0147$.

Reaction Velocity in Buffer Solutions.—The possibility that the unexpectedly high speed which had been observed in the early stages of the autocatalysed reaction might be due to the catalytic effect of water molecules led us to investigate the velocity of the reaction in buffer solutions of different p_H and various concentrations. For a buffer solution containing the weak acid HA and the salt MA, the observed reaction velocity may be represented by

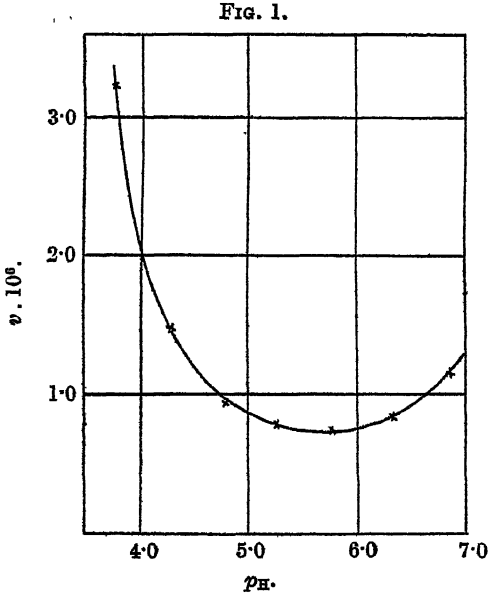
$$v = v_h + v_{OH} + v_w + v_a + v_m \quad . \quad . \quad . \quad . \quad (1)$$

in which the successive partial velocities correspond with the catalytic action of the hydrogen ion, the hydroxyl ion, the water molecule, the acid ion A^-, and the undissociated acid molecule HA. When the acid–salt ratio of the buffer mixture has a fixed value, the first three partial velocities are constant and the above equation may be written

$$v = v_0 + v_b \quad . \quad . \quad . \quad . \quad . \quad . \quad (1a)$$

where v_0, which represents the velocity at zero buffer concentration, depends only on the hydrogen-ion concentration, and v_b, which represents the catalytic effect of the buffer constituents, is proportional to the concentration of the buffer solution. In other words, the measured velocity v is a linear function of the concentration of the buffer. Velocity measurements for a fixed buffer ratio and varying buffer concentration lead, therefore, by linear extrapolation to the corresponding v_0, and such v_0 values in their dependence on p_H correspond with points on the water catenary (H^+–H_2O–OH^-).

Acetate buffers were used for the most part, but the higher p_H values were stabilised by means of phosphate buffers. Since the solvent contains 5% of alcohol, the dissociation constants of the acetic and phosphoric acids are appreciably less than for pure water. In the case of acetic acid this reduction is indicated by measurements of conductivity and of hydrogen potential, and comparative observations on the catalytic activity of acetic acid in water and in 5% alcohol suggest that the constant is reduced from $1{\cdot}85 \times 10^{-5}$ to $1{\cdot}7 \times 10^{-5}$. It will be assumed that the proportional reduction in the second-stage constant K_2 for phosphoric acid has the same value, *i.e.*, if $K_2 = 1{\cdot}1 \times 10^{-7}$ for aqueous solution, the value for 5% alcoholic solution becomes $1{\cdot}0 \times 10^{-7}$.



In Table II the results are summarised. The buffer mixtures are indicated in col. 1; col. 2 gives the p_H; col. 3 the hydrogen-ion concentrations derived from the ionisation constants of the acids; col. 4 the concentrations of the acid (c') and salt (s); col. 5 the observed initial velocities; and col. 6 the values of v_0 derived by extrapolation from the straight line which gives the connexion between v and c' (or s).

When the values of v_0 are plotted against p_H the catenary curve shown in Fig. 1 is obtained. According to this the minimum velocity v_i is $0{\cdot}75 \times 10^{-6}$, and the p_H of the isocatalytic point 5·68 or $[H^+]_i = 2{\cdot}1 \times 10^{-6}$. This minimum velocity is about twelve times the magnitude of the velocity due to the joint action of the hydrogen and hydroxyl ions, for the latter is given by $u_i = 2k_h[H^+]_i = 2 \times 0{\cdot}0147 \times 2{\cdot}1 \times 10^{-6} = 0{\cdot}062 \times 10^{-6}$. The difference between v_i and u_i must be due to the catalytic action of the

FIG. 1.

The water catenary (v_0–p_H) for the mesityl oxide–iodine reaction.

water molecules; in other words, $v_w = 0{\cdot}69 \times 10^{-6}$. Furthermore, if $K_w = 10^{-14}$, we derive from $[H^+]_i = k_{OH}K_w/k_h$ the value $k_{OH} = 6{\cdot}5$ for the catalytic coefficient which characterises the hydroxyl ion. From $k_h = 0{\cdot}0147$, $k_{OH} = 6{\cdot}5$, and $v_w = 0{\cdot}69 \times 10^{-6}$, the reaction

velocities corresponding with the water catenary may now be calculated by use of the equation

$$v_0 = 0{\cdot}0147[H^+] + 6{\cdot}5[OH^-] + 0{\cdot}69 \times 10^{-6}$$

and in Table III these are compared with the velocities derived from the buffer solution experiments. Col. 2 shows the hydrogen-ion concentration; cols. 3, 4, and 5 the partial velocities v_h, v_{OH}, and v_w, respectively; col. 6 the calculated velocity v_0; and col. 7 the observed velocity.

From the reaction-velocity data for the buffer solutions, it is possible to derive the values of k_m and k_a for the buffer constituents HA and A^-. If $q = c'/s$ is the ratio of acid to salt in the buffer mixture, the equation for the velocity may be written

$$\begin{aligned} v &= v_0 + (k_a + k_m q)s \\ &= v_0 + ls \end{aligned}$$

where $l = k_a + k_m q$ is the slope of the curve which is obtained when the velocity for a given buffer ratio is plotted against the buffer concentration of the salt. If q' and l' are corresponding values for a second series of buffers, we obtain

$$k_m = (l - l')/(q - q') \quad . \quad . \quad . \quad (2) \qquad k_a = (ql' - q'l)/(q - q') \quad . \quad . \quad . \quad (3)$$

The values derived in this way are $k_m = 3{\cdot}5 \times 10^{-6}$ for the acetic acid molecule, $k_a = 7 \times 10^{-6}$ for the acetic ion, $k = 3 \times 10^{-6}$ for the H_2PO_4' ion, and $k = 30 \times 10^{-6}$ for the HPO_4'' ion. The much greater activity of the HPO_4'' ion compared with the H_2PO_4' ion is consistent with the general relation that the activity of the anion increases as the ionisation constant of the corresponding acid diminishes.

Acetic Acid as Catalyst.—Under the conditions of these experiments, the reaction velocity is determined by the joint action of the hydrogen ion, the acetic acid molecule, and the water molecule, for the general equation may be written

$$\begin{aligned} v &= (k_h + k_a - k_m)[H^+] + k_m c_1 + v_w \quad . \quad . \quad . \quad (1b) \\ &= 0{\cdot}0147\,[H^+] + 3{\cdot}5 \times 10^{-6} c_1 + 0{\cdot}69 \times 10^{-6} \end{aligned}$$

where c_1 is the concentration of the acetic acid. The velocity may be measured by titration of the residual iodine with thiosulphate or by the colour-disappearance method used in the case of hydrochloric acid. Both methods have been applied with concordant results.

In Table IV, col. 1 gives the method of observation, col. 2 the concentration of the acetic acid, col. 3 the hydrogen-ion concentration calculated from $K = 1{\cdot}7 \times 10^{-5}$, col. 4 the velocity calculated from equation (1*b*), and col. 5 the observed initial velocity. It is apparent that the observations made with acetic acid are satisfactorily interpreted in terms of (1*b*).

The Autocatalysed Reaction.—When the mesityl oxide and iodine are dissolved in "conductivity" water, the only catalysts would appear to be the hydrogen ion, the hydroxyl ion, and the water molecule. When the reaction has proceeded far enough to permit of a measurement of the fall in the iodine concentration, the hydrogen-ion concentration of the solution is controlled by the hydriodic acid formed, and the equation for the velocity may be written

$$v = dx/dt = k_h x + k_{OH} K_w / x + v_w \quad . \quad . \quad . \quad (4)$$

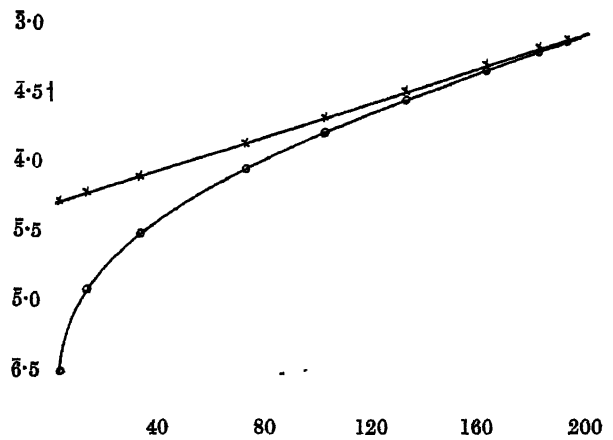
If the numerical values of k_h, k_{OH}, K_w, and v_w are introduced in this equation, it is at once apparent that the partial velocity due to the hydroxyl ion may be entirely neglected when the reaction has reached the stage of measurable x values. The equation then becomes

$$dx/dt = k_h x + v_w \quad . \quad . \quad . \quad . \quad . \quad . \quad (4a)$$

which by integration yields

$$k_h t = 2{\cdot}30 \log_{10}(x + v_w/k_h) + \text{constant} \quad . \quad . \quad . \quad (4b)$$

Since $v_w/k_h = 0{\cdot}000047$, it follows that $\log (x + 0{\cdot}000047)$ should be a linear function of t.



In the determination of x, the samples to be titrated were run into a dilute acetate buffer p_H 5·7, which corresponds with the minimum velocity on the water catenary. The experimental data for such an experiment under autocatalytic conditions were:

t (mins.)	3	13	33	73	103	133	163	183	193
$x . 10^4$	0·030	0·115	0·30	0·875	1·585	2·71	4·41	6·03	7·04

The graphs of log $(x + 0{\cdot}000047)$ and of log x against t are shown in Fig. 2. If the reaction velocity were entirely controlled by the hydrogen-ion concentration, the latter should be a straight line. The fact that the slope of the curve increases as we approach the beginning of the reaction is a clear indication of the intervention of some other catalytic effect, whilst the linearity of the first graph would seem to show that this catalytic effect is represented by the action of the water molecules.

Since this line intersects the ordinate for $t = 0$ at $\bar{5}{\cdot}67$, which is $\log_{10} 0{\cdot}000047$, it follows that $x = 0$ when $t = 0$. Interpreted in

FIG. 2.

Autocatalysis of the mesityl oxide–iodine reaction. Plots of log $(x + 0{\cdot}000047)$ *(curve* ×*) and of log* x *(curve* ⊙*) against time.*

the light of the relations shown by the autocatalysed reaction between acetone and iodine (Dawson, J., 1927, 458), the conclusion to be drawn from this is that the catalytic action of the hydroxyl ion, as represented by the second term in (4), has no appreciable influence on the course of the autocatalysed mesityl oxide reaction. This accords with the relatively low value of $k_{OH}/k_h = 440$ for this reaction, whereas the corresponding ratio for the acetone reaction is 15,000. In the former case the hydrogen-ion concentration of the minimum velocity (*M.V.*) point is $2{\cdot}1 \times 10^{-6}$, whilst for the acetone reaction it is $12{\cdot}5 \times 10^{-6}$ (compare Dawson and Key, this vol., p. 543).

Although, therefore, there can be no doubt that the reaction velocity, as represented by (4), passes through a minimum value, the incidence of this corresponds with a value of x which is far too

small for quantitative measurement. The *M.V.* point would appear to be reached in about 2 minutes, and because of the large catalytic effect of the water molecules ($v_w = 0{\cdot}69 \times 10^{-6}$) as compared with that due to the hydrogen and hydroxyl ions ($v_h + v_{OH} = 0{\cdot}06 \times 10^{-6}$), the incidence of minimum velocity has very little influence on the course of the autocatalysed reaction.

In the derivation of (4*b*) it was assumed that the concentration of the mesityl oxide remains constant throughout the autocatalysed reaction. When this is not the case, the equation for the velocity becomes

$$dx/dt = k_h x(1 - x/m) + v_w(1 - x/m) \quad . \quad . \quad (5a)$$

which on integration becomes

$$k_h t = 2{\cdot}30/(1 + v_w/k_h m).\log_{10}(x + v_w/k_h)/(1 - x/m) + \text{constant} \quad (5b)$$

where m is the molar concentration of the mesityl oxide.

In the experiment shown in Fig. 2, the total fall in the concentration of the mesityl oxide amounts to 2%, and when equation (4*b*) is applied to the interval between $t = 163$ and $t = 193$ minutes, at which stage of the reaction the effect of the water molecules is small compared with that due to the hydrogen ion, we obtain $k_h = 0{\cdot}01435$, and this, when corrected for the fall in the mesityl oxide concentration below the standard value of 0·035 mol. per litre, gives $k_h = 0{\cdot}0146$, in close agreement with the figure previously given.

Comparison of the Coefficients for the Acetone and Mesityl Oxide Reactions.—As a matter of practical convenience, the velocity coefficients which have been derived from the experiments with acetone and mesityl oxide are in both cases expressed in terms of the respective concentrations of these substances which were actually used in the observations. The concentration of the acetone was 0·272 molar (20·0 c.c. per litre), and that of the mesityl oxide 0·035 molar (4·00 c.c. per litre). In the comparison instituted in Table V, the two series of coefficients are referred to molar concentration of the ketone. The last column shows the ratios of the corresponding coefficients.

TABLE V.

Catalytic coefficient.	Acetone reaction.	Mesityl oxide reaction.	Ratio.
k_h	$1{\cdot}72 \times 10^{-3}$	420×10^{-3}	233
k_{OH}	25	185	7·5
$k_w = v_w/55$	5×10^{-10}	3700×10^{-10}	750
k_m ($CH_3{\cdot}CO_2H$)	$5{\cdot}5 \times 10^{-6}$	100×10^{-6}	18
k_a ($CH_3{\cdot}CO_2^-$)	15×10^{-6}	200×10^{-6}	13

In considering these ratios, it should be noted that the value for k_h can be determined much more precisely than the values for the

other catalytic entities. Indirect methods have to be used in the derivation of the value for k_{OH}, and in the case of k_w the activity of the water molecule in the acetone reaction is so very small that the degree of precision is limited. It is, however, quite clear that the ratio varies widely with the nature of the catalysing entity. In the case of the hydroxyl ion, the acetic ion, and the acetic acid molecule, the change in the magnitude of the catalytic coefficient on passing from the acetone to the mesityl oxide reaction is of the same order; for the hydrogen ion and for the water molecule the change is much greater. It does not seem possible to explain these differences.

Summary.

The reaction between mesityl oxide and iodine in dilute aqueous solution is similar to, but more rapid than, the reaction between acetone and iodine.

The iodine takes no part in the primary change, but the rate at which it disappears affords a measure of the transformation of the mesityl oxide, which is probably of the keto–enol type. The reaction is catalysed by hydrogen ions, hydroxyl ions, and water molecules, and also by other acid molecules and the corresponding anions.

The catalytic coefficients for H^+, OH^-, H_2O, $CH_3{\cdot}CO_2H$, $CH_3{\cdot}CO_2^-$, $H_2PO_4^-$, and $HPO_4^=$ have been determined. The relative values of these coefficients for the mesityl oxide reaction differ very considerably from their relative values for the acetone reaction.

The course of the autocatalysed reaction can be explained in terms of the joint catalytic action of the hydrogen ion and the water molecule.

Mesityl oxide has been prepared in pure condition, and anomalies recorded in the literature of this substance are ascribed to the presence of impurities.

The authors desire to acknowledge the assistance rendered in the preliminary stages of this work by Mr. L. H. Angus, Mr. G. Claxton, and Dr. C. R. Hoskins. One of us (A. K.) is indebted to the Department of Scientific and Industrial Research for a grant which has enabled him to take part in this work.

THE UNIVERSITY, LEEDS. [*Received, June 1st*, 1928.]

CCLXXXIV.—*Hydrolysis in Solutions of Potassium Laurate as measured by Extraction with Benzene.*

By JAMES WILLIAM MCBAIN and MONROE EATON.

THE hydrolysis of soap solutions is a property only of the simple fatty ions, and its extent is largely due to the almost quantitative disappearance of free fatty acid to form acid soap. Thus all soap solutions are alkaline, far more so than would be expected from the dissociation constants of the fatty acids,* and concentrated soap solutions are less alkaline than dilute ones. Likewise, contrary to a still almost universal preconception, soap solutions are always unsaturated with regard to fatty acid, in spite of the low solubility of the fatty acid (McBain, Taylor, and Laing, J., 1922, **121**, 621; McBain and Buckingham, J., 1927, 2679, which see for further references).

The present communication develops the methods employed by McBain and Buckingham (*loc. cit.*) with sodium palmitate, applying them to various solutions of potassium laurate with and without other additions at 25°. Reference should be made to the previous paper for a discussion of many of the points at issue and the general nature of the results previously obtained.

EXPERIMENTAL.

The work to be described consists of experiments on the composition of a wide range of solutions of potassium laurate with and without additions of alkali or lauric acid. Additional experiments are described which were designed (1) to show that complete reversible equilibrium is attained,† (2) to find the concentration of lauric acid in benzene that is in equilibrium with unaltered aqueous potassium laurate solutions, (3) to measure the solubility of the various constituents in benzene singly and together, (4) to measure the alkalinity by hydrogen electrode and by indicator, and finally (5) to study the effect of potassium chloride and of carbon dioxide upon the alkalinity and extractability of the aqueous potassium laurate. A few results with aqueous sodium laurate are given for comparison, and some experiments have been carried out with acid

* The dissociation constants are known for the saturated fatty acids up to decoic acid, and hence for the next member with an even number of carbon atoms, lauric acid, the dissociation constant must be 1×10^{-5}, which is not so very weak (S. Smiles and P. O. Herzog, "Chemische Konstitution und Physikalische Eigenschafte," p. 526; E. Franke, *Z. physikal. Chem.*, 1895, **16**, 477).

† This was demonstrated for the first time in the experiments of McBain and Buckingham (*loc. cit.*).

potassium laurate, and also with carbon tetrachloride instead of benzene as extracting solvent.

The chief experiments are the determinations of the compositions of aqueous and benzene layers in equilibrium with each other. For the complete interpretation of the data several subsidiary items of information are required. For example, it is found that the approximate solubility of potassium laurate at 25° is 70 g. per 100 g. of water and 0·005 g. per 100 g. of benzene, showing that for the purposes of most of the experiments the soap itself is insoluble in benzene. However, in the section dealing with acid soap it will be shown that when the benzene contains a large proportion of lauric acid the soap is highly soluble in it, forming acid soap. The potassium laurate used was specially made by Kahlbaum but contained 0·5 equiv. % excess of alkali, whereas the sodium laurate contained 1·8 equiv. % excess of lauric acid. They were dried to constant weight at 110°. Kahlbaum's lauric acid was used, and its solubility in 100 g. of benzene at 25° was 186 g.; at 40° there is miscibility in all proportions. The solubility in water at 25° is 0·00017 g. of undissociated lauric acid per 100 g. of water, as determined by conductivity (see p. 2173).

Since the method of analysis of the non-aqueous layer was to evaporate the solution to dryness and weigh the residue of lauric acid, blank experiments were necessary to show that there was no appreciable loss. It was found that when 10 c.c. of a 1·5% benzene solution of lauric acid were evaporated nearly to dryness during ¾ hour and the heating was continued for 4 hours at 80°, the maximum loss by volatilisation was 2% of the total lauric acid originally in the benzene. In the extraction experiments, evaporation was carried only to dryness and the temperature was never allowed to rise above 75°, and in most cases the solutions were far more dilute. Hence the error must have been inappreciable.

The benzene used was dried over calcium chloride or potassium hydroxide and twice distilled. It boiled at 79·5—80·5° and left no residue on evaporation. Boiled-out conductivity water ($\kappa = 2 \times 10^{-6}$ mho) was used throughout. Concentrations are all expressed in weight normality (N_w), *i.e.*, as mols. of solute per 1000 g. of solvent. Kahlbaum's purest potassium chloride was dried at 125° for a day; it was insoluble in benzene.

The soap solutions were brought into equilibrium with the benzene layer in horizontal glass tubes about 3 cm. wide and 20 cm. long, which were rotated on their axis at a speed of 11 revs./min. for 48 hours. Even this very gentle stirring tends to emulsify the layers. Hence the tubes were allowed to stand in a vertical position until at least half the benzene layer had cleared. As much as possible

of the clear layer was then pipetted out, weighed, and evaporated to dryness at 70°. From this and a knowledge of the original composition of the system it was then possible to calculate the concentrations and the amounts of lauric acid which had passed out of or into the aqueous layer. The original system was always made up by weighing the constituents into a tube which was immediately sealed to minimise evaporation of the benzene.

Extraction of Lauric Acid from Aqueous Potassium Laurate by Benzene.

The three-component systems here described consist of three phases, the aqueous phase, the benzene solution of extracted lauric acid, and the sediment of the acid soap in the aqueous layer. However, it is much more interesting to add lauric acid as a fourth component with a view to find the concentration of lauric acid in benzene which is just in equilibrium with unaltered soap solution, a higher concentration giving up lauric acid to the soap solution and a lower concentration partly extracting it. The extractability was shown to be the same after one month as after a few days.

Table I gives the results of the equilibrium experiments with potassium laurate with and without added excess of lauric acid. Table II records for comparison a few experiments on sodium laurate. It is seen that sodium laurate is distinctly more extractable than potassium laurate even when the fact is taken into account that the specimen used contained excess of lauric acid (see p. 2167).

The very definite result from these two tables is that the benzene layer is unsaturated with respect to fatty acid. Since the benzene layer is in true reversible equilibrium with the soap layer, the latter must be equally unsaturated. Even when a very appreciable excess of fatty acid is added to the system so that the aqueous layer contains more equivalents of fatty radical than of potassium or sodium, the benzene layer is still very far from being saturated with respect to fatty acid.

Almost every writer has assumed that there is excess of fatty acid, free in liquid or emulsified form, in ordinary soap solutions. This belief is definitely shown to be false by the results of these quantitative experiments and those of McBain and Buckingham (*loc. cit.*). All the soap solutions are alkaline and unsaturated with regard to free fatty acid. Hence when excess of free fatty acid is added to the soap solution it disappears through combination with the soap to form acid soap. An aqueous solution even of acid soap containing twice as much fatty radical as of sodium or potassium is still appreciably alkaline. Experiments described later show that when the non-aqueous layer is made nearly saturated

with fatty acid, practically all the soap disappears from the aqueous soap solution.

* In experiments with 1·0N_w-potassium laurate, emulsification was so great that it was only after 2 months' standing that about one-tenth of the benzene layer could be withdrawn for analysis, and the lauric acid in two such samples was too small to be weighable. This is probably due to (*a*) the small concentration of hydrolysable simple laurate ion, and (*b*) the completeness with which any fatty acid formed is combined in this high concentration of soap.

† A saturated solution of lauric acid would have been 9·3N_w.

* A saturated solution of lauric acid would have been 9·3N_w.

Referring to the data of Tables I and II, it is evident that the amount of fatty acid extracted from an aqueous soap solution increases with the various factors as expected; *i.e.*, the extractability increases with increasing proportion of extracting solvent, with decreasing alkalinity of the soap, with increasing amounts of fatty acid added to the soap solution, or with increasing dilution of the soap, and hence increased proportion of hydrolysable simple fatty ion.

TABLE II.

Equilibrium experiments in which aqueous solutions of sodium laurate were shaken at 25° with benzene.

* Concentration of L' has not been measured in solutions of NaL at 25°; it is therefore assumed to be the same as that in a KL solution of the same concentration.

With very dilute soap solutions, the effect of carbon dioxide becomes a serious source of error. Although carbon dioxide is a much weaker acid than any of the fatty acids, we find that if it is passed through an $N/100$-soap solution in the process of extraction, the whole of the fatty acid passes into the benzene layer owing to complete neutralisation of the hydroxyl ion in the aqueous layer by the carbonic acid. The results with solutions below 0·01N_w are increasingly influenced by ingress of carbon dioxide, in spite of precautions taken. In four out of six experiments with 0·0005N_w-potassium laurate, practically all the lauric acid was removed by the benzene. This is to be expected in a solution sufficiently dilute, although a minute trace of free lauric acid must always remain dissolved in the aqueous phase.

In order to evaluate the concentrations of the various constituents in a soap solution in equilibrium with a benzene solution of fatty acid, it is necessary to know the distribution ratio for lauric acid, the dissociation constant of water (K_w), and the dissociation constant of the lauric acid ($K_a = 1 \times 10^{-5}$). The concentration of simple laurate ion in aqueous soap solution is known from previous studies of freezing point and conductivity (McBain and Jenkins, J., 1922, **121**, 2325). Since the concentration of undissociated lauric acid in the aqueous layer is proportional to that in the benzene layer multiplied by the distribution ratio, the equation for hydrolytic equilibrium is:

$$\frac{[\mathrm{L'}]}{[\mathrm{OH'}] \times N_w \text{ of lauric acid in } \mathrm{C_6H_6}} = K = \frac{K_a}{K_w} \times \text{distribution ratio.}$$

The distribution ratio may be estimated from the results for 0·1N_w-potassium laurate, since this solution was most carefully studied,

and, when neutral (that is, having potassium and laurate stoicheiometrically equivalent to each other), was found to be in equilibrium with the benzene layer, which was $0{\cdot}0055N_w$ with respect to lauric acid. If the hydrolysis alkalinity be taken as $0{\cdot}0009N_w$-OH′, and the concentration of simple laurate ion as $0{\cdot}026N_w$, the distribution ratio would be

$$\frac{0{\cdot}026 \times 10^{-14}}{0{\cdot}0009 \times 0{\cdot}0055 \times 10^{-5}} = 0{\cdot}5 \times 10^{-5},$$

whence the hydrolytic constant $K = 5000$.

This distribution ratio ($0{\cdot}5 \times 10^{-5}$) is that employed in the calculation of the results in Table III, although it is four times larger than the ratio of the solubilities of lauric acid in water and benzene. The discrepancy is not surprising in view of the fact that a saturated solution of lauric acid in benzene is $9{\cdot}3N_w$ and contains almost twice as much lauric acid as benzene. There is a closely similar discrepancy in the distribution ratio of palmitic acid between water and xylene at 90° when saturated solutions are compared with ordinary dilutions.

This approximate distribution ratio enables us to indicate the approximate concentration of free fatty acid in all the soap solutions studied. The most interesting solutions are those whose composition has not been altered, owing to the exactly requisite quantity of lauric acid having previously been added to the benzene layer, so that the two phases are already in equilibrium when first brought together. The results for the series of concentrations of aqueous solutions of potassium laurate containing equivalent quantities of potassium and total fatty radical are contained in Table III.* The concentration of acid soap (N_w) referred to the water, although part of the acid soap is a sediment, is given in the last column of Table III. It is merely the difference in the normality of the OH′ and of the free fatty acid, since if no fatty acid had disappeared to form acid soap, the concentrations of free fatty acid and OH′ must have been identical.

The most striking feature of Table III is that in all pure soap solutions the concentration of free fatty acid is wholly negligible in comparison with the hydrolysis alkalinity. In other words, as

* In calculating the values for N_w of OH′ in Tables I and II, the values for the concentration of laurate ion, L′, as given for unaltered soap solution in Table III are reduced if either lauric acid is extracted from the soap solution by the benzene layer or conversely, forming acid soap. This is allowed for in Tables I and II by multiplying the values for L′ in Table III by the ratio (total laurate radical)/(total potassium), in the aqueous layer, or (total potassium)/(total laurate radical) in the aqueous layer, whichever ratio is less than unity.

TABLE III.

The concentrations of some of the constituents of aqueous potassium laurate solutions at 25°, there being equal equivalents of potassium and laurate radicals in the water, as deduced from the concentration of lauric acid in the benzene layer in equilibrium with the aqueous layer.

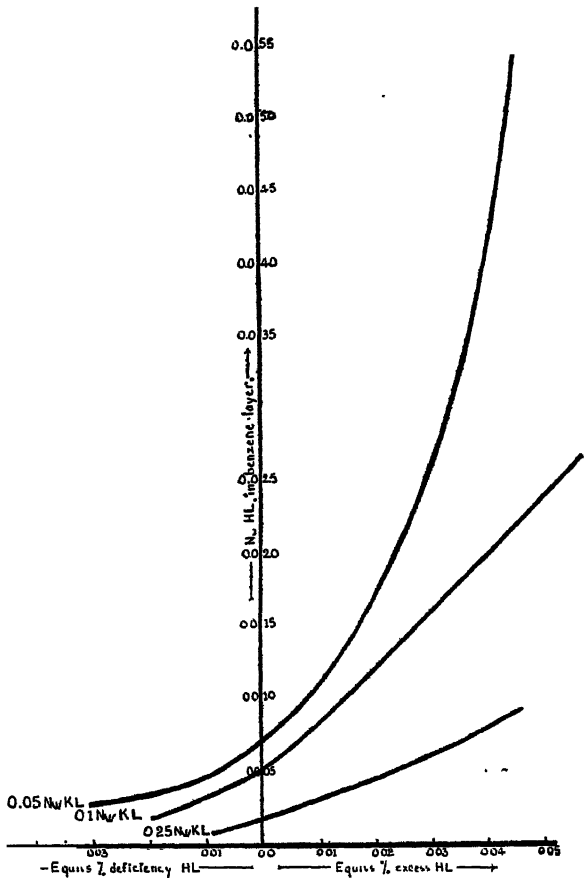
* N_w of lauric acid (HL) combined with soap (KL) to form such acid soap as HL,KL.

seen from the practical identity of the last two columns of Table III, the fatty acid set free by hydrolysis goes almost quantitatively to form acid soap.



The solubility of lauric acid in water was determined by conductivity and the mode of calculation used by McBain and Taylor (*Z. physikal. Chem.*, 1911, **76**, 179); the specific conductivity of the saturated solution was $4{\cdot}54 \times 10^{-6}$, whence the normality of the undissociated lauric acid in saturated solution in water at 25° is $8{\cdot}8 \times 10^{-6} N_w$.† In pure water, the laurate ion would provide an additional $1 \times 10^{-5} N_w$. This is 300 times greater than the actual concentration of free lauric acid found in a $0{\cdot}1N_w$-solution of potassium laurate, illustrating the utter impossibility of fatty acid in the free liquid or solid state existing in a soap solution. As a check upon the possibility that the solubility of fatty acid in water might be enhanced by such solvents as benzene, the solubility of the lauric acid was similarly determined with water saturated in one case with benzene and in the other with carbon tetrachloride. The specific conductivities were $5{\cdot}23 \times 10^{-6}$ and $4{\cdot}61 \times 10^{-6}$, respectively, whence it is evident that the solubility is not appreciably enhanced. Hence the distribution ratio of lauric acid must be fairly constant for the more dilute soap solutions studied, especially in comparison with the very large changes in the concentration of the benzene layer.

In dilute soap solutions, the percentage of hydrolysis is at a maximum (*e.g.*, it is 9% in $0{\cdot}001N_w$-soap) though the absolute concentration of all constituents is least. In very concentrated

† Lauric acid is therefore much less soluble than silver laurate, although a saturated aqueous solution of lauric acid gives a just noticeable turbidity on addition of excess of silver nitrate.

solution, on the other hand, the crystalloidal constituents including the laurate ion are practically all replaced by colloid except for the sodium or potassium ions also present. The hydrolysis alkalinity therefore passes through a maximum because the colloid serves merely as a reserve from which hydrolysable laurate ion can be

FIG. 1.

The concentration of lauric acid in the benzene layer in equilibrium with solutions of potassium laurate containing deficiency or excess of lauric acid.

formed. However, even the colloidal undissociated soap may play a rôle in the formation of the acid soap. Acid soap itself is a colloidal electrolyte though often of low solubility, hence the extent of its formation does not closely follow the law of mass action. For example, taking a series of benzene solutions of lauric acid sufficiently concentrated for lauric acid to pass from the benzene into the soap

layer, the formation of acid soap does not increase as rapidly as the concentration of the benzene layer.

Fig. 1 of the paper of McBain and Buckingham (*loc. cit.*), which referred to $0{\cdot}1N_w$-sodium palmitate at 90°, shows that fatty acid may be extracted from any soap solution even in the presence of excess of alkali; and likewise that any soap solution is alkaline even when excess of fatty acid has been added. Fig. 1 of the present paper, taken from the results in Table I, shows the similar relations with potassium laurate when excess of alkali or acid is present; it gives the concentration of lauric acid in the benzene layer in equilibrium with aqueous soap layer of the composition indicated. The soap solutions on the alkaline side are those from which some of the laurate radical has been extracted by the benzene layer in the form of lauric acid. The designations of the three curves refer to the total concentration of potassium throughout.

Finally, a few experiments may be noted in which it appears that the relative extracting power of benzene and carbon tetrachloride goes parallel with the solubility of lauric acid therein, as expected (Table IV).

TABLE IV..

Solutions of $0{\cdot}05N_w$-potassium laurate.

Soap soln. g.).	Solvent (g.).	Lauric acid in solvent. Before (g.).	After (g.).	After (N_w).*
		Benzene.		
30·86	8·64	0·0	0·00508	0·00294

		Carbon tetrachloride.		
56·05	24·61	0·0	0·00624	0·00127
32·60	18·73	0·0	0·00389	0·00104

* A saturated solution of lauric acid in benzene would be $9{\cdot}3N_w$, and in carbon tetrachloride $5{\cdot}1N_w$.

Acid Soaps.

As we have seen, pure benzene scarcely dissolves potassium laurate, but it is far otherwise when a large amount of lauric acid is simultaneously present in the benzene. When mixtures of benzene, lauric acid, and potassium laurate are heated together, the whole system becomes homogeneous, and on cooling, crystallisation occurs. In four such experiments the single liquid layer was removed for analysis at 25°, with the following results, potassium laurate being determined as carbonate after ignition:

HL in benzene, N_w	0·042	0·451	3·56	9·28
KL in benzene, N_w	0·0002	0·020	0·065	0·192

The crystals deposited from the above solutions were found by analysis to have the exact composition KL,HL, thus again showing that the solubility of potassium laurate in benzene containing lauric acid is attributable to the formation of acid soap. A crystalline acid soap of this composition was described by Oudemann (*Jahresber.*, 1863, 331) as resulting from warming the potassium laurate and lauric acid in this proportion with aqueous alcohol, but subsequent writers have been unanimous in assuming that acid soap of a definite composition did not occur (see, however, McBain and Stewart's recent description of the definite crystalline acid oleate, KOl,HOl; J., 1927, 1392).

The results given in Table I are not affected by the information just tabulated, since the concentration of lauric acid in the benzene layer was usually well below $0{\cdot}1N_w$. McBain and Buckingham refrained from employing solutions of palmitic acid in xylene exceeding $0{\cdot}25N_w$ in equilibrium experiments with sodium palmitate, because they had observed that with very high concentrations of palmitic acid in xylene the residue on evaporation was greater than the original palmitic acid, and this is now seen to be due to sodium palmitate having entered the xylene layer. They stated that the formation of acid soap was indicated by the soap layer becoming absolutely opaque.

A series of experiments shown in Table V was carried out using a saturated solution of lauric acid in benzene, and the aqueous phase was taken for analysis after filtering off any sediment of acid soap. There was very little emulsification, and most of the acid soap dissolved in the non-aqueous layer. With $0{\cdot}1N_w$-aqueous potassium laurate, both layers were finally almost as clear as water. This is in marked contrast to the experiments reported in Table I, where the aqueous layer became clouded with acid soap when the concentration of lauric acid in the benzene exceeded $0{\cdot}01N_w$.

TABLE V.

Effect of saturated solution of lauric acid in benzene ($9{\cdot}3N_w$) *upon aqueous solutions of potassium laurate at* 25°.

Benzene soln. (g.).	Aqueous soln. (g.).	Aqueous soln. before (N_w).	N_w of total laurate radical left in aqueous layer.
3·701	4·956	0·100	0·0026
4·352	9·444	0·100	0·0051
4·873	6·095	0·250	0·0086
3·591	5·487	0·250	0·0111
8·947	6·442	0·493	0·0039

It is seen from Table V that the soap is almost quantitatively removed from the aqueous solution by contact with a saturated solution of lauric acid in benzene. The aqueous solution must at

last be on the acid side because the lauric acid in the benzene so greatly exceeds the amount of soap in the system. In other words, an aqueous soap solution whose p_H is less than 7 can hardly be prepared. The slight residue of laurate radical in the aqueous layer is probably colloidal acid soap not removed by filtration but materially decreased by increasing the proportion of the benzene layer.

Solid potassium laurate is also capable of largely removing lauric acid from benzene solution, as is shown by the following tabulation of two experiments at 25° in which benzene solutions of lauric acid were used which were too dilute to dissolve much acid soap.

KL, before (g.).	Benzene (g.).	Ratio, total L to total K.	HL, before (g.).	HL left in benzene (g.).	HL removed (%).
3·658	49·37	2·0	3·120	0·423	86·5
0·7336	19·52	1·5	0·3427	0·0048	98·5

Another illustration of the formation of acid soap is given by the action of carbon dioxide upon soap solutions. When a small amount of carbon dioxide is passed over the surface of a soap solution, crystals gradually appear in the upper part of the solution. These crystals are not removed from the solution by extraction with benzene, hence they are not lauric acid. They cannot be potassium laurate, since the solutions are only about 1/30 saturated and the crystals are not dissolved by shaking. We may conclude, therefore, that the first product of the action of carbon dioxide on potassium laurate solutions is acid soap. Soap solutions which have been left exposed to the air for some time show a similar behaviour.

In order to demonstrate the formation of crystalloidal acid soap in aqueous potassium laurate solutions in contact with benzene solutions of lauric acid, an experiment was performed in which the solutions were allowed to stand without shaking. A $0{\cdot}5N_w$-solution of potassium laurate was run into a tube under a saturated solution of lauric acid in benzene. The tube was then sealed and allowed to stand for 2 days. A cake of crystalline acid soap $\frac{1}{4}''$ thick was formed between the benzene and water layers. From the lower side of the cake, long needles could be seen radiating from various points into the aqueous layer. The crystals were insoluble in water and benzene.

Since potassium laurate is very soluble in water and lauric acid is very soluble in benzene, the formation of a solid solution of potassium laurate in lauric acid under the conditions observed in this experiment is more improbable than the formation of a

definite chemical compound. The proof of the existence of definite crystalline acid laurates and palmitates will shortly be published.

Acid soap is a better emulsifying agent than neutral soap, as is evident from the observation made during the experiments of Table I. Miss Laing (*Proc. Roy. Soc.*, 1925, **105**, 28) found that unless the soap solution contains a small excess of alkali the material adsorbed in soap films is acid soap. It may also be mentioned that ready emulsification occurs when a potassium laurate solution, too dilute to contain colloidal soap, is mixed with benzene containing lauric acid.

Effect of Salt upon Extraction and Hydrolysis.

McBain and Buckingham (*loc. cit.*) found that the presence of various salts diminishes the extractibility of aqueous sodium palmitate, in very similar fashion. They pointed out that this was ascribable to repression of the dissociation of the soap into simple laurate ion which is the hydrolysable constituent, and they surmised that the hydrolysis alkalinity was likewise lessened, in accordance with the findings of McBain and Martin (J., 1914, **105**, 957), who used the hydrogen electrode. That a salt greatly decreases the extractability in the case of potassium laurate also is clearly shown in Table VI.

TABLE VI.

Effect of potassium chloride on extractibility of $0{\cdot}1N_w$*-potassium laurate by benzene at* 25°.

Soap soln. (g.).	KCl (N_w).	Benzene (g.).	HL in benzene. Before (g.).	After (g.).	After (N_w).
40·02	0	11·03	0	0·00504	0·00230
49·67	0·0114	10·21	0	0·00215	0·00104
52·41	0·0220	20·28	0	0·00465	0·00112
64·13	0·0499	14·52	0	0·00135	0·00064
35·47	0·2272	5·88	0	0·00079	0·00067

The hydrolysis alkalinity of the final solution in Table VI cannot be calculated, because the concentration of hydrolysable laurate ion is also being diminished. On the other hand, it is possible that formation of acid soap might be facilitated through increase in undissociated potassium laurate and through lowering of the solubility of acid soap by salt, both of which factors act in the direction of increasing the hydrolysis alkalinity. However, it seems probable that the dominant factor is repression of laurate ion with consequent lowering of hydrolysis alkalinity on addition of salt. Direct determinations of the hydrolysis alkalinity are required for a complete answer to this problem.

In Table VII a series of experiments is recorded in which the soap was maintained at $0{\cdot}1N_w$ and the potassium chloride at $0{\cdot}143N_w$; also the weight of soap solution was always 3·5 times that of the benzene, but varying amounts of lauric acid were added.

TABLE VII.

Concentration of lauric acid in the benzene layer at 25° in the five-component system where only the amount of added lauric acid is varied.

HL in benzene, before, g.	0·0021	0·0085	0·0243	0·0708
„ „ after, g.	0·00301	0·00546	0·00876	0·01117
„ „ „ , N_w	0·00161	0·00234	0·00404	0·00517

Comparison of the results given in Table VII with those of Table I or Table III shows that, whereas unaltered $0{\cdot}1N_w$-potassium laurate is in equilibrium with a $0{\cdot}0032N_w$-solution of lauric acid in benzene, the equilibrium concentration in presence of the salt is lowered to $0{\cdot}0023N_w$. In every case salt lowers the extractability, and, for a given addition of lauric acid, increases the amount of acid soap produced in the system.

Summary.

1. The compositions of benzene solutions of lauric acid in equilibrium with various solutions of potassium laurate at 25° have been determined, and the experiments extended to solutions containing various additions.

2. Unaltered soap solutions contain the merest trace of free fatty acid—only a few units per cent. of that capable of dissolving in water. The fatty acid corresponding to the hydrolysis alkalinity is almost quantitatively combined as acid soap.

3. Acid soap forms as a sediment whenever carbon dioxide gains access to the soap solutions. Solid potassium laurate, as well as its aqueous solution, extracts lauric acid from its concentrated solutions in benzene, forming acid soap. The definite crystalline compound, acid potassium laurate, KL,HL, is found to exist, and it is fairly soluble in hot benzene. A concentrated solution of lauric acid in benzene almost quantitatively removes soap. Presence of salts promotes the formation of acid soap but diminishes the extractability of aqueous soap solution.

Our thanks are due to Dr. M. E. Laing for constant assistance.

STANFORD UNIVERSITY, CALIFORNIA. [*Received, June 11th,* 1928.]

CCLXXXV.—*The Rotatory Dispersion of Certain Isomeric Butyl Esters of* l-*Mandelic Acid.*

By CHARLES EDMUND WOOD, ALBERT EDWARD CHRISMAN, and SYDNEY DIGGARY NICHOLAS.

THE interesting points associated with these esters are that mandelic acid is the simplest hydroxy-acid in the aromatic series and is analogous to lactic acid in the aliphatic series; both *l*-mandelic and *l*-lactic acid are configuratively related to *d*-tartaric acid, but the esters of the first exhibit rotatory dispersion entirely in the negative region, whereas the esters of the second in the homogeneous condition exhibit rotatory dispersion which is situated in general in the positive region (Wood, Such, and Scarf, J., 1923, **123**, 600; 1926, 1928).

Rotatory Power.

The following table indicates that the primary branching of the *n*-butyl chain enhances very considerably the high negative rotation of the *n*-ester; further branching of the chain to the *tert.*-ester brings about a diminution of negative rotation.

Specific rotations $[\alpha]^{t}_{\lambda}$ of *l*-mandelates at 45° and 75°.

Ester.	λ 6708.	λ 5893.	λ 5461.	λ 5086.	λ 4359.
			Temp. 45°.		
n-Butyl	−66·3°	−91·1°	−111·0°	−133·6°	−189·0°
*iso*Butyl	73·7	101·9	123·5	148·8	214·3
tert.-Butyl	56·4	78·0	94·5	114·1	162·6
d-sec.-Butyl	48·2	67·5	82·0	99·2	151·1
			Temp. 75°.		
n-Butyl	−61·3°	−84·3°	−102·1°	−122·4°	−174·0°
*iso*Butyl	68·0	93·1	113·0	134·8	192·0
tert.-Butyl	52·8	72·9	88·2	106·5	152·8
d-sec.-Butyl	44·3	61·5	75·0	90·75	140·1

These results are analogous with respect to the zero axis to those obtained for the alkyl *l*-lactates situated in the positive region, and it appears, therefore, that in both cases the esters, of relative configuration "*d*," formed from a primary *iso*-alcohol have greater rotatory power than the esters of the corresponding normal alcohol, and that further branching of the chain, resulting in the tertiary esters, effects a diminution in rotatory power. The changing alkyl group is contrasted with the strongly negative phenyl group in the mandelates and compared with the positive methyl group in the lactates, and the progressive change of the alkyl grouping leads to a regularity in rotatory effect in the positive and the negative region respectively. The mere comparison of the position of the dispersion curves with respect to the zero axis does not infer a

relative configuration relationship. The types of symmetry (Wood, Such, and Scarf, *loc. cit.*) and of asymmetry produced with the accumulation of identical radicals near the asymmetric carbon atom result in a similar relative position of the dispersion curves of the normal, *iso*-, and *tert.*-esters for "*d*"-mandelic and "*l*"-lactic acids.

d-sec.-Butyl *l*-mandelate, containing two centres of optical asymmetry of opposite rotatory power and of the same relative configuration, exhibits a marked decrease in specific rotation which is very pronounced in the violet end of the spectrum. The effect of the active mandelic acid radical, however, dominates the rotatory power, which in all cases is high.

Rotational Displacements in Related Series.

Consideration of Table I shows that (1) the molecular rotatory power is displaced to the right as the normal series of esters is ascended, particularly in passing from the methyl to the ethyl ester; (2) the molecular rotations of the *iso*-esters of lactic, tartaric, glyceric (*iso*butyl), and malic (*iso*butyl) acids are greater than those of the corresponding normal esters, these being situated in the positive region; (3) the molecular rotations of the *iso*-esters of mandelic, α-hydroxybutyric, and glyceric (*iso*propyl) acids exhibit a reverse behaviour, being displaced towards the left; (4) both the tertiary esters of lactic and mandelic acids are displaced towards the zero axis.

The above compounds are of relative configuration "*d*," and although observation (1) may serve in general (Clough, J., 1918, **113**, 526) as a criterion for configuration, no such rule can be applied to the relationship between the *n*-, *iso*-, and *tert.*-esters.

The *n*-esters of tartaric, lactic, hexahydromandelic (Wood and Comley, J., 1924, **125**, 2630), and mandelic acids form an interesting group; for the group, as well as each series, shows a displacement towards the right, the mandelic acid series being situated far down in the negative region, the hexahydromandelic acid series almost on the zero axis, and the tartrates and lactates in the positive region.

In the acetyl and benzoyl derivatives of mandelic acid, acetylation causes a similar displacement of the rotations of both the methyl and the ethyl esters, without change of order, further into the negative region (Freudenberg and Markert, *Ber.*, 1925, **58**, 1753). Similar displacements occur for the diacetyl- and dibenzoyl-*d*-tartrates, as indicated by Table II. (The temperatures 30°, 90°, and 110° have been taken to avoid extrapolation.) When the lactates are considered, however, acetylation causes a *right* displacement without change of order (Freudenberg and Markert, *Ber.*,

1927, **60**, 2447), and it is noteworthy that the temperature–rotation curves are at maxima. On benzoylation a change of order occurs with displacement into the negative region (Freudenberg and Rhino, *Ber.*, 1924, **57**, 1547).

The *d*-malates afford an almost exact parallel, except that the benzoyl derivatives are in the positive region (Walden, *Z. physikal. Chem.*, 1895, **17**, 245; Frankland, J., 1899, **75**, 337).

The peculiar displacement of the methyl with respect to the ethyl ester was first noted by Frankland (*loc. cit.*; compare also the *o*-, *m*-, and *p*-toluoyl derivatives, in which this order persists).

The rule that a hydroxy-acid of "*d*" configuration shows a right displacement in passing from the methyl to the ethyl ester is broken by the benzoyl-lactates, the rotational values of which are far removed from the region of anomaly and in the negative region; it is also broken by the *d*-benzoylmalates and they are situated in the region of anomaly and exhibit positive rotation (Freudenberg and Noë, *Ber.*, 1925, **58**, 2404).

l-Glyceric acid ("*d*") obeys the rule for the esters of its acetyl derivative, but is exceptional with respect to those of its benzoyl derivative (Frankland and Price, J., 1897, **71**, 253). The di-*o*-, -*m*-, and -*p*-toluoyl derivatives are similar to the dibenzoyl esters in behaviour.

It is thus seen to be difficult to draw up a general rule connecting displacement and configuration for *iso*-esters, and esters of acetyl and benzoyl derivatives. A certain generality holds, however: when acetylation of the esters causes a displacement to the left, the order of the rotations is maintained in the benzoyl derivatives (*e.g.*, the mandelates and tartrates), and when it causes a displacement to the right, the order of the rotations is reversed in the benzoyl derivatives (*e.g.*, lactates and malates). In general, benzoylation of the esters causes a left displacement into the negative region, but the benzoylmalates are situated in the positive region, the methyl ester having suffered a right and the ethyl ester a left displacement.

In the case of the methyl and ethyl acetyltartrates, although the displacements are respectively left and right, yet a study of the dispersion and temperature–rotation diagrams shows that in both cases the rotational displacement has resulted in a more extended field of anomaly, the effect in both cases being similar. The corresponding benzoyl derivatives show rotationally right displacements (without change in order). The dispersion and temperature–rotation diagrams indicate that the methyl monobenzoyl ester has attained maxima for certain wave-lengths, whilst the ethyl ester has just passed maxima; here again the effects of benzoylation

are similar. Owing to the detailed data available with respect to these esters a deeper interpretation of rotational values has been possible, resulting in exact comparison in particular regions of anomaly.

Although similar displacements occur in certain derivatives of mandelic and tartaric acids, yet it should be noted that, in the former, increase of the acyl chain of both the methyl and ethyl esters produces displacements to the right (from the data given by Walden, *Z. physikal. Chem.*, 1895, **17**, 706), whereas in the latter, displacements to the left occur (from data given by Frankland and Wharton, J., 1899, **75**, 337), resulting in the methyl esters being carried progressively further into the negative region and the ethyl ester from the positive to the negative region. The mandelates are allied in this respect to the malates which are situated in the positive region, the molecular rotational displacements moving only slowly further into the positive region with increase of the acyl chain.

Comparative data for lactic acid are afforded by the *iso*butyl ester and its derivatives (Wassmer and Guye, *J. Chim. phys.*, 1903–4, **1**, 257), in which the molecular rotation passes through a maximum at the propionyl derivative:

	Ester.	Acetyl-	Propionyl-	Butyryl-	derivative.
$[M]_D$	+22·5	+91·2	+95·8	+82·7	
t	18°	20°	18·5°	19°	

The observations of Freudenberg and his collaborators with respect to certain derivatives of the amino-acids are of importance. The following data indicate a *right* rotational displacement on passage from the methyl to the ethyl ester, both compounds being of configuration denoted by "*l*":

Methyl acetyl-*l*-aspartate	$[M]^{20°}_{5780}$ −31°;	$[M]^{100°}_{5780}$ −25°
Ethyl „ „	„ −21°;	„ −18° *
Methyl benzoyl-*l*-alanine	$[M]^{19°}_{5780}$ +13·7°	
Ethyl „ „	$[M]^{20°}_{5780}$ +98·6° †	

* Freudenberg and Noë, *Ber.*, 1925, **58**, 2399.
† Freudenberg and Rhino, *Ber.*, 1924, **57**, 1547.

Thus this empirical method breaks down when applied to the naturally occurring amino-acids. Anomaly, however, is a true criterion for their configuration.

Rotatory Dispersion.

The dispersion ratios for the *n*-, *iso*-, and *tert.*-esters are sensibly constant as indicated in the table below.

Ester.	λ 6708.	λ 5893.	λ 5461.	λ 5086.	λ 4359.
			Dispersion ratios at 45°.		
n-Butyl	0·602	0·821	1	1·207	1·703
*iso*Butyl	0·598	0·820	1	1·203	1·715
tert.-Butyl	0·601	0·823	1	1·204	1·720
d-sec.-Butyl	0·588	0·823	1	1·210	1·843
			Dispersion ratios at 75°.		
n-Butyl	0·603	0·828	1	1·203	1·705
*iso*Butyl	0·602	0·821	1	1·195	1·708
tert.-Butyl	0·600	0·829	1	1·208	1·730
d-sec.-Butyl	0·590	0·820	1	1·210	1·868

The slight irregularity for the tertiary ester, particularly for 75° and λ 4359, was confirmed on a new preparation of the ester. The dispersion curves tend to diverge from the corresponding curves of the *n*- and *iso*-esters and to become steeper on proceeding into the violet end of the spectrum. Thus the substitution of branched chains for the normal chain has apparently little effect on the value of the dispersion ratios, as in the results obtained for the corresponding esters of lactic acid. The magnitudes of the ratios vary considerably on proceeding from the lactates to the mandelates.

The ratios for *d-sec.*-butyl *l*-mandelate show greatest divergence from an average value for light of short wave-length.

It is to be noted that the ratio $[\alpha]^{t^\circ}_{4359}/[\alpha]^{t^\circ}_{5461}$ lies above the minimum value 1·57 for cases of simple rotatory dispersion. All the esters exhibit normal and complex rotatory dispersion. The chief points of interest with regard to the dispersion diagrams are: (1) The curves obtained by plotting $1/\alpha$ against λ^2 show curvature; (2) increase of temperature decreases the rotation; (3) the dispersion curves are very nearly parallel, only slight convergency and divergency occurring at the red and blue ends of the spectrum, respectively; (4) no intersections take place in either the α–λ or $[\alpha]$–λ curves; (5) the dispersion is allied to that of the lower normal esters of *l*-hexahydromandelic acid (Wood and Comley, J., 1924, **125**, 2630), *i.e.*, it is similar in general character to that exhibited by certain of the *n*-alkyl *l*-lactates in the positive region. From a consideration of (3), (4), and (5), it is inferred that the esters are not in proximity to the region of anomaly.

The rotatory dispersion exhibited by *d-sec.*-butyl *l*-mandelate is a simple example of the superposition of the partial rotations of two asymmetric centres in a single molecule (the centres possessing rotations of opposite sign and different dispersion ratios). The esterification of mandelic acid, which has a high negative rotation ($[\alpha]^{20^\circ}_D$, in water, 156·8°), with *sec.*-butyl alcohol, which has a low positive rotation ($[\alpha]^{20^\circ}_D$ 13·56°), results in the formation of an ester showing a decrease of rotation compared with the other isomeric esters investigated, the effect not being marked enough to cause the

appearance of visual anomaly, and the dispersion data indicate the dominant centre to be the asymmetric mandelyl group. It follows, therefore, that the partial rotations of the two asymmetric centres should be of comparable magnitude for visual anomaly. This case is different from that of *d-sec.*-butyl *d*-lactate, in which the rotatory powers of the two centres are comparable and favourable for anomaly in the visible region.

Effect of Change of Temperature.

The esters are sensitive to temperature change, the change in rotatory power being more pronounced in the blue region of the spectrum; an increase in temperature causes a decrease in rotation. The temperature–rotation curves for the longer wave-lengths are nearly linear, but as the wave-length decreases the curvature increases uniformly. They form a series of curves converging to a small extent in the direction of increase of temperature; they are slightly convex and inclined to the axis of zero rotation. Curvature is most apparent in the *d-sec.*-butyl ester. Unsuccessful attempts were made with certain of these esters to see whether at higher temperatures a more definite change in curvature could be realised.

The temperature range over which the esters were investigated was comparatively small owing to the low decomposition and racemisation temperature, which occurred at 105—110°, for the *n-*, *iso-*, and *d-sec.*-esters, and at 95—100° for the tertiary ester.

EXPERIMENTAL.

Resolution of Mandelic Acid.—Mandelic acid was resolved by the precipitation and fractional crystallisation of its morphine salt (McKenzie, J., 1899, **75**, 966) with the following modification. 50 G. of mandelic acid (1 mol.) were neutralised with 95 g. of morphine (1 mol.) in 400 c.c. of water and evaporated on a water-bath to a gum; while this was still warm, 400 c.c. of alcohol were added and the mixture was allowed to cool; addition of a nucleus of the pure active salt and vigorous stirring and scratching then precipitated the impure morphine *l*-mandelate, m. p. 185°, rising to 223—224° after two recrystallisations from absolute alcohol; $[\alpha]_D^{18°}$ — 110·5° in water ($c = 0{\cdot}9499$; $l = 2$). Yield, 47 g. The alkaloid was precipitated from an aqueous solution of the salt with ammonia and filtered off, the acidified solution extracted with ether, the extract dried, the solvent distilled, and the acid recrystallised from benzene; m. p. 133·5°; $[\alpha]_D^{20°}$, in water, —157·2° ($c = 2{\cdot}01$; $l = 2$). This was the highest rotation observed in a large number of resolutions.

Resolution by means of quinine was best effected from dilute

alcohol. Mandelic acid (7·6 g.; 1 mol.) and quinine (8·1 g.; ½ mol.) dissolved in 200 c.c. of 40% alcohol were gradually cooled to 0°. Crystallisation proceeded slowly, and the salt recrystallised from absolute alcohol had m. p. 180—181° (decomp.) and $[\alpha]_D^{21°}$, in alcohol, −143·3° ($c = 0·579$; α −1·66°; $l = 2$). McKenzie (*loc. cit.*) gives 202° for the *l*-salt and 180° for the *d*-salt. The *l*-mandelic acid obtained after decomposition of the salt and recrystallisation from water had $[\alpha]_D^{20°}$ — 156·6° (c = approx. 2% in water); yield, 55%.

n-*Butyl* l-*Mandelate*.—Concentrated sulphuric acid (2·6 g.) was added carefully to a mixture of 8·7 g. of *l*-mandelic acid and 13 g. of *n*-butyl alcohol (b. p. 117°); the mixture was refluxed for 8 hours on a water-bath, diluted with dry ether, neutralised with potassium carbonate, filtered, dried over anhydrous sodium sulphate, and the ether evaporated. Excess of alcohol was removed at a low temperature in a vacuum. The *ester* was dissolved in light petroleum (b. p. 40—60°) and cooled in a freezing mixture; the resulting crystals were recrystallised eight times and obtained in long, colourless needles, m. p. 38·5° (corr.). Yield, 7·8 g. (62%). (Found: C, 69·05; H, 7·7; equiv. by saponification, 207·8. $C_{12}H_{16}O_3$ requires C, 69·2; H, 7·7%; equiv., 208·2).

Comparative data available for this ester are as follows:

	Smiles and Walker (*J. Physical Chem.*, 1909, **13**, 580).	Present authors.
M. p.	31°	38·5°
$d_{4°}^{50°}$	1·0460	1·0443
$d_{4°}^{60°}$	1·0370	1·0355
$[M]_D^{50°}$	−192·2°	−186·99°
$[M]_D^{60°}$	−187·4°	−181·79°

Rotations were taken with a 1 dcm. tube. The rotatory dispersion is complex.

The ester decomposed at about 110°. Densities determined:

Temp.	39·1°	61·1°	80·0°	102·7°
$d_{4°}^{t°}$	1·0536	1·0346	1·0182	0·9983

$d_{4°}^{43·3°} = 1·0504$. $d_{4°}^{61·5°} = 1·0345$. $d_{4°}^{81°} = 1·0174$. $d_{4°}^{102·1°} = 0·9988$.

iso*Butyl* l-*Mandelate*.—The preparation was similar to that of the normal ester [10 g. of *l*-acid, 15 g. of *iso*butyl alcohol (b. p. 106·5°), and 3 g. of sulphuric acid], and the crude ester purified as follows. A regulated current of dry air was drawn through a dilute solution of the ester in light petroleum (b. p. 40—60°), which was cooled in a freezing mixture. The gradual removal of the solvent caused crystallisation of the ester; eight to ten recrystallisations were necessary to give material of constant rotation and of m. p. 35·5° (corr.). Yield, 8·5 g. (60%) (Found: C, 69·1; H, 7·65; equiv., 208·4. Calc. for $C_{12}H_{16}O_3$: C, 69·2; H, 7·7%; equiv., 208·2). Walden (*Z. physikal. Chem.*, 1895, **17**, 706) gives $[M]_D^{20°} - 209°$; $[\alpha]_D^{20°} -100·73°$.

A 1 dcm. tube was employed for the measurements. The ester exhibits complex rotatory dispersion.

Above 105° decomposition of the ester was noted. Densities determined:

Temp.	38·5°	61·2°	80·1°	102·3°
$d_{4°}^{t°}$ ...	1·0536	1·0337	1·0173	0·9977

	$d_{4°}^{42°} = 1·0506.$	$d_{4°}^{59°} = 1·0357.$	$d_{4°}^{81°} = 1·0165.$	$d_{4°}^{99°} = 1·0007.$

4359	217·01	202·97	188·65	179·03

tert.-*Butyl* l-*Mandelate*.—To a mixture of *tert.*-butyl alcohol (10 g.; b. p. 83°/760 mm.), *l*-mandelic acid (10 g.), and 10 c.c. of light petroleum (b. p. 75—80°), sulphuric acid (3 g.) was added in the cold and the mixture refluxed on a water-bath for 4 hours; 4—5 volumes of dry, light petroleum (b. p. 40—60°) were then shaken with the reaction mixture, and the upper layer was neutralised with potassium carbonate, filtered, dried over anhydrous sodium sulphate, and the ether evaporated. The excess of alcohol was removed in a vacuum, and the *ester* recrystallised 8 times, as for the preceding ester, to a constant rotation and m. p. 65°. Yield 6·8 g. (45%) (Found: C, 69·4; H, 7·8%; equiv., 208·6). A peculiarity was noted in the behaviour of samples of the esters when

kept in a vacuum desiccator: the rotation increased and a compound of low m. p. was formed which rendered crystallisation of the ester difficult; this was most pronounced in the tertiary ester and may be due to the formation of a lactide or ether.

Rotations were taken in a 1 dcm. tube. The ester exhibits complex rotatory dispersion.

Decomposition was noted above 95°. Densities determined:

Temp.	19·0°	37·5°	59·6°	79·6°
$d^{t°}_{4°}$	1·0682	1·0520	1·0325	1·0146

		$d^{38·7°}_{4°} = 1·0507$.	$d^{58·3°}_{4°} = 1·0335$.	$d^{78·5°}_{4°} = 1·0157$.
λ.	$[\alpha]^{21°}_{\lambda}$.	$[\alpha]^{38·7°}_{\lambda}$.	$[\alpha]^{58·3°}_{\lambda}$.	$[\alpha]^{78·5°}_{\lambda}$.

6152	74·06	71·44	67·83	65·01
5893	82·70	79·53	75·55	72·32
5589	94·54	90·66	86·16	82·52
5461	100·20	96·03	91·48	87·46
5324	107·04	102·52	97·72	93·60
5086	121·11	116·02	110·20	105·63
4861	134·03	129·04	123·12	118·05
4678	146·65	141·20	135·02	129·98
4455	164·83	158·30	151·33	145·30
4359	172·40	165·75	157·85	151·64

d-sec.-*Butyl* l-*Mandelate*.—To a mixture of 8 g. of *d-sec.*-butyl alcohol (b. p. 99°/757 mm.; $[\alpha]^{27°}_{D}$ + 13·56°) and 10 c.c. of light petroleum (b. p. 75—80°), cooled in ice and salt, sulphuric acid (2·6 g.) was added, followed by 8 g. of *l*-mandelic acid. The mixture was refluxed on a water-bath for 6 hours and the *ester* isolated in a similar way to the tertiary ester; after 2 fractionations it had b. p. 88°/0·05 mm. and $\alpha^{20°}_{D}$ 77·50°. A further preparation gave the same result, and a third fractionation was unnecessary. Yield, approx. 6 g. (50%) (Found: C, 69·2; H, 7·6%; equiv., 208·4).

Hydrolysis of the ester. 4 G. of the ester were treated with caustic potash and steam-distilled; the recovered alcohol was converted into the hydrogen phthalate of m. p. 46—47°, $[\alpha]^{20°}_{D}$ + 38·9° (m. p. of original hydrogen phthalate 48°, and $[\alpha]^{20°}_{D}$ + 39·5° in alcohol). Acid hydrolysis and extraction with ether gave a specimen of acid which on recrystallisation once from benzene had m. p. 133°, $[\alpha]^{20°}_{D}$ −156·3° (m. p. of original acid 133·5°, and $[\alpha]^{20°}_{D}$ −156·8°).

A 0·5-dcm. polarimeter tube was employed, and the ester was found to exhibit complex rotatory dispersion. Decomposition was noted at 105—110°. Densities determined:

Temp.	3·0°	18·0°	43·5°	68·5°	93·0°
$d^{t°}_{4°}$	1·0746	1·0623	1·0410	1·0209	0·9992

	$d^{4°}_{4°}$ = 1·0742.	$d^{19·8°}_{4°}$ = 1·0607.	$d^{49·8°}_{4°}$ = 1·0360.	$d^{68·2°}_{4°}$ = 1·0207.	$d^{91·4°}_{4°}$ = 1·0014.

Summary.

1. In the isomeric butyl mandelates, the *iso*butyl ester shows an increase and the *tert.*-ester a decrease of negative rotation when compared with the *n*-ester. Pronounced decrease in rotation takes place when there are two asymmetric centres of opposite sign in the molecule, but without visual anomaly. For visual anomaly the partial rotations of the two asymmetric centres should be of comparable magnitude.

2. All the esters exhibit normal and complex rotatory dispersion.

3. Increase of temperature causes a decrease in rotation of the esters. No maxima or minima occur in the temperature–rotation diagrams.

4. Comparison of the rotation data of the *n*-, *iso*-, and *tert.*-esters affords no generalisation for relative configuration purposes.

5. Rotational displacements in related series are discussed as a guide to configuration.

UNIVERSITY OF BIRMINGHAM,
EDGBASTON.

[*Received, June 13th*, 1928.]

CCLXXXVI.—*The Catalytic Hydrogenation of Different Types of Unsaturated Compounds. Part III. The Hydrogenation of Conjugated Systems.*

By SERGUEY V. LEBEDEV and ANASTASIA O. YAKUBCHIK.

In Part II (this vol., p. 823) we classified conjugated systems according to their method of catalytic hydrogenation, and made a study of the hydrogenation of isoprene as being representative of Type II—the most complicated of the four types. It was also shown that a

diagram of the whole process could be constructed from a few suitably chosen experimental data. We have now studied three other compounds of the same type, *viz.*, di*iso*propenyl, divinyl, and piperylene and our former conclusions are confirmed and extended.

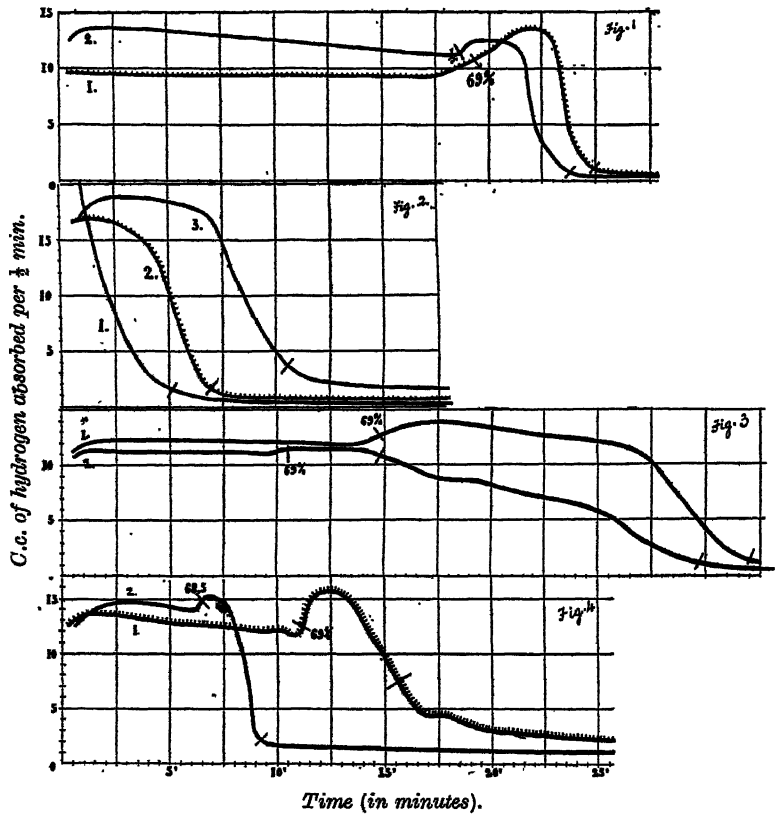
EXPERIMENTAL.

(A) *Diisopropenyl.*

A solution of pinacol (1 mol.) in acetic anhydride (4 mols.) was introduced drop by drop into warm acetic anhydride in which a small quantity of crystalline phosphoric acid was dissolved. Distillation gave a mixture of di*iso*propenyl and acetic acid, and redistillation over metallic sodium gave di*iso*propenyl, b. p. 69°, $d_4^{20°}$ 0·7262, $d_4^{0°}$ 0·7444 (yield, 85—90%).

The hydrogenation of di*iso*propenyl proceeds at a similar rate to that of isoprene, and the corresponding curve (Fig. 1; 1) is nearly the same, 68—70% of the hydrogen necessary for saturation being absorbed at a uniform velocity. The end of this stage is what we have called "the critical point of hydrogenation of the conjugated system" (*loc. cit.*), for it corresponds to the disappearance of this system. In the next stage the rate of absorption increases, and then falls abruptly to the third and last section. The proportions of hydrogen absorbed in the different sections * as calculated from Fig. 1 are:

Section	1	2	3
Hydrogen, %	69	22·5	8·5



The formula of di*iso*propenyl, $CH_2{:}CMe{\cdot}CMe{:}CH_2$, indicates the following possibilities for the process of hydrogenation: (1) 1 : 2- or 3 : 4-Addition of 1 mol. to give *as.*-methyl*iso*propylethylene. (2) 1 : 4-Addition of 1 mol. to give tetramethylethylene. (3) Addition of 2 mols. of hydrogen, giving di*iso*propyl. It will be shown later that the second section of the curve corresponds to the hydrogenation of methyl*iso*propylethylene, and the third to that of tetramethylethylene. Before the critical point (68—70% of hydrogen absorbed) all three possible substances are formed simultaneously.

The Hydrogenation Process prior to the Critical Point.—In order to study the process of hydrogenation up to the critical point, we interrupted it after the addition of 25% and 50% of hydrogen, and investigated the products. Di*iso*propenyl was removed as a solid compound with sulphur dioxide as in the case of isoprene (*loc. cit.*);

* The sections of the curves are separated by dashes which are placed on the indefinite intermediate parts of the curve in such a position that these parts are divided in proportion to the velocities of hydrogenation on the horizontal portions concerned.

and the remaining products were estimated by our method of hydrogenation of mixtures.

25% *Hydrogenation.* To 17·4114 g. of di*iso*propenyl, 2527 c.c. of hydrogen were added (see Table IV, No. 2), and the product was treated with sulphur dioxide at 0° and kept for 8 days. The liquid was distilled on a steam-bath into a vessel containing alkali at 0°, and the hydrocarbon layer, when separated and distilled over

metallic sodium, boiled at 58—68°. The distillate was then analysed by the hydrogenation method. For this purpose 2·2385 g. were fully hydrogenated and absorbed 361 c.c.; if the hydrocarbons consisted of hexylenes only, 627 c.c. would have been required; hence the composition was: hexylenes 57·6%; di*iso*propyl 42·4% (see Table IV, No. 4). From the hydrogenation curve (Fig. 2; 1) we can determine the composition of the hexylenes. The first section (up to the dash) pertains, as will be shown later, to methyl-*iso*propylethylene, and the second to tetramethylethylene. In

Table I are given the amounts of hydrogen absorbed in different sections of the curve and the calculated compositions of the reduction products; Table II shows the composition of the original product of hydrogenation.*

† See p. 2195.

50% *Hydrogenation.* To 14·228 g. of di*iso*propenyl, 4187 c.c. of hydrogen (1 mol.) were added. The hydrogenation product was freed from di*iso*propenyl as before, and kept saturated with sulphur dioxide for 10 days. When freed from the residue and distilled over metallic sodium, the hydrocarbons boiled at 57—68°. The composition of this mixture was investigated by the hydrogenation method: 1·5969 g. of substance absorbed 278·5 c.c. of hydrogen; if the hydrocarbons consisted of hexylenes only, 456·5 c.c. would have been required. The composition was therefore hexylenes 61%, di*iso*propyl 39% (see Table IV, No. 5).

The nature of hexylenes as determined by the examination of the two sections of the curve (Fig. 2; 2) leads to the results given in Table I, from which it is possible to deduce the composition of the product before its treatment with sulphur dioxide, having regard to the fact that at 50% hydrogenation the amount of di*iso*propyl

* The calculation is as follows: 100 Mols. of di*iso*propenyl require 50 mols. of hydrogen for 25% hydrogenation; if x mols. of hexylenes and y of di*iso*propyl have been formed, we have $x + 2y = 50$, and $x : y = 57·5 : 42·5$; hence $x = 20·2$; $y = 14·9$; and di*iso*propenyl (by diff.) = 64·9.

formed is equal to the quantity of di*iso*propenyl remaining in the mixture. The composition thus calculated is shown in Table II.

In order to decide which section of the curve relates to *as.*-methyl-*iso*propylethylene, the product * of 50% hydrogenation (freed from di*iso*propenyl) was hydrogenated in admixture with a standard asymmetrically disubstituted ethylene, *viz.*, camphene; in Table III are shown (1) the amounts of hydrogen required in the various stages as calculated from the weight taken; (2) the amount of hydrogen actually absorbed by the hydrogenation (for numerical data, see Table IV, Expt. 6). Fig. 2, No. 3 is the corresponding curve. The table and the curve clearly show that camphene is hydrogenated in the first section of the curve; hence, according to the rule given in Part I (J., 1925, **127**, 417), *as.*-methyl*iso*propylethylene is also hydrogenated in this section and tetramethylethylene in the second.

TABLE III.

C.c. of hydrogen absorbed in the sections of the hydrogenation curve for the mixture with camphene.

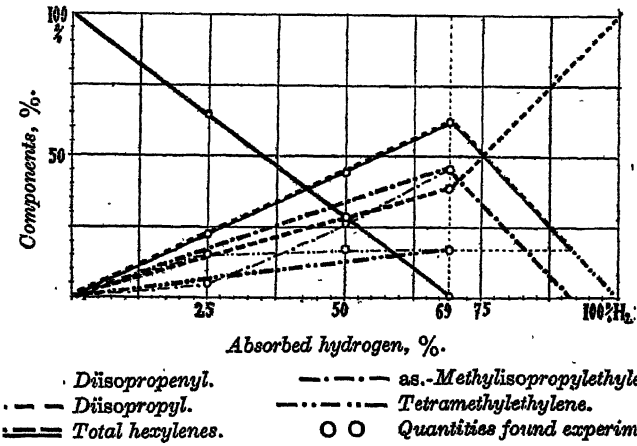
	1011	

69% *Hydrogenation (up to the critical point).* In Part II (*loc. cit.*) two methods of determining the critical point were described. (1) It corresponds to a break in the curve at the end of the first stage, such as is clearly seen at 69% hydrogenation in Figs. 1 and 4. (2) It can be deduced from the amount of di*iso*propenyl present at any moment of the process before the critical point, for the line representing this amount (see Fig. 5) cuts the axis of abscissæ at the percentage of hydrogenation corresponding to the critical point. In the product of 50% hydrogenation the amount of di*iso*propenyl was 28% (see Table II), and the continuation of the line through this point cuts the axis at 69·5%, in agreement with the value obtained by method (1).

As the conjugated system is no longer present beyond the critical point, the treatment of the product by sulphur dioxide becomes unnecessary, and the risk of isomerising the unsaturated substances (see Part II) is avoided. For the addition of the remaining 31% of hydrogen we have two well-defined sections of the curve: the first,



* The composition of the product used in this experiment differed from that mentioned in Table I. It was: saturated substance, 33; methyl*iso*propylethylene, 9; tetramethylethylene, 58%.

pertaining to methyl*iso*propylethylene, corresponds to 22·5% of hydrogen, and the second, relating to tetramethylethylene, to 8·5% (see p. 2191). The amounts of hexylenes corresponding to different sections are obtained by doubling the percentage of hydrogen absorbed over these sections. The composition calculated in this way is given in the third part of Table II.

General Survey of the Hydrogenation of Diisopropenyl.

The diagram representing the hydrogenation of di*iso*propenyl (Fig. 5) is based on the data given in Table II. It is similar to that of isoprene, as might be anticipated from the similarity of the two critical points, *viz.*, 68—70% for di*iso*propenyl and 69—71% for

FIG. 5.

isoprene. A further resemblance is to be found in the fact that the experimentally determined quantities of di*iso*propenyl, di*iso*propyl, and *total* hexylenes lie on practically straight lines.

The lines for individual hexylenes, however, show breaks, doubtless owing to the circumstance that the relative quantities at 25% and 50% hydrogenation are altered by isomerisation during the treatment with sulphur dioxide, which, as shown later, rapidly converts *as.*-methyl*iso*propylethylene into tetramethylethylene. It is therefore improbable that the deviations are real; on the contrary, there is reason to believe that the curves should be straight lines, as shown by the thicker lines in the diagram. In Table II there are two sets of figures each for 25% and 50% hydrogenation; the experimental values are affected by the isomerisation, whereas the others were obtained from the diagram and are more likely to be correct.

Hydrogenation of Diisopropenyl mixed with Standard Ethylenic Derivatives of Different Degrees of Substitution.

We undertook the hydrogenation of mixtures of di*iso*propenyl with ethylenic derivatives in order (1) to obtain sufficient hydrogenation curves to determine the position of the critical point, and (2) to determine the course of formation of the saturated molecules in the hydrogenation of a conjugated system. The numerical data and the results obtained are summarised in Tables IV, V, and VI. In Tables V and VI are shown (1) the amounts of hydrogen calculated for the three sections of the curve of di*iso*propenyl according to the scheme on p. 2191, and (2) the amounts of hydrogen which are actually absorbed in the sections of the curve in the hydrogenation of di*iso*propenyl in admixture with the standard ethylenic derivatives.

From Tables IV, V, and VI and the corresponding curves we note the following circumstances. The added standard ethylenic derivatives are generally hydrogenated after the critical point in the places determined by their degree of substitution. Thus, camphene is hydrogenated in the second section of the curve (Fig. 3; 1), together with methyl*iso*propylethylene, and tetramethylethylene in the third section (Fig. 4; 2). Crotonic acid (Fig. 3; 2) and trimethylethylene * (Fig. 4; 1), having no other substance of the same degree of substitution among the hydrogenation products, form a new section inserted between sections 2 and 3. Yet the *iso*propylethylene, added as a standard monosubstituted ethylene, is hydrogenated in the first section together with the conjugated system (Fig. 1; 2). The critical point retains its position and is clearly defined in every case.

The Formation of Fully Saturated Molecules prior to the Critical Point.—The hydrogenation in admixture with camphene requires a special study. Here two facts are of importance: (1) The beginning of the hydrogenation of an *as.*-disubstituted ethylene either formed in the actual process (methyl*iso*propylethylene) or added initially (camphene; methyl-*tert.*-butylethylene †), is distinctly separated from the end of the first section. (2) The whole of the *as.*-disubstituted standard added is hydrogenated after the

* In the case of this compound, the volume of hydrogen in the second section is increased at the expense of the third section (compare Table IV, No. 10 and Table VI). This occurred because the trimethylethylene used contained some *as.*-methylethylethylene which, being an *as.*-disubstituted ethylene, is naturally hydrogenated together with the similarly substituted methyl*iso*propylethylene. The curve is very long and only a part of the third section is included.

† The hydrogenation of di*iso*propenyl in admixture with *as.*-methyl-*tert.*-butylethylene has given the same results as with camphene.

critical point, and therefore does not alter the amount of fully saturated molecules formed before this point. This suggests that the fully saturated molecules formed before the critical point are not formed directly from the component to which the section relates, but from the conjugated system by addition of 2 mols. of hydrogen, either simultaneously or in such a rapid succession as to appear to be so.

Hence, of the two assumptions made in Part II (this vol., p. 834), the second is obviously correct.

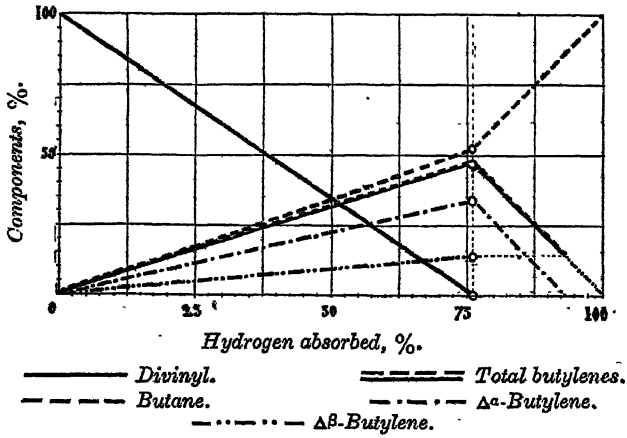
Isomerisation of as.-*Methylisopropylethylene by the Action of Sulphur Dioxide.*

We stated above (p. 2194) that the use of sulphur dioxide caused an isomerisation which affected the apparent composition of the hydrogenation products of di*iso*propenyl. In order to demonstrate this, the 50%-hydrogenation product, freed from di*iso*propenyl, was saturated with sulphur dioxide at 0°, and kept in a sealed tube at 100° for 3 days. The resulting hydrocarbons were freed from sulphur dioxide and analysed by the hydrogenation method: 2·049 g. absorbed 352 c.c., whereas 577 c.c. of hydrogen would have been required if the hydrocarbons contained hexylenes only; hence the composition was: hexylenes 61%, di*iso*propyl 39%. The hydrogenation curve has two sections: in that corresponding to methyl*iso*propylethylene 44 c.c. were absorbed, equivalent to 7·5% of this hydrocarbon, and the absorption of 308 c.c. in the other section indicated 53·5% of tetramethylethylene.

Comparison of these proportions with those for the original material (Table I) shows a large decrease (38 to 7·5%) for methyl-*iso*propylethylene and a corresponding increase (23 to 53·5%) in tetramethylethylene. Moreover, these changes are much more extensive than those involving the amylenes derived from isoprene (see Part II, p. 835).

(B) *Divinyl.*

Divinyl, prepared by pyrogenetic decomposition of naphtha, was converted to the tetrabromide (m. p. after recrystallisation 113—115°), regenerated by zinc in alcoholic solution, and collected over saturated brine. A measured volume (usually 200—300 c.c.) was dissolved in alcohol containing platinum-black and hydrogenated at 0°, the amount of divinyl taken being calculated from the volume of hydrogen absorbed. The hydrogenation curve is given in Fig. 7.



In the hydrogenation of divinyl, $CH_2{:}CH{\cdot}CH{:}CH_2$, three products can be formed, *viz.*, *n*-Δ^{α}- and Δ^{β}-butylene and butane. The rules given in Part I (*loc. cit.*) postulate three sections on the curve, and these can, in fact, be observed. The first, relating to the conjugated

system, ends at the critical point; the second pertains to Δ^{α}-, and the third to Δ^{β}-butylene. The presence of the 1 : 4 hydrogenation product proves that divinyl belongs to our Type II of conjugated systems. The critical point on the curve is at 76% of hydrogenation. The amounts of hydrogen absorbed in the different sections as calculated from Fig. 7 are:

Section			
Hydrogen, %			

Calculation from the hydrogen absorbed in the sections of the curves for divinyl in admixture with trimethylethylene (Fig. 8; 3) and with tetramethylethylene (Fig. 9; 2) gives similar figures. These two offer a good example for such a calculation, for on both curves all

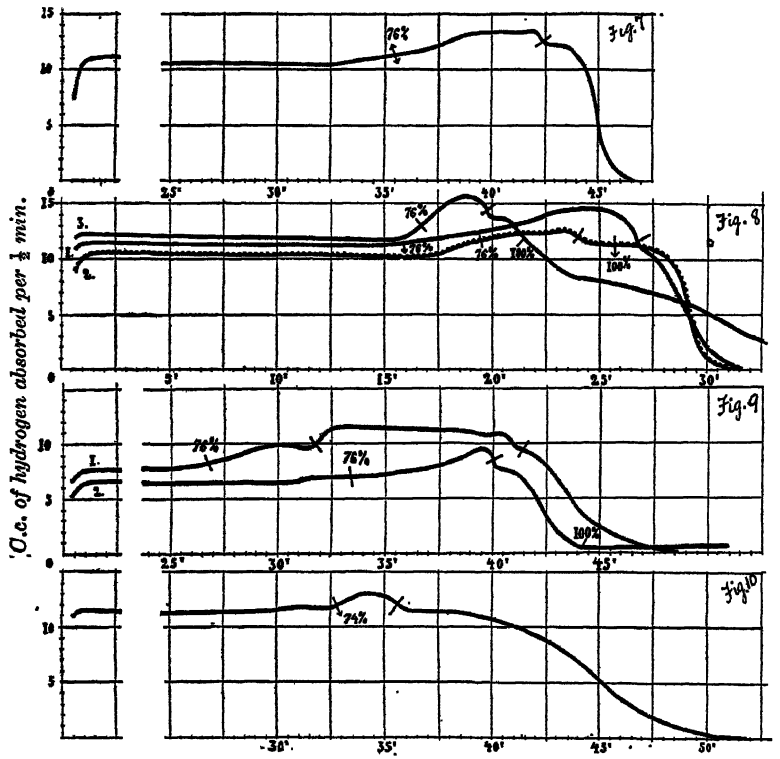


FIG. 6.

the divinyl is hydrogenated before the admixed substances. The figure 100% on these curves shows the point where the hydrogenation of divinyl is completed. The first of these curves shows clearly all the three sections; on the second the limits of the third section are very clearly marked. The composition of the hydrogenation product at the critical point, as calculated from the amounts of hydrogen absorbed, is: Divinyl, 0; butane, 52; Δ^{α}-butylene, 34; Δ^{β}-butylene, 14%; and Fig. 6 is constructed from these values.

Hydrogenation of Divinyl in Admixture with Monoethylenic Derivatives of Different Degrees of Substitution.—The curves in Figs. 7, 8, and 9 represent the hydrogenation of divinyl in admixture with ethylenic derivatives, and, in conjunction with the data of Tables VII and VIII, they provide the material necessary for following the course of the process. Both for divinyl alone and for its mixtures

the critical point is at 76% of hydrogenation. As in the case of other conjugated systems of Type II, the position of the critical point is not always clearly marked. The curve for the mixture with Δ^{β}-butylene (Fig. 8; 2) is very similar to that of pure divinyl (Fig. 7), but is more prolonged in the last section. The dash marked 100% on the curves indicates the point where, by calculation, divinyl is consumed and hydrogenation of the admixed component begins.

(C) *Piperylene.*

Piperylene, $CH_2{:}CH{\cdot}CH{:}CH{\cdot}CH_3$, was obtained from piperidine by Hofmann's method (*Ber.*, 1881, **14**, 664); it had b. p. 41·5°; $d_4^{20°}$ 0·6852. In spite of its unsymmetrical nature, piperylene can yield only two pentenes on hydrogenation, for the 1 : 2 and 1 : 4 addition of 1 mol. of hydrogen both lead to the same *s.*-methylethylethylene. It is therefore impossible to determine whether 1 : 4-addition actually occurs, but the properties of piperylene (*e.g.*, its tendency to polymerise, and its energetic

* The sections thus denoted are due to substances which, in the absence of similarly substituted compounds among the products of hydrogenation, have formed their own sections.

reaction with sulphur dioxide) would suggest that some of the *s*.-methylethylethylene is formed in this way.

Piperylene evidently belongs to our Type II of conjugated systems. Its hydrogenation curve (Fig. 10) has three sections: that before the critical point (74% hydrogenation) is nearly horizontal; the second, due to propylethylene, corresponds to the more rapid absorption of 6·5% of hydrogen; and the third (19·5% of hydrogen) relates to *s*.-methylethylethylene (see Table X).

The amounts of hydrogen absorbed in the corresponding sections of the hydrogenation curves of piperylene in admixture with different derivatives of ethylene give nearly similar figures, the critical point usually corresponding to 72% hydrogenation (see Table IX).

The figures of the last column serve to calculate the composition of the hydrogenation product at the critical point. The amount of the particular pentene corresponding to each section is obtained by doubling the percentage of hydrogen absorbed over that section.

TABLE IX.

Percentages of hydrogen absorbed in the sections of the curves for piperylene.

Hydrogenation of Piperylene Mixed with Standard Ethylenic Derivatives of Different Degrees of Substitution.—We have examined a number of mixtures of piperylene with ethylenic derivatives of different degrees of substitution. The numerical data for these mixtures are in Tables X and XI. The construction of Table XI is similar to that of Table V.

	508		504		784		554		485	

From Tables X and XI the following facts emerge. (1) In the mixture of piperylene with safrole (a monosubstituted ethylene) the critical point is not clearly marked, for the safrole is partially hydrogenated in the first section (Fig. 12; 1). (2) The mixture with camphene gives a peculiar curve, for this *as.*-disubstituted ethylene has no pentene of the same degree of substitution among the products of hydrogenation; hence it forms an independent section (A) on the curve. (3) Anethole (Fig. 12; 3) and *s.*-methylethylethylene, being of the same degree of substitution, hydrogenate simultaneously. (4) Methylheptenone (Fig. 13; 1) and tetramethylethylene (Fig. 13; 2), like camphene, form independent sections (B). These derivatives of ethylene are to be found in the last sections of the curves in the places determined by their degree of substitution.

Summary.

(1) The study of the hydrogenation of di*iso*propenyl confirms and extends the general conclusions previously drawn from the study of isoprene.

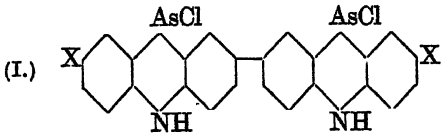
(2) The amounts of all the components formed during the process of hydrogenation are shown in the hydrogenation diagram of Type II of conjugated systems as straight lines joining the zero point of the diagram with the corresponding points lying on the ordinate of the "critical point of hydrogenation."

(3) Saturated compounds are formed before the critical point is reached, because some molecules add two molecules of hydrogen simultaneously.

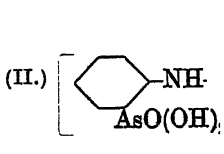
(4) The mono-ethylenic derivatives of different degrees of substitution, either formed in the process of hydrogenation or added initially, are hydrogenated after the critical point in places determined by their degrees of substitution. The mono-substituted ethylenes do not follow this rule, but hydrogenate partially or completely before the critical point.

(5) Piperylene and divinyl belong to Type II of conjugated systems. Diagrams are constructed showing the whole course of hydrogenation of these hydrocarbons.

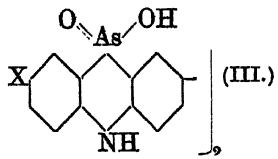
MILITARY MEDICAL ACADEMY,
LENINGRAD.



[*Received, May 29th*, 1928.]



CCLXXXVII.—10-*Chloro*-5:10-*dihydrophenarsazine and its Derivatives. Part VI. Compounds containing Two Nitrogen and Two Arsenic Atoms in Six- and Five-ringed Systems.*

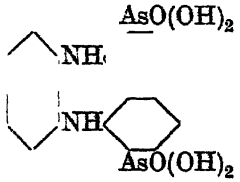


By CHARLES STANLEY GIBSON and JOHN DOBNEY ANDREW JOHNSON.

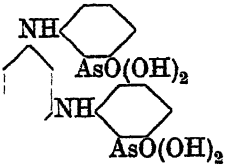
BY employing and extending the methods of preparation and synthesis described in previous papers (J., 1926, 450, 464, 2241; 1927, 247, 2499), compounds of the type I (X = H or Me) can be obtained. If, for example, benzidine (1 mol.) be condensed with *o*-bromophenylarsinic acid (2 mols.), 4:4-*bis*(*diphenylamine-2'-arsinic acid*) (II) is obtained. This acid when reduced with sulphur dioxide in the presence of alcohol, hydrochloric acid, and a trace of iodine is readily converted into 2:2'-*bis*(10-*chloro*-5:10-*dihydrophenarsazine*) (I; X = H). The compound so obtained appears to be identical with that prepared by condensing *NN'*-diphenylbenzidine (1 mol.) with arsenious chloride (2 mols.). The only means of comparing these two products is by microscopic examination, since they are

insoluble and their melting points cannot be determined in the ordinary way. By the methods already described, the chloro-

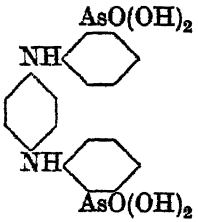
compound (I; X = H) has been oxidised to 2 : 2′-*bis*(*phenarsazinic acid*) (III; X = H), and from the latter the corresponding *bromo*-compound is readily obtained by the usual method of reduction.



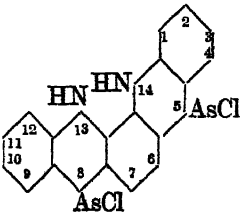
The condensation of *NN′*-di-*p*-tolylbenzidine with arsenious chloride gave 2 : 2′-*bis*(10-*chloro*-8-*methyl*-5 : 10-*dihydrophenarsazine*) (I; X = Me), from this 2 : 2′-*bis*(8-*methylphenarsazinic acid*) (III; X = Me) was obtained by oxidation, and the chloro-, *bromo*-, and *iodo*-compounds were prepared from the acid by reduction.



The above halogen compounds are intensely coloured, do not melt below 320°, and are practically insoluble in all the usual organic solvents. An acid of the type (II) can be recrystallised from dilute acetic acid, but acids of the type (III; X = H or Me) are insoluble in all solvents. They can, however, be purified conveniently through their crystalline disodium salts. This makes it possible to obtain the reduced halogen derivatives from them in a state of purity and, in the case of the chloro-compounds (I), these can be compared with the products of condensation of arsenious chloride and the di-secondary amines.



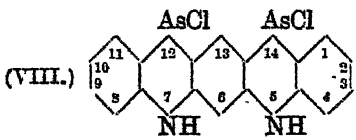
o-Bromophenylarsinic acid condensed with *o*-, *m*-, and *p*-phenylenediamines to give (IV) 1 : 2-, (V) 1 : 3-, and (VI) 1 : 4-*phenylenediaminodi*-o-*phenylarsinic acid*, respectively, but only the condensation with *m*-phenylenediamine was really satisfactory. The compound (IV) could not be purified and was reduced immediately in the presence of hydrochloric acid to 5 : 8-*dichloro*-13 : 14* : 5 : 8-*tetrahydroisobenzarsazinephenarsazine* (VII). This is the only possible constitution of a compound formed in this way. Owing to its sparing solubility, this compound could not be purified in the



* For simplicity, it is preferred for these complex compounds to write the numbers of the hetero-atoms of lower atomic weight before those of the hetero-atoms of higher atomic weight in spite of the ordinary rule of order of numbering. This system is adhered to throughout this paper.

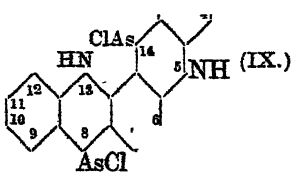
ordinary way, but by oxidising it to the diarsinic acid, freeing the latter from non-acidic impurities by solution in sodium hydroxide,

(IV.) 



(V.) 

(VI.) 



(VII.) 

and again reducing the precipitated acid, it was obtained in a reasonable state of purity. Contrary to expectation, this compound was not produced by condensing *NN'*-diphenyl-*o*-phenylenediamine (1 mol.) (Clemo, Perkin, and Robinson, J., 1924, **125**, 1780; Gibson and Johnson, this vol., p. 1988) with arsenious chloride (2 mols.), but the preliminary change in colour noticed might indicate the formation of an intermediate compound (compare Burton and Gibson, J., 1926, 454).

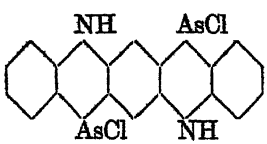
After purification by crystallisation from acetic acid, the diarsinic acid (V), when reduced in the presence of hydrochloric acid, yielded without difficulty a compound which can have either formula (VIII) or (IX). The product was highly crystalline and bright yellow. It

(VIII.) 

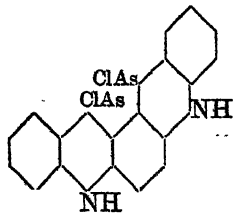
12 : 14-*Dichloro*-5 : 7 : 12 : 14-*tetrahydrobenzarsazinephenarsazine.*

(IX.) 

8 : 14-*Dichloro*-5 : 13 : 8 : 14-*tetrahydrobenzarsazinephenarsazine.*



differed from the bright red compound, obtained by condensing pure *NN'*-diphenyl-*m*-phenylenediamine (1 mol.) with arsenious chloride (2 mols.) under the usual conditions, not only in colour but also in crystalline form when viewed under the microscope. The latter condensation product could also have a constitution represented by either (VIII) or (IX). When these two dichloro-compounds were separately oxidised to the diarsinic acids and these acids



separately reduced back to dichloro-compounds, products having the same colour (yellow) but different properties were obtained. The insolubility of the compounds and the absence of melting points, however, prevented absolute comparisons being made. In spite of the apparent differences between the two dichloro-compounds, specimens of the diarsinic acid [5 : 7 : 12 : 14(or 5 : 13 : 8 : 14)-*benzarsazinicphenarsazinic acid*] prepared from both, when purified through the highly crystalline *disodium salt*, appeared to be identical. From this acid, by reduction in the presence of hydrobromic acid and hydriodic acid respectively, the sparingly soluble, highly crystalline, and coloured *dibromo-* and *di-iodo*-compounds were easily obtained.

When the above diarsinic acid was treated with hypophosphorous acid, no reduction took place until iodine was added, and the substance then precipitated was not the cacodyl compound but the above di-iodo-compound. The necessity for the presence of iodine (or hydriodic acid) for reduction of quinquevalent arsenic in organic compounds by hypophosphorous acid to take place has been pointed out by previous workers.

NN'-Diphenyl-*p*-phenylenediamine (1 mol.) condenses readily with arsenious chloride (2 mols.) and the compound produced may be either 7 : 14-*dichloro*-5 : 12 : 7 : 14-*tetrahydrobenzarsazinephenarsazine* (X) or 13 : 14-*dichloro*-5 : 8 : 13 : 14-*tetrahydrobenzarsazinephenarsazine* (XI). The product appeared to be homogeneous,

(X.)

(XI.)

and being sparingly soluble, was oxidised to the corresponding 5 : 12 : 7 : 14(or 5 : 8 : 13 : 14)-*benzarsazinicphenarsazinic acid*, which again was purified through its *disodium* salt. The acid when reduced in the presence of hydrochloric acid gave the above-mentioned dichloro-compound, an orange-red, highly crystalline substance which, like the isomeric substances, does not melt below 320°. Similarly, the *dibromo*-compound with analogous properties was obtained by reducing the acid in the presence of hydrobromic acid, but the di-iodo-compound could not be obtained pure.

The work now described emphasises the highly crystalline nature and intense colour of the homologues of 10-chloro-5 : 10-dihydrophenarsazine and of the corresponding bromo- and iodo-compounds,

even when these derivatives possess a much more complicated structure which renders them insoluble and high-melting solids.

EXPERIMENTAL.

4:4-*Bis*(*diphenylamine-2'-arsinic acid*) (II).—A mixture of benzidine (3·45 g.; 1 mol.), *o*-bromophenylarsinic acid (11·3 g.; 2 mols.), anhydrous potassium carbonate (8·8 g.), amyl alcohol (40 c.c.), and a trace of copper powder was boiled under reflux for 5 hours; the product was steam-distilled to remove amyl alcohol and filtered while hot. On acidifying the filtrate with dilute hydrochloric acid, a discoloured acid was precipitated. This was obtained as a white powder, unmelted at 320°, by recrystallisation from dilute acetic acid (Found: As, 25·3. $C_{24}H_{22}O_6N_2As_2$ requires As, 25·7%).

2:2'-*Bis*(10-*chloro*-5:10-*dihydrophenarsazine*) (I; X = H).—(*a*) The preceding compound (crude, 1·2 g.), dissolved in a hot mixture of alcohol (25 c.c.) and hydrochloric acid (20 c.c.) to which a trace of iodine had been added, was reduced by passing sulphur dioxide for a few minutes. The precipitated *chloro-compound* was washed with alcohol and ether and dried at 120° (Found: Cl, 12·7. $C_{24}H_{16}N_2Cl_2As_2$ requires Cl, 12·8%).

(*b*) *NN'*-Diphenylbenzidine (m. p. 250°; from toluene) was prepared from diphenylamine by the method described by Wieland and Wecker (*Ber.*, 1922, **55**, 1804) for the preparation of *NN'*-di-*p*-tolylbenzidine; yield, 60%. The method described by Wieland and Müller (*Ber.*, 1913, **46**, 3296) gives a poor yield, as Marqueyrol and Muraour (*Bull. Soc. chim.*, 1914, **15**, 186) have shown.

A mixture of *NN'*-diphenylbenzidine (23·1 g.; 1 mol.), arsenious chloride (27·8 g.; 2·2 mols.), and *o*-dichlorobenzene (100 c.c.) was boiled under reflux for 5 hours. (The mixture while still cold developed a greenish-blue coloration: this has been frequently noticed in other condensations of this type and it may indicate the formation of a primary addition compound which is subsequently transformed into the ring condensation product; compare Burton and Gibson, J., 1926, 454.) Hydrogen chloride was freely evolved as soon as boiling commenced, and solid matter began to separate after about 30 minutes. The liquid was filtered while hot, the residue washed several times with hot *o*-dichlorobenzene to remove unchanged soluble materials, and the last trace of *o*-dichlorobenzene removed from the product by heating at 160° for a short time. In this condensation, it is important that carefully purified materials should be used; otherwise, highly coloured by-products are formed and these render the purification of the main product a matter of considerable difficulty. Yield, 58% (Found: As, 26·9. $C_{24}H_{16}N_2Cl_2As_2$ requires As, 27·1%).

2 : 2′-*Bis*(10-*chloro*-5 : 10-*dihydrophenarsazine*) formed by either of the above methods is a pale orange-yellow, microcrystalline powder, insoluble in all the usual organic solvents and such solvents as acetylene tetrachloride, *o*-dichlorobenzene, and nitrobenzene. It is slightly soluble in boiling naphthalene and crystallises from it in minute prisms on cooling. It remains unmelted at 325°.

(*c*) 2 : 2′-Bis(10-chloro-5 : 10-dihydrophenarsazine) was also prepared from 2 : 2′-bis(phenarsazinic acid) by a similar method to that used for the corresponding bromo-compound (see below).

2 : 2′-*Bis*(*phenarsazinic acid*) (III; X = H).—The use of chloramine-T (Burton and Gibson, J., 1924, **125**, 2275) for the oxidation of the preceding compound was impracticable because of the insolubility of the latter in acetone or water. 2 : 2′-Bis-(10-chloro-5 : 10-dihydrophenarsazine) (5 g.) was boiled with acetic acid (100 c.c.) in order to obtain the substance in a fine state of division. To the cooled suspension, hydrogen peroxide (20 vol.; 16 c.c.) was added and the mixture carefully heated to boiling. The colour of the chloro-compound changed to greyish-brown and in about 5 minutes oxidation was completed. (Because of their insolubility in acetic acid, oxidation of the chloro-compounds described in this communication does not proceed so readily and completely as in the case of the substances previously described; compare J., 1927, 2514.) Water (250 c.c.) was added to the cooled mixture and the solid matter was filtered off, well washed with water, and boiled with dilute aqueous sodium hydroxide. The solution obtained was filtered from non-acidic substances and treated with 20% aqueous sodium hydroxide until the hot, deep brown solution began to deposit the colourless crystalline *disodium* salt. This was filtered off when cold, well drained on the filter, dissolved in a small quantity of hot water, and reprecipitated as before with 20% sodium hydroxide solution. The disodium salt prepared in this way was obtained in short colourless needles, slightly soluble in cold water and more soluble in hot. For analysis, it was well washed with ice-cold water and dried at 160—165° (Found: Na, 7·6. $C_{24}H_{16}O_4N_2As_2Na_2$ requires Na, 7·8%). From a solution of the disodium salt in warm water, dilute hydrochloric acid precipitated 2 : 2′-*bis*(*phenarsazinic acid*) as a white and somewhat gelatinous precipitate (3·5 g.). It was washed with water and dried at 140—145° (Found: As, 27·3. $C_{24}H_{18}O_4N_2As_2$ requires As, 27·35%).

2 : 2′-Bis(phenarsazinic acid) is a white amorphous powder insoluble in the ordinary organic solvents and remains unmelted at 325°. As it was insoluble in a hot mixture of alcohol and hydrochloric acid, attempts to prepare a hydrochloride were unsuccessful. The potassium salt resembles the sodium salt; the magnesium,

calcium, and barium salts are white microcrystalline precipitates; the mercurous and mercuric salts are heavy white precipitates, the latter somewhat crystalline; the silver salt is a white curdy precipitate soluble in ammonia; and the cupric salt is a pale greenish-blue, curdy precipitate. The acid itself is soluble in ammonia, but, being such a weak acid, is precipitated on boiling, ammonia escaping. Attempts to reduce the acid in acetic acid suspension to a cacodyl compound by means of hypophosphorous acid were unsuccessful.

2:2′-*Bis*(10-*bromo*-5:10-*dihydrophenarsazine*) (formula as I) was prepared by reducing with sulphur dioxide a suspension of 2:2′-bis-(phenarsazinic acid) (1·8 g.) in a hot mixture of alcohol (20 c.c.) and hydrobromic acid (const. b. p.; 12 c.c.) to which a trace of iodine had been added, an orange-yellow colour being developed; the precipitate was washed with alcohol and dried at 140° (Found: Br, 24·7. $C_{24}H_{16}N_2Br_2As_2$ requires Br, 24·9%).

2:2′-*Bis*(10-*chloro*-8-*methyl*-5:10-*dihydrophenarsazine*) (I; X = Me) was prepared from arsenious chloride (10·5 g.), *NN*′-di-*p*-tolylbenzidine [prepared according to the method of Wieland and Wecker (*loc. cit.*) and obtained as colourless plates, m. p. 234°, much more soluble in toluene than *NN*′-diphenylbenzidine] (9·5 g.), and *o*-dichlorobenzene (38 c.c.) as described for 2:2′-bis(10-chloro-5:10-dihydrophenarsazine); yield, 64%. It was obtained in small orange-red crystals (Found: Cl, 12·4. $C_{26}H_{20}N_2Cl_2As_2$ requires Cl, 12·2%).

It was also prepared by reducing with sulphur dioxide a hot suspension of 2:2′-bis(8-methylphenarsazinic acid) (1·2 g.; see below) in alcohol (25 c.c.) and hydrochloric acid (20 c.c.) containing a trace of iodine. Owing to the insolubility of the acid and of the chloro-compound it was necessary to heat the mixture for 30 minutes on the water-bath and to shake it frequently in order to obtain complete reduction. The product was washed with alcohol–hydrochloric acid and with alcohol and dried at 140° (Found: Cl, 12·1. $C_{26}H_{20}N_2Cl_2As_2$ requires Cl, 12·2%).

2:2′-*Bis*(8-*methylphenarsazinic acid*) (III; X = Me) was prepared in 64% yield by oxidising the preceding compound (9·5 g.) in acetic acid (150 c.c.) suspension with hydrogen peroxide (20 vol.; 32 c.c.) as described for 2:2′-bis(phenarsazinic acid). It was purified through its *disodium* salt, which forms short colourless needles closely resembling in properties the disodium salt of 2:2′-bis(phenarsazinic acid). The salt was washed with 90% alcohol, absolute alcohol, and ether and dried at 140—150° (Found: Na, 7·5. $C_{26}H_{20}O_4N_2As_2Na_2$ requires Na, 7·4%). When a warm aqueous solution of the disodium salt was acidified with dilute

hydrochloric acid, 2 : 2′-*bis*(8-*methylphenarsazinic acid*) was precipitated as a white amorphous powder. It does not melt at 320° (Found: As, 26·0. $C_{26}H_{22}O_4N_2As_2$ requires As, 26·0%).

2 : 2′-*Bis*(10-*bromo*-8-*methyl*-5 : 10-*dihydrophenarsazine*) (formula as I; X = Me) was prepared from the preceding acid (1·0 g.), suspended in a boiling mixture of alcohol (25 c.c.) and hydrobromic acid (const. b. p.; 20 c.c.) containing a trace of iodine, as described for the preceding chloro-compound. It was a red micro-crystalline substance. For analysis it was dried at 140° (Found: Br, 22·8. $C_{26}H_{20}N_2Br_2As_2$ requires Br, 22·7%).

2 : 2′-*Bis*(10-*iodo*-8-*methyl*-5 : 10-*dihydrophenarsazine*) was prepared in a similar manner to the corresponding chloro-compound from 2 : 2′-bis(8-methylphenarsazinic acid) (1·4 g.), alcohol (25 c.c.), and hydriodic acid (approx. 30%; 20 c.c.). It was a purplish-red solid which was unmelted at 320° (Found: I, 32·9. $C_{26}H_{20}N_2I_2As_2$ requires I, 33·2%).

5 : 8-*Dichloro*-13 : 14 : 5 : 8-*tetrahydroisobenzarsazinephenarsazine* (VII).—The condensation of *o*-phenylenediamine (5·3 g.; 1 mol.) with *o*-bromophenylarsinic acid (27·4 g.; 2 mols.) by boiling with potassium carbonate (21·4 g.), a trace of copper powder, and amyl alcohol (100 c.c.) for 5 hours gave a very discoloured product. All attempts to purify it in the ordinary way were unsuccessful. The crude product (2·0 g.), dissolved in a boiling mixture of alcohol (20 c.c.) and hydrochloric acid (16 c.c.) containing a trace of iodine, was reduced with sulphur dioxide in the usual way and a discoloured product again resulted. Since this could not be crystallised, it (3·4 g.) was suspended in acetic acid (30 c.c.) and oxidised with hydrogen peroxide (20 vol.; 4·2 c.c.) as previously described. The insoluble product was dissolved in hot dilute aqueous sodium hydroxide, the solution filtered, and the filtrate acidified. The precipitated acid was reduced again as just described. The precipitated *chloro-compound* was dark brown, insoluble in all the usual solvents, and remained unmelted at 320° (Found: Cl, 15·15. $C_{18}H_{12}N_2Cl_2As_2$ requires Cl, 14·9%).

1 : 3-*Phenylenediaminodi*-o-*phenylarsinic Acid* (V).—A mixture of *m*-phenylenediamine (m. p. 95°; 5·26 g.; 1 mol.), *o*-bromophenylarsinic acid (27·4 g.; 2 mols.), anhydrous potassium carbonate (21·4 g.), amyl alcohol (100 c.c.), and a trace of copper powder was boiled under reflux for 5 hours. The product was worked up as described for 4 : 4-bis(diphenylamine-2′-arsinic acid). The somewhat discoloured *acid* obtained (22% yield) was crystallised with difficulty from dilute acetic acid and dried at 160° (Found: As, 29·25. $C_{18}H_{18}O_6N_2As_2$ requires As, 29·5%). It is a colourless solid, unmelted at 325°, insoluble in water, sparingly soluble in

glacial acetic acid and in dilute mineral acids. Its ready solubility in a mixture of hydrochloric acid and alcohol distinguishes it from the corresponding ring acid.

12 : 14(or 8 : 14)-*Dichloro*-5 : 7 : 12 : 14(or 5 : 13 : 8 : 14)-*tetrahydrobenzarsazinephenarsazine* (VIII or IX) was prepared by reducing a boiling solution of the preceding acid (5·4 g.) in alcohol (54 c.c.) and hydrochloric acid (43 c.c.) in the usual way. The precipitated chloro-compound (69% yield) was washed with alcohol and dried at 140°. It formed clusters of slender yellow prisms (Found: As, 31·25; Cl, 14·5. $C_{18}H_{12}N_2Cl_2As_2$ requires As, 31·4; Cl, 14·9%).

When *NN'*-diphenyl-*m*-phenylenediamine (5·95 g.), arsenious chloride (9·17 g.), and *o*-dichlorobenzene (34 c.c.) were boiled for 5 hours, stout red prisms formed, which were filtered off from the hot solution, washed with hot *o*-dichlorobenzene and with benzene, and dried at 140° (yield, 7·75 g.; 71%) (Found: Cl, 15·1%).

The products of these two preparations remained unmelted at 320° but did not appear to be identical. Apart from their differences in colour and crystalline form when viewed under the microscope, the former had a more pronounced effect on the mucous membrane than the latter. The diarsinic acid obtained from each on oxidation (see below) gave on reduction a chloro-compound: that derived originally from 1 : 3-phenylenediaminodi-*o*-phenylarsinic acid had a marked tendency to crystallise and a marked effect on the mucous membrane, whereas that derived originally from *NN'*-diphenyl-*m*-phenylenediamine was amorphous and had no effect on the mucous membrane. Both substances were sufficiently soluble in acetone to impart to it a yellow colour, which was discharged on addition of an equal volume of a dilute aqueous solution of chloramine-T, a small quantity of a white substance (unmelted at 325°) being precipitated.

5 : 7 : 12 : 14(or 5 : 13 : 8 : 14)-*Benzarsazinicphenarsazinic acid* was prepared from either form of the foregoing compound by oxidation with hydrogen peroxide in glacial acetic suspension, as described for 2 : 2'-bis(phenarsazinic acid), the quantities being proportional. The product was purified through the *disodium* salt, which formed colourless soft needles, almost insoluble in cold or hot 20% aqueous sodium hydroxide and but slightly soluble in cold water. For analysis, the salt was washed with 90% alcohol, absolute alcohol, and ether and dried at 140—145° (Found: Na, 9·1. $C_{18}H_{12}O_4N_2As_2Na_2$ requires Na, 8·9%). When first precipitated, the free *acid* was somewhat gelatinous, but it was finally obtained as a white amorphous powder similar in properties to the other arsinic acids described in this communication (Found: As, 31·8. $C_{18}H_{14}O_4N_2As_2$ requires

As, 31·8%). The acid also forms crystalline calcium and barium salts, both insoluble in hot and in cold water, a white gelatinous silver salt soluble in aqueous ammonia, heavy white gelatinous lead and mercuric salts, a pale yellow gelatinous mercurous salt, and a brown gelatinous ferric salt.

12 : 14(or 8 : 14)-*Dibromo*-5 : 7 : 12 : 14(or 5 : 13 : 8 : 14)-*tetrahydrobenzarsazinephenarsazine*.—A hot suspension of the preceding compound (1·0 g.) in alcohol (20 c.c.) and hydrobromic acid (const. b. p.; 16 c.c.) containing a trace of iodine was reduced in the usual way. The product was washed with a mixture of alcohol and hydrobromic acid, then with alcohol and ether, and dried at 150° (Found: Br, 27·95. $C_{18}H_{12}N_2Br_2As_2$ requires Br, 28·3%). It crystallised in deep yellow prisms and remained unmelted at 325°.

12 : 14(or 8 : 14)-*Di-iodo*-5 : 7 : 12 : 14(or 5 : 13 : 8 : 14)-*tetrahydrobenzarsazinephenarsazine*.—(*a*) This was prepared in a similar manner to the preceding dibromo-compound (Found: I, 38·1. $C_{18}H_{12}N_2I_2As_2$ requires I, 38·5%). It was a deep red, microcrystalline powder resembling the bromo- and chloro-compounds in general properties. It is somewhat interesting that when 5 : 7 : 12 : 14(or 5 : 13 : 8 : 14)-benzarsazinicphenarsazinic acid is boiled with a mixture of alcohol and concentrated hydriodic acid no reduction of the arsenic takes place.

(*b*) 5 : 7 : 12 : 14(or 5 : 13 : 8 : 14)-Benzarsazinicphenarsazinic acid (0·8 g.) was boiled with acetic acid (20 c.c.) and to the hot suspension hypophosphorous acid (*d* 1·136; 10 c.c.) was added. No reduction took place. On addition of iodine (3·3 g.) in small portions to the boiling suspension, a vigorous reaction took place and a deep red, microcrystalline powder was precipitated. This substance was formed as soon as the first trace of iodine was added and no signs of the preliminary formation of a cacodyl compound were observed. When all the iodine had been added, the liquid was treated with a further 30 c.c. of acetic acid, cooled, and filtered. The product, washed with acetic acid, alcohol, and ether and dried at 140°, appeared to be identical with that obtained as described under (*a*) (Found: I, 38·0%).

On warming the above dichloro-compound with dilute ammonia on the water-bath for an hour, the colour changed from yellow to greyish-white. The product was readily soluble in hot or cold *n*-propyl and benzyl alcohols and also in hot glacial acetic acid, thus behaving exactly like 10 : 10′-oxy-5 : 10-dihydrophenarsazine (Burton and Gibson, J., 1926, 462).

The condensation of *p*-phenylenediamine with *o*-bromophenylarsinic acid, carried out as described for *m*-phenylenediamine, gave a much discoloured product which it was found impossible to purify.

7 : 14(or 13 : 14)-*Dichloro*-5 : 12 : 7 : 14(or 5 : 8 : 13 : 14)-*tetrahydrobenzarsazinephenarsazine* (X or XI) was prepared by boiling *NN'*-diphenyl-*p*-phenylenediamine (m. p. 145°; 15·6 g.; 1 mol.), arsenious chloride (24·1 g.; 2·2 mols.), and *o*-dichlorobenzene (90 c.c.) for 5 hours under reflux. The product (yield, 49%) was worked up as in similar condensations, being finally washed with benzene and dried at 130° (Found: Cl, 14·9. $C_{18}H_{12}N_2Cl_2As_2$ requires Cl, 14·9%). It was unmelted at 320°. When it was oxidised to the arsinic acid (see below), and this reduced in the manner described for similar substances, the chloro-compound was reobtained in orange-red, doubly refracting, prismatic needles (Found: Cl, 14·6%).

5 : 12 : 7 : 14(or 5 : 8 : 13 : 14)-*Benzarsazinicphenarsazinic Acid.*—The oxidation of the preceding compound (12·2 g.) with hydrogen peroxide (20 vol.; 20 c.c.) in acetic acid (122 c.c.) suspension was carried out as described for 2 : 2'-bis(phenarsazinic acid), but the reaction took a somewhat longer time. Water (244 c.c.) was added and, after cooling, the crude acid was filtered off and purified through the *disodium* salt. On addition of 20% sodium hydroxide solution to the hot discoloured solution of the disodium salt, the latter was precipitated in large flat plates. This particular disodium salt appeared to crystallise the most easily of all the disodium salts in this series. The salt was purified by dissolving it in warm water, adding 33% sodium hydroxide solution, and allowing the salt to crystallise slowly; it was then obtained in colourless flat plates and needle-shaped crystals. The salt can also be crystallised from aqueous acetone. For analysis, it was washed with 90% alcohol and absolute alcohol and dried at 140° (Found: Na, 8·8. $C_{18}H_{12}O_4N_2As_2Na_2$ requires Na, 8·9%).

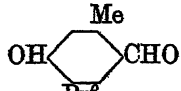
5 : 12 : 7 : 14(or 5 : 8 : 13 : 14)-*Benzarsazinicphenarsazinic acid* was precipitated by the addition of hydrochloric acid to a warm aqueous solution of the preceding sodium salt. It was recrystallised with difficulty from dilute acetic acid and obtained in colourless rhomb-shaped plates, which did not melt at 320° although slight darkening took place somewhat above 290° (Found: As, 31·6. $C_{18}H_{14}O_4N_2As_2$ requires As, 31·8%). It was sparingly soluble in hot glacial acetic acid and insoluble in water. Although the acid was slightly soluble in a mixture of alcohol and hydrochloric acid, the hydrochloride was not isolated. The salts resemble those of the isomeric acid except that the calcium salt appears to be slightly soluble in water.

7 : 14(or 13 : 14)-*Dibromo*-5 : 12 : 7 : 14(or 5 : 8 : 13 : 14)-*tetrahydrobenzarsazinephenarsazine.*—The preceding acid (0·75 g.), suspended in a hot mixture of alcohol (18 c.c.) and hydrobromic acid (38%; 15 c.c.) containing a trace of iodine, was reduced as described

for the chloro-compound. The product formed deep red, doubly refracting, prismatic needles resembling those of the chloro-compound. It was unmelted at 320° and insoluble in all the usual solvents (Found: Br, 27·9. $C_{18}H_{12}N_2Br_2As_2$ requires Br, 28·3%).

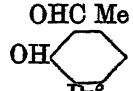
The di-iodo compound was prepared in an analogous manner or by the hypophosphorous acid reduction method but could not be purified.

We wish to thank Mr. C. M. Roberts, Assistant in the Chemistry Department, for valuable help in some of the preparative work connected with this investigation.



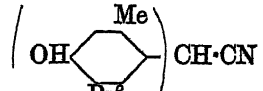
GUY'S HOSPITAL MEDICAL SCHOOL,
(UNIVERSITY OF LONDON), S.E. 1. [*Received, June 6th*, 1928.]

CCLXXXVIII.—*By-products of the Gattermann Aldehyde Reaction.*



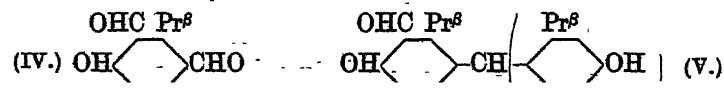
By FRANK BELL and THOMAS ANDERSON HENRY.

THE Gattermann synthesis of *p*-hydroxybenzaldehydes, depending on the primary production of an aldimine by the action of hydrocyanic acid on a phenol, has been the subject of a considerable number of modifications, mainly designed to avoid the use of anhydrous hydrocyanic acid. That due to Adams and Montgomery (*J. Amer. Chem. Soc.*, 1923, **45**, 2373; 1924, **46**, 1518) has been used in these laboratories (Henry and Sharp, J., 1926, 2432), and the present paper gives an account of certain by-products isolated during the preparation of *p*-hydroxybenzaldehydes by this method.

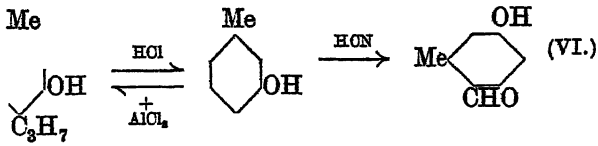


Thymol is stated to give a quantitative yield of the corresponding *p*-aldehyde (I), but a trace of the *o*-aldehyde (II) is invariably formed, together with a small amount of *dithymylacetonitrile* (III).

(I.)

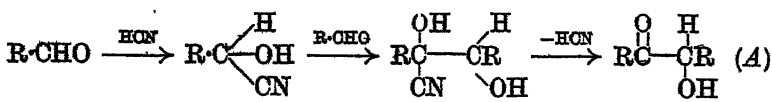


(II.)



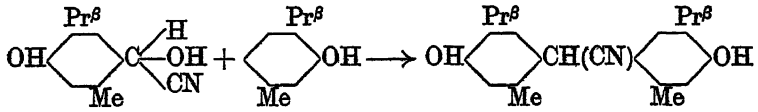
(III.)

Carvacrol gives analogous products. Kobek (*Ber.*, 1883, **16**, 2104) isolated a small amount of carvacroldialdehyde (IV) when preparing



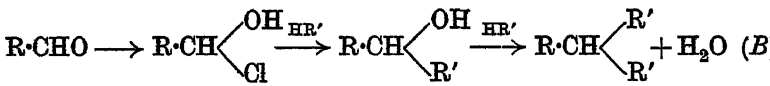
carvacrolaldehyde by the Reimer–Tiemann process, and the formation of this dialdehyde in the Gattermann reaction is now

shown by the isolation of its condensation product (V) with carvacrol. In some experiments with thymol, *iso*propylbenzene and *m*-cresolaldehyde (VI) (*o*-cresolaldehyde in the case of carvacrol) were isolated, the amounts of these compounds being greatest when the yield of aldehyde was least. This result was traced to the fact that under the conditions of aldehyde formation it is possible to convert thymol almost completely into *m*-cresol and *iso*propylbenzene



when no hydrocyanic acid is present, thus providing a further example of the reversibility of the Friedel–Crafts synthesis (compare Jacobsen, *Ber.*, 1885, **18**, 339). The possibility of utilising this reaction to introduce the *iso*propyl group into compounds dissolved in non-reactive solvents, *e.g.*, ether, xylene, or *p*-cymene, still awaits examination. A recent paper (Berry and Reid, *J. Amer. Chem. Soc.*, 1927, **49**, 3142) describes the transfer of an *iso*propyl group from di*iso*propylbenzene into naphthalene.

The conditions of the formation of substituted acetonitriles, such as dithymylacetonitrile (III), have been examined. It is well known that aromatic aldehydes show very varying behaviour on treatment with potassium cyanide in aqueous–alcoholic solution. One group, which includes benzaldehyde, *p*-chlorobenzaldehyde (Hantzsch and Glover, *Ber.*, 1907, **40**, 1519), and *o*-methoxybenzaldehyde (Irvine, J., 1901, **79**, 670), readily yields the corresponding benzoins, whereas *o*- and *p*-hydroxybenzaldehydes undergo resinification, and in still other cases, *e.g.*, *o*-nitrobenzaldehyde (Ekecrantz and Ahlqvist, *Ber.*, 1908, **41**, 878; 1910, **43**, 2606), a variety of products other than the benzoin is obtained. There is little doubt of the correctness of Lapworth's theory of the benzoin change (J., 1903, **83**, 995; compare Greene and Robinson, J., 1922, **121**, 2182), according to which the aldehyde, R·CHO, first adds on hydrogen cyanide, then combines with a further molecule of aldehyde, and finally eliminates hydrogen cyanide as in (*A*). It seemed possible that the cyanohydrin phase in the condensation might be detected in the case of



even the hydroxybenzaldehydes, if some substance were present in the solution with which the cyanohydrin might react to form a

stable product. Accordingly mixtures of hydroxybenzaldehydes with the corresponding phenols were warmed with potassium cyanide. In one case only was crystalline material isolated, thymolaldehyde and thymol giving a 12% yield of dithymylacetonitrile.

It might be anticipated that the yield of the nitrile would be considerably increased if the potassium cyanide were replaced by hydrogen cyanide. With this end in view hydrogen chloride was passed into a dry benzene solution of, *e.g.*, thymolaldehyde and thymol containing zinc cyanide in suspension. Only derivatives of triphenylmethane were obtained, and this result is interpreted as indicating that cyanohydrins are not formed under these experimental conditions. The readiness of condensation suggests that the hydrogen chloride forms an intermediate addition product with the aldehyde as shown in (*B*). If, however, an alcoholic

solution of equimolecular quantities of the aldehyde and phenol is treated with hydrogen cyanide and the mixture is heated to the boiling point after the addition of zinc chloride, three types of behaviour are shown.

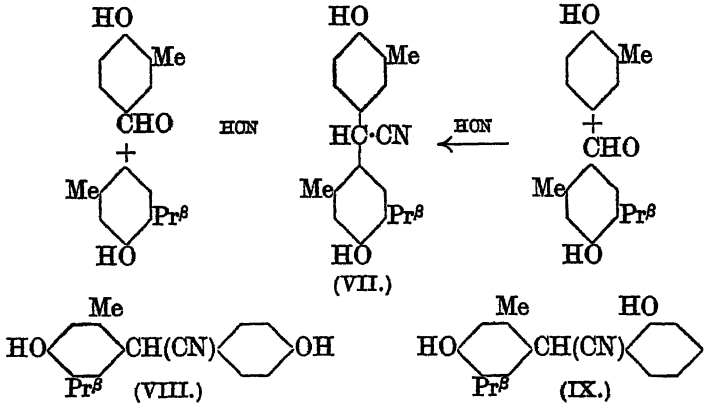


TABLE I.

(Behaviour of substituted benzaldehydes; CHO in position 1.)

A (produce nitriles).	B (produce triphenylmethane derivatives).	C (unreactive).
Me : Pr$^{\beta}$: OH = 2 : 5 : 4	Benzaldehyde.	NO_2 = 2
Me : Pr$^{\beta}$: OH = 5 : 2 : 4	Cl = 2 or 4	
Me : OH = 3 : 4	NO_2 = 3 or 4	
OH = 2 or 4	HO = 3	
OH : OH = 3 : 4		
OMe = 4		

(1) The aldehydes in column A (Table I) give the corresponding diarylacetonitriles, in some cases in quantitative yields. That it is the nuclear hydrogen atom para to the hydroxyl group in the phenol, which is involved in this condensation is clear from the fact that *o*-cresolaldehyde and thymol give the same product (VII) as thymolaldehyde and *o*-cresol. Even when the *o*- and *p*-positions are both equally accessible, as in phenol, condensation takes place

almost exclusively in the *p*-position, the product then formed being (VIII), and the isomeride (IX) could not be detected.

(2) On the other hand, benzaldehyde itself and its derivatives shown in column B (Table I) give triphenylmethane derivatives, and since the yield of these substances greatly exceeds that obtained when hydrogen cyanide is absent, it seems likely that reaction (II) is in operation in place of, or in addition to, reaction (I) :—

$$\text{(I)}\ \text{R·CHO} + \text{HR'·OH} \longrightarrow \text{R·CH(OH)·R'·OH} \xrightarrow{\text{HR'·OH}} \text{R·CH(R'·OH)}_2 + \text{H}_2\text{O}.$$

$$\text{(II)}\ \text{R·CH(OH)·CN} + \text{HR'·OH} \xrightarrow[-\text{HCN}]{} \text{R·CH(OH)·R'·OH}$$

o-Nitrobenzaldehyde is unique in so far as it is isolated from the reaction mixture in the form of its cyanohydrin, which is apparently very unreactive.

This variety of results is all the more remarkable since mandelic acid and mandelonitrile condense normally with a whole series of phenols (Bistrzycki and Flatau, *Ber.*, 1895, **28**, 989; 1897, **30**, 124; Bistrzycki and Simonis, *Ber.*, 1898, **31**, 2812; Cramer, *ibid.*, p. 2813; Simonis, *ibid.*, p. 2821). Considerable further investigation is required to determine the influence of (*a*) substituents and (*b*) physical conditions, *e.g.*, acidity of the solution, on the relative reactivity of the hydroxyl and cyano-groups of cyanohydrins. We have little doubt that the triphenylmethane formation indicates cyano-group reactivity, the intermediate diphenylmethane derivative undergoing further condensation under the experimental conditions, whereas nitrile formation indicates hydroxyl group reactivity (*C*).

$$\text{R·C(H)(OH)(R')} \xleftarrow[-\text{HCN}]{\text{HR'}} \text{R·C(H)(OH)(CN)} \xrightarrow[-\text{H}_2\text{O}]{\text{HR'}} \text{R·C(H)(R')(CN)} \quad . \quad . \quad (C)$$

The fact that the substituted nitriles do not undergo further con-

densation to triphenylmethane derivatives is only in line with the diminished reactivity of the cyano-group which is shown by its resistance to hydrolytic agents. It appears that the hydroxyl group by virtue of its lone pairs of electrons is a more ready electron source than the cyano-group and that when the nucleus of a cyanohydrin has a positive character the hydroxyl group will tend to become, relative to the cyano-group, less negative, and at the same time less reactive.

EXPERIMENTAL.

Thymolaldehydes and By-products.—Into an ice-cold, well-stirred mixture of thymol (50 g.), zinc cyanide (100 g.), and benzene (200 c.c.; distilled from phosphoric oxide), was passed a rapid stream of dry hydrogen chloride until it ceased to be absorbed. Aluminium chloride (75 g.) was then added and the stirring continued for 4 hours in a slow current of hydrogen chloride. Towards the end, the reaction bottle was kept immersed in water at about 50°. The semi-solid product was transferred into 10% hydrochloric acid and distilled in steam until thymolaldehyde appeared in the condenser. The residue left on the removal of the solvent from the benzene layer of the steam distillate was distilled in three fractions; the residue in the flask then set solid and proved to be *p*-thymolaldehyde (I). The first fraction, b. p. 60—80°/15 mm., consists mainly of *iso*propylbenzene and is occasionally negligible in amount (see below). The second (b. p. 100—110°/15 mm.) and third (b. p. 110—120°/15 mm.) fractions were dissolved in alcohol and treated with aqueous-alcoholic semicarbazide solution. The precipitate immediately given with fraction 2, after repeated extraction with boiling alcohol, formed a white powder, m. p. 262° (decomp.), which was identified as *m*-cresolaldehyde semicarbazone (Found: C, 55·1; H, 5·6; N, 21·3. Calc.: C, 56·0; H, 5·7; N, 21·8%) by hydrolysis in the following manner: A mixture of the substance (3 g.), sulphuric acid (10 c.c.), and water (50 c.c.) was heated to boiling and the resultant *m*-cresolaldehyde (VI) removed in a current of steam. It crystallised from petroleum in long needles, m. p. 63° (Found: C, 70·4, 70·3; H, 5·8, 6·0. Calc.: C, 70·6; H, 5·9%).

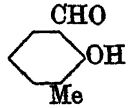
In the case of fraction 3 acicular crystals gradually separated and after repeated crystallisation from alcohol had m. p. 198° (Found: C, 61·5; H, 7·2; Sem., 31·4%). The semicarbazide group (Sem. = $N{\cdot}NH{\cdot}CO{\cdot}NH_2$) was estimated by the method of Veibel (*Bull. Soc. chim.*, 1927, **41**, 1410). This compound can only be the *semicarbazone* of 2-aldehydo-3-methyl-6-*iso*propylphenol (*o*-thymolaldehyde) (II) ($C_{12}H_{17}O_2N_3$ requires C, 61·3; H, 7·2; Sem., 31·1%).

The residue left after steam distillation was extracted with ether, and the extract evaporated. Two methods of purifying the crude

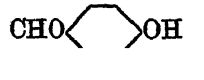
p-aldehyde (about 50 g.; identical with the yield obtained by Gattermann's original method, *Ber.*, 1898, **31**, 1765) were adopted: (1) extraction with 25% alcohol, a small crystalline residue, m. p. 205°, being finally obtained; (2) crystallisation from alcohol, the final low-melting crops being dissolved in chloroform and filtered from a small amount of the same substance, m. p. 205°, subsequently shown to be dithymylacetonitrile (see p. 2224). 4-Aldehydo-3-methyl-6-*iso*propylphenol (I) forms colourless needles, m. p. 135°; when aqueous-alcoholic semicarbazide solution is added to its alcoholic solution the slightly impure *semicarbazone* separates in deep yellow needles, m. p. 222° (Found: C, 60·6, 60·7; H, 7·3, 7·3%), which rapidly become colourless on recrystallisation from acetic acid or alcohol and melt at 226° (Found: C, 61·2; H, 7·3; Sem., 30·5. $C_{12}H_{17}O_2N_3$ requires C, 61·3; H, 7·2; Sem., 31·1%).

Attempts to convert *p*-thymolaldehyde into the corresponding dialdehyde by (*a*) the Adams and Montgomery method, (*b*) the Gattermann method were unsuccessful. This failure is not surprising in view of the highly substituted character of the ring, and also of the disinclination of hydrogen cyanide to attack the position ortho to a hydroxyl group. It may be mentioned that even *p*-cresol gives a very small yield of the aldehyde when submitted to the same treatment as produces a satisfactory yield from *o*-cresol (see below).

Action of Aluminium Chloride on Thymol.—As it was surmised that the formation of *iso*propylbenzene in the reaction just described was due to interaction of thymol and benzene in presence of aluminium chloride, a well-stirred mixture of thymol (25 g.), dry benzene (200 c.c.), and aluminium chloride (35 g.) was warmed at about 50° for 4 hours while a current of dry hydrogen chloride was passed in. The clear solution was poured into 10% hydrochloric acid and distilled in steam. The benzene layer of the steam distillate was separated and evaporated and the residue obtained was distilled in a vacuum, giving fractions b. p. 60°, 95—100°, 100—118°, and *ca.* 170°/15 mm. The low-boiling fraction (about 10 g.) was redistilled under ordinary pressure, and the fraction, b. p. 150—155°, redistilled from sodium. It then boiled constantly at 153° and agreed in properties with *iso*propylbenzene (Found: C, 90·3; H, 9·9. Calc.: C, 90·0; H, 10·0%). The fraction, b. p. 95—100°/15 mm., gave pure *m*-cresol, b. p. 200—202° (6 g.), which was identified as its *p*-nitrobenzoyl derivative. The higher-boiling fraction consisted of neutral substances, being apparently a mixture of *m*-tolyl ether and thymyl ether. When the above reaction was carried out in the presence of toluene a fraction, b. p. 65—75°/15 mm., was obtained which on redistillation had b. p. 175—180°, being slightly impure *p*-cymene.



Carvacrolaldehydes and By-products.—The preparation was effected as described for thymolaldehyde (see above). The steam distillate gave fractions, b. p. 60°, 100—110°, 110—120°, and 120—130°/15 mm., and a residue of the *p*-aldehyde, which could be sublimed at 150°/1 mm. The first fraction consisted of *iso*propylbenzene (see below). The remaining fractions were dissolved separately in alcohol and treated with aqueous-alcoholic semicarbazide solution. The fraction, b. p. 100—110°/15 mm., gave crude *o*-cresolaldehyde semicarbazone (compare thymol above), and from the fraction, b. p. 110—120°/15 mm., was isolated a trace of material which crystallised from pyridine or acetic acid in thick, pale yellow prisms, m. p. 275° (Found: C, 73·2; H, 7·9; N, 7·8%). It is suggested that this compound is the *semicarbazone* of 4-hydroxy-3-aldehydo-5-methyl-2-*iso*propylphenyldicarvacrylmethane (V) ($C_{33}H_{43}O_4N_3$ requires C, 72·7; H, 7·9; N, 7·7%) formed by the interaction of carvacrol and carvacroldialdehyde during the distillation. The fourth fraction, b. p. 120—130°/15 mm., gave more soluble material, which crystallised from aqueous alcohol in long glistening needles, m. p. 180° (Found: C, 61·3; H, 7·3; Sem., 31·5%), and must be the *semicarbazone* of 2-aldehydo-6-methyl-3-*iso*propylphenol (*o*-carvacrolaldehyde semicarbazone) ($C_{12}H_{17}O_2N_3$ requires C, 61·3; H, 7·2; Sem., 31·1%).



The ether-soluble portion of the residue left after steam distillation was repeatedly extracted by decantation with petroleum (b. p. 90—120°), which slowly removed the *p*-carvacrolaldehyde (30—40 g.) as colourless plates, m. p. 102°. With aqueous-alcoholic semicarbazide solution this yielded a slightly impure, deep yellow *semicarbazone*, m. p. 222° (Found: C, 60·8; H, 7·3%), which on crystallisation from acetic acid gave colourless needles, m. p. 224° (Found: Sem., 31·1. $C_{12}H_{17}O_2N_3$ requires C, 61·3; H, 7·2; Sem., 31·1%). The tar which remained after the complete removal of this aldehyde was moistened with alcohol and kept for several weeks. Crystals slowly formed, which after recrystallisation from aqueous alcohol had m. p. 240° and were subsequently shown to consist of dicarvacrylacetonitrile (see p. 2223).

Action of Aluminium Chloride on Carvacrol (compare corresponding experiment with thymol, p. 2220).—Fractions, b. p. 60° (11 g.), 100° (11 g.), and 102—115°/15 mm. (5 g.) were obtained. The residue, after being heated to 150°/1 mm., crystallised from petroleum in long thick needles, m. p. 148—150° (0·3 g.) (Found: C, 83·3, 83·7; H, 8·5, 8·8%). This substance was not obtained in sufficient quantity for identification. The low-boiling fraction was almost pure *iso*propylbenzene, and the intermediate fraction gave *o*-cresol, b. p. 188—190° (7 g.), identified as the *p*-nitrobenzoate.

Reimer–Tiemann Reaction with Carvacrol.—Carvacrol (20 g.), sodium hydroxide (40 g.), water (300 c.c.), and chloroform (25 g.) were used. The reaction mixture was acidified and distilled in steam. The distillate consisted of unchanged carvacrol and the *o*-aldehyde, isolated only as its semicarbazone (see above). The residue was purified as described above and gave a very small yield of the *p*-aldehyde, identical with that described above.

o-Cresolaldehydes.—Preparation as above, *o*-cresol (50 g.) being used in place of thymol. The steam distillate, freed from solvent, boiled at 85—90°/15 mm. (15 g.), leaving only a small residue of the *p*-aldehyde. To a solution of the fraction, b. p. 85—90°/15 mm., in alcohol (15 c.c.) was added aqueous-alcoholic semicarbazide solution. The resultant precipitate (3 g.) was repeatedly extracted with boiling alcohol; the residue then remained unchanged in m. p. (248°, decomp.) by crystallisation from pyridine, from which it separated in glistening needles. It was identified as the *semicarbazone* of 6-aldehydo-2-methylphenol (X) (Found: C, 55·5;

(X.) 

(XI.)

H, 5·8; N, 21·6; Sem., 38·5. $C_9H_{11}O_2N_3$ requires C, 56·0; H, 5·7; N, 21·8; Sem., 37·8%), by hydrolysis to the corresponding aldehyde, which was then converted into the known phenylhydrazone.

The ether-soluble portion of the residue left after steam distillation was extracted with boiling water until all the *p*-aldehyde (XI) (about 20 g.) had been removed, leaving an uncrystallisable tar. The *p*-aldehyde gave a *semicarbazone* crystallising from acetic acid in needles, m. p. 216° (Found: N, 21·8; Sem., 37·2. $C_9H_{11}O_2N_3$ requires N, 21·8; Sem., 37·8%).

Action of Potassium Cyanide on Hydroxybenzaldehydes.—(1) No crystalline material could be isolated from the gums obtained by the action of potassium cyanide on alcoholic solutions of salicylaldehyde, *p*-hydroxybenzaldehyde, or carvacrolaldehyde, either alone or when mixed with phenol or carvacrol respectively.

(2) Nine mixtures of thymolaldehyde, alone and with thymol, potassium cyanide and aqueous alcohol were heated under reflux for varying periods. In only one experiment (*a*) in which thymol was omitted was any yield of substance, m. p. 205°, obtained, and experiment (*b*) furnished the highest yield of the series.

(*a*) Thymolaldehyde (3·6 g.), alcohol (6 c.c.), potassium cyanide (1 g.), and water (2 c.c.) were mixed and heated at 100° for 1 hour. After 2 days the mixture was made acid and left for 10 days. The resultant tar was filtered off, and the residual solid crystallised from

alcohol. Yield, 0·25 g.; m. p. 205°. As this experiment could not be repeated, it is assumed that the thymolaldehyde used in the first instance must have contained thymol.

(*b*) Thymolaldehyde (18 g.), alcohol (60 c.c.), thymol (12 g.), potassium cyanide (6 g.), and water (12 c.c.) were mixed and heated at 100° for 20 hours. After 2 days concentrated hydrochloric acid (10 c.c.) was added, and after 2 days more the mixture was poured into water and extracted with ether. The ethereal extract was evaporated, and the dried residue extracted with hot chloroform. The insoluble matter (4·0 g.) had m. p. 205° (see below).

Thymolaldehyde and benzonitrile underwent no interaction when a concentrated alcoholic solution was boiled under reflux or allowed to stand for some days. In the hope of obtaining the compounds in better yields, the following experiments were tried. (1) Thymolaldehyde (10 g.), thymol (20 g.), zinc cyanide (20 g.), and dry benzene (200 c.c.) were well stirred while a slow stream of dry hydrogen chloride was passed in. The mixture was maintained at 40—60° for the last 2 hours. The highly coloured, viscous mass was transferred into 10% hydrochloric acid by the aid of a small bulk of boiling alcohol, and then distilled in steam. The tarry residue was extracted with ether, the extract evaporated, and the dried mass boiled with chloroform. The colourless residue (15 g., m. p. 276°) after crystallisation from aqueous alcohol formed prisms, m. p. 280° (Found: C, 80·2; H, 8·6%). This substance must be *trithymylmethane* ($C_{31}H_{40}O_3$ requires C, 80·8; H, 8·7%), a conclusion which was confirmed by the preparation of the acetyl derivative. The compound (2·5 g.) and acetic anhydride (15 c.c.) were heated under reflux for 2 hours. On cooling, the liquid filled with crystals of *triacetylthymylmethane*, which after recrystallisation from benzene–petroleum formed glistening leaflets, m. p. 186° (Found: Ac, 22·0. $C_{37}H_{46}O_6$ requires Ac, 22·0%).

(2) Carvacrolaldehyde (10 g.) and carvacrol (25 c.c.), treated as in (1), gave *tricarvacrylmethane*, m. p. 275° (Found: C, 80·8; H, 8·8%). The compound was acetylated as described above and yielded *triacetylcarvacrylmethane*, which after crystallisation from petroleum formed leaflets, m. p. 185° (Found: C, 76·1; H, 8·1. $C_{37}H_{46}O_6$ requires C, 75·8; H, 7·9%). Both compounds gave the customary large depression in melting point when mixed with the corresponding derivatives of thymol.

Little condensation occurs if the zinc cyanide is omitted in these experiments. Moreover the yield of triphenylmethane derivatives is considerably greater than when the experiment is conducted in alcoholic solution with hydrogen chloride or zinc chloride as condensing agent.

Action of Hydrogen Cyanide on Substituted Benzaldehydes.—General method. Dry hydrogen cyanide from potassium ferrocyanide (70 g.; method of Johnson and Lane, *J. Amer. Chem. Soc.*, 1921, **43**, 357) was passed into a solution of equimolecular proportions of the aldehyde (10 g.) and the phenol in absolute alcohol (50—100 c.c.). Zinc chloride (20—25 g.) was then added, the mixture boiled for 2 hours, and the solution poured into 10% hydrochloric acid. Excess of the reagents was removed in a current of steam, and the residual solid or plastic mass filtered off.

(1) Thymolaldehyde and thymol combined to give a quantitative yield of *dithymylacetonitrile*, which after recrystallisation from alcohol formed prismatic needles, m. p. 205° (Found: C, 78·4; 78·5; H, 8·2, 8·1; N, 4·3, 4·2. $C_{22}H_{27}O_2N$ requires C, 78·3; H, 8·0; N, 4·1%). No combination occurred when the zinc chloride was omitted.

Dithymylacetonitrile was not attacked by boiling hydrochloric acid or by sulphuric acid (50—65%), and higher concentrations produced resinous masses (compare Michael and Jeanprêtre, *Ber.*, 1892, **25**, 1615). Hydrolytic experiments with 3% hydrogen peroxide (Radziszewski, *Ber.*, 1885, **18**, 355) or 100% phosphoric acid (Berger and Olivier, *Rec. trav. chim.*, 1927, **46**, 600) were also unsuccessful. The substance (5 g.) was heated at 100° with potassium hydroxide (20 g.) in 90% alcohol (100 c.c.) for 10 hours. After standing 2 days, the solution was poured into 10% hydrochloric acid and the precipitated *dithymylacetamide* crystallised from alcohol. It formed a colourless, heavy crystalline powder, m. p. 243° (decomp.) (Found: C, 73·8; H, 8·2. $C_{22}H_{29}O_3N$ requires C, 74·4; H, 8·2%). *Diacetylthymylacetonitrile*, formed by heating dithymylacetonitrile (3 g.) with acetic anhydride (15 c.c.) and recrystallising the product from chloroform–petroleum, formed needles, m. p. 174° (Found: C, 74·3, 74·1; H, 7·5, 7·5; Ac, 20·4. $C_{26}H_{31}O_4N$ requires C, 74·1; H, 7·4; Ac, 20·4%). On hydrolysis with dilute alcoholic potassium hydroxide it regenerated dithymylacetonitrile, m. p. 205°.

(2) Carvacrolaldehyde and carvacrol, treated in like manner, gave a quantitative yield of *dicarvacrylacetonitrile*, which crystallised from aqueous alcohol in prisms, m. p. 240° (Found: C, 78·3; H, 8·2; N, 3·7. $C_{22}H_{27}O_2N$ requires C, 78·3; H, 8·0; N, 4·1%). *Diacetylcarvacrylacetonitrile* crystallised from alcohol in colourless needles, m. p. 196° (Found: C, 74·0; H, 7·6; N, 3·5. $C_{26}H_{31}O_4N$ requires C, 74·1; H, 7·4; N, 3·3%).

(3) Thymolaldehyde and carvacrol, or carvacrolaldehyde and thymol, gave *thymylcarvacrylacetonitrile*, which formed prisms, m. p. 227°, from alcohol (Found: C, 78·1; H, 8·3. $C_{22}H_{27}O_2N$ requires C, 78·3; H, 8·0%). It yielded a *diacetyl* derivative, m. p.

145° (Found: C, 73·7; H, 7·4. $C_{26}H_{31}O_4N$ requires C, 74·1; H, 7·4%).

(4) *o*-Cresolaldehyde and thymol, or thymolaldehyde and *o*-cresol, gave *tolylthymylacetonitrile* (VII), the first pair giving a quantitative and the second a 70% yield. It crystallised from aqueous alcohol in prisms, m. p. 153° (loss in weight on drying at 100° = 10·4%) (Found for dry substance: C, 77·1; H, 7·3. $C_{19}H_{21}O_2N$ requires C, 77·3, H, 7·1%). The substance (5 g.) was warmed with potassium hydroxide (20 g.) in 90% alcohol (100 c.c.) at 100° for 24 hours. The solution was poured into 10% hydrochloric acid and extracted with ether. The ethereal extract was shaken with dilute sodium carbonate solution, and the aqueous and ethereal layers were separated and well washed with ether and water respectively. The ethereal layer was evaporated, and the dried residue extracted with hot benzene. The residual *tolylthymylacetamide* crystallised from alcohol in prisms, m. p. 211° (Found: C, 72·6; H, 7·4; N, 4·7. $C_{19}H_{23}O_3N$ requires C, 72·9; H, 7·3; N, 4·5%). The aqueous layer was poured into 10% hydrochloric acid, and the resulting gum dried in a vacuous desiccator. After boiling with benzene, it formed a pale brown powder, m. p. 188°. It was free from nitrogen and must be crude *tolylthymylacetic acid* (Found: C, 71·2, 71·6, 71·2; H, 7·1, 7·2, 6·9. $C_{19}H_{22}O_4$ requires C, 72·6; H, 7·0%). *Acetyltolylacetylthymylacetonitrile* forms prisms, m. p. 131° (Found: Ac, 23·3. $C_{23}H_{25}O_4N$ requires Ac, 22·7%).

(5) *p*-Hydroxybenzaldehyde and thymol gave a brown resinous mass, which crystallised from chloroform in needles, m. p. 142°. Recrystallised from benzene, *p-hydroxyphenylthymylacetonitrile* (VIII) formed large prisms, which on drying at 110° lost 12·6% by weight and left a residue, m. p. 144° (Found: C, 76·3; H, 6·8. $C_{18}H_{19}O_2N$ requires C, 76·8; H, 6·8%). Phenol and thymolaldehyde gave an 80% yield of the same substance.

(6) Anisaldehyde (*p*-methoxybenzaldehyde) and thymol gave a thick oil, which was extracted with ether. The gum remaining after evaporation of the ether was dissolved in chloroform. After some days crystals separated, which were well washed with petroleum and repeatedly recrystallised from benzene, pure *anisylthymylacetonitrile* being obtained in 10% yield. It formed large prisms, m. p. 106° (Found: C, 77·6; H, 7·2. $C_{19}H_{21}O_2N$ requires C, 77·3; H, 7·1%).

(7) Salicylaldehyde and thymol gave a resin, which crystallised from chloroform in prisms, m. p. 142°, and when dried at 110° lost 18·9% by weight (Found, for dry substance: C, 76·6; H, 6·9. $C_{18}H_{19}O_2N$ requires C, 76·8; H, 6·8%). The yield of purified *o-hydroxyphenylthymylacetonitrile* (IX) was less than 50% of the theoretical.

(8) Protocatechualdehyde and thymol gave a gummy mass, which was extracted with benzene, and the product repeatedly crystallised from chloroform. *Catechylthymylacetonitrile* formed prisms, m. p. 147—149° (Found: N, 4·7. $C_{18}H_{19}O_3N$ requires N, 4·7%).

(9) Benzaldehyde and thymol gave a quantitative yield of phenyldithymylmethane, which crystallised in prisms, m. p. 167—168°, containing one molecule of alcohol (loss in weight at 110° = 10·5%; calc., 11%). This description agrees with that of Russanow (*Ber.*, 1889, **22**, 1947).

(10) *m*-Hydroxybenzaldehyde and thymol gave a poor yield of m-*hydroxyphenyldithymylmethane*, which crystallised from chloroform in prisms, m. p. 165° (Found: C, 80·5; H, 8·1. $C_{27}H_{32}O_3$ requires C, 80·2, H, 7·9%).

(11) *o*-Nitrobenzaldehyde and thymol gave a product, which crystallised from chloroform in needles, m. p. 95—97°, and proved to be *o*-nitrobenzaldehydecyanohydrin (Found: C, 54·1; H, 3·5. Calc.: C, 53·9%; H, 3·4%). The fact that this cyanohydrin survives the general method of treatment (see above) is remarkable. No different result was obtained when phenol was used in place of thymol.

(12) *m*-Nitrobenzaldehyde and thymol gave an almost quantitative yield of m-*nitrophenyldithymylmethane*, which crystallised readily from aqueous alcohol in prisms, m. p. 171° (Found: C, 74·7; H, 7·2. $C_{27}H_{31}O_4N$ requires C, 74·8; H, 7·2%).

(13) *p*-Nitrobenzaldehyde and thymol gave a tarry mass; this after several recrystallisations from benzene formed colourless needles, which became pale yellow on drying and then melted at 145° (loss in weight on drying, 20·9. $C_{27}H_{31}O_4N,1\frac{1}{2}C_6H_6$ requires loss, 21·2%) (Found for the residual p-*nitrophenyldithymylmethane*: C, 75·0; H, 7·2. $C_{27}H_{31}O_4N$ requires C, 74·8; H, 7·2%). The mother-liquor contained *p*-nitrobenzaldehydecyanohydrin.

(14) *p*-Chlorobenzaldehyde and thymol gave a quantitative yield of p-*chlorophenyldithymylmethane*, which crystallised from alcohol in prisms; these, dried at 110°, lost 15·0% by weight, and the residue melted at 156° (Found: C, 76·4; H, 7·3. $C_{27}H_{31}O_2Cl$ requires C, 76·7; H, 7·3%).

(15) *o*-Chlorobenzaldehyde and thymol gave a viscid mass, which, however, readily crystallised from aqueous alcohol to give an almost theoretical yield of o-*chlorophenyldithymylmethane*. Dried at 110°, this lost 16·6% by weight, and the residue melted at 138° (Found: C, 76·4; H, 7·2. $C_{27}H_{31}O_2Cl$ requires C, 76·7; H, 7·3%).

Since it might be suggested that when triphenylmethane formation occurs, combination takes place between the aldehyde and the

phenol before the hydrogen cyanide is introduced, the experiments with *m*-nitro- and *o*- and *p*-chloro-benzaldehydes were repeated, the thymol not being added until after the passage of the hydrogen cyanide. The experimental results were unaltered, and this is not surprising in face of the results of the following experiments.

(*a*) The experiment with *p*-chlorobenzaldehyde (14 above) was repeated, this time without the addition of zinc chloride. No combination occurred.

(*b*) *p*-Chlorobenzaldehyde (5 g.), thymol (10·7 g.), and zinc chloride (20 g.) in absolute alcohol (40 c.c.) were heated under reflux for 4 hours and then poured into 10% hydrochloric acid and the excess of the reagents was removed in steam. The residual crude *p*-chlorophenyldithymylmethane weighed 4 g. (25% yield).

(*c*) *m*-Nitrobenzaldehyde and thymol treated as in (*b*) gave crude *m*-nitrodithymylmethane in only 20% yield.

The authors desire to express their thanks for assistance in the experimental work to the late Mr. S. E. Pusey and to Mr. H. C. Clarke.

CCLXXXIX.—*Polyiodide Equilibrium in Aqueous and Salt Solutions.*

By JOHN STANLEY CARTER.

THERE is abundant evidence to show that the dissolution of iodine in solutions of iodides involves the formation of polyiodides, and that in dilute solutions the whole of the combined iodine is present as tri-iodide. Consequently, saturation of dilute solutions of iodides with iodine involves the establishment of the equilibrium $I' + I_2 \rightleftarrows I_3'$. When active masses are identified with actual concentrations the equilibrium expression is $K = [I'] \times [I_2]/[I_3']$. If the solutions are dilute, the concentration of free iodine may be assumed to be constant and equal to the solubility in the pure solvent.

The measurements now recorded have reference to the solubility of iodine at 25° in solutions of sodium iodide, the concentrations of which were varied between fairly wide limits, (*a*) pure water and (*b*) a $1{\cdot}698M_w$-sodium sulphate solution being used as solvents. The relevant data are in Tables I and II, all concentrations being expressed as mols. per 1000 g. of water, since this mode of expression has already been found satisfactory in correlating solubility measurements in aqueous and concentrated salt solutions (J., 1925, **127**,

2861). The solubility data have been utilised on the assumption that the only polyiodide present is the tri-iodide, and that the iodide and the tri-iodide have no influence on the solubility of iodine as such. The concentration of tri-iodide is then given by the difference between the observed solubility s and the solubility s_0 in the iodide-free solvent. The concentration of uncombined iodide is the difference between the initial concentration of iodide c and that of the tri-iodide. The last column gives the values of K. Iodide and polyiodide are assumed to be completely ionised in both media.

52·53	11·90	1·347	572·9	203·5	0·689

A consideration of the data shows that the value of K is not constant, the variation being such as to indicate that the tendency to form higher polyiodides (*e.g.*, pentaiodide) increases with increasing initial concentration of iodide. The value of K for the two series follows the same course, but changes relatively very slowly between $c = 0{\cdot}002$ and $0{\cdot}1$. It is in this region that the results are most suitable for correlating the two series of measurements, since in these dilute solutions practically the whole of the combined iodine may be assumed to be present as tri-iodide, and K should be constant. Actual constancy is, of course, not observed, but the magnitude of K is approximately the same in both series and the drift in the value is small. In view of the nature of the assumptions involved, this approximate agreement with the requirements of the mass-law equation is not unsatisfactory and supports the view that the relation between active masses and actual concentrations is much closer than would be anticipated from con-

siderations of the theory of activities. The value of the ratio $[I']/[I_3']$ is about 1·05 for the sulphate-free solutions and about 3·5 for the sulphate solutions. Apart from the fact that it indicates that the extent of polyiodide formation is greatly depressed in presence of sulphate, the difference between these values is also of interest from the point of view of the theory of activities. Although, in the absence of values for the activity coefficients concerned, it is impossible to make a quantitative prediction, a consideration of the ideas associated with the theory of activities leads to the conclusion that within this concentration range the value of this ratio should be practically independent of the presence of added salts.

Results in extremely dilute solutions are considerably influenced by small errors in the actual determination of the dissolved iodine, but it is considered that the observed effects are real.

Jakowkin (*Z. physikal. Chem.*, 1896, **20**, 19), Dawson (J., 1901, **79**, 238), and Pearce and Eversole (*J. Physical Chem.*, 1924, **28**, 245) have investigated the partition of iodine between solutions of iodides and an organic solvent and found that K is approximately constant for dilute solutions, but not for concentrated solutions. This is clearly shown by the data presented in Table III, which refer to the equilibria established when iodine is distributed between carbon tetrachloride and fairly concentrated solutions of sodium iodide; under C and W are recorded the concentrations of iodine (mols./1000 g. of solvent) in the carbon tetrachloride and aqueous phases, respectively, and under $[I_2]$ are tabulated the concentrations of the uncombined iodine in the aqueous layer, calculated from a knowledge of the distribution ratio. The last column contains the values of K computed on the assumption that the only polyiodide present is the tri-iodide.

The ratio in which iodine is distributed between water and carbon tetrachloride was first determined:

$C \times 10^3$ (approx.) ...	57	46	25	21	10
Partition ratio	54·8	54·2	53·5	53·6	53·2
				53·5	

A curve was then drawn from the data, the assumption being made that neither the iodide nor the polyiodide has any influence on the value of the distribution ratio: as the salting-out effect of the iodide ion is practically nil, this assumption is not unreasonable.

The values of K apparently tend towards constancy when the concentration of iodine is small. The data indicate the presence of polyiodides more complex than the tri-iodide in the more concentrated solutions.

Experimental.—Iodine, sodium sulphate, and carbon tetrachloride were purified by customary methods. The sodium iodide contained no impurity other than water. The usual precautions were taken in determining solubilities and distribution ratios.

My thanks are due to Professor H. M. Dawson for suggesting these experiments and for his criticism and advice.

UNIVERSITY OF LEEDS. [*Received, June 12th*, 1928.]

CCXC.—*The Laws of Aromatic Substitution. Part IX.*

By BERNHARD FLÜRSCHEIM and ERIC LEIGHTON HOLMES.

IN Part VIII (this vol., p. 1607), the *o*-, *p*-, and *m*-percentages produced by nitration of the complete series $C_6H_5\cdot C(R_1)(R_2)(R_3)$ (R_1 and R_2 = Cl,CO_2Et,H; R_3 = Cl,CO_2Et) have been accurately determined. The results have shown that a polar effect, which had long been recognised by one of us where *o*-substitution is concerned and had been postulated by Robinson also for the *m*- and *p*-positions, actually exists, and may be very pronounced, in *all* positions. At the same time, an alternating effect (quantitative factor "*q*"), as postulated by one of us (*e.g.*, $C_6H_5\cdots C(=)Cl$ and $C_6H_5—C(=)\cdots CO_2Et$), has been found to be superposed on the polar effect, tending in the above series to reverse the relative order in which the substituents would cause *m*-substitution if their polar effects were the only factor.

The present investigation has been extended to compounds wherein R_1 or R_1 and R_2 = CN and covers the following series:

$C_6H_5\cdot CH_2\cdot CN$;

$C_6H_5\cdot CHCl\cdot CN$, $C_6H_5\cdot CH(CO_2Et)\cdot CN$, $C_6H_5\cdot CH(CN)_2$, $C_6H_5\cdot CH(OH)\cdot CN$;

$C_6H_5\cdot C(CO_2Et)_2\cdot CN$, $C_6H_5\cdot C(CO_2Et)(CN)_2$;

also $C_6H_5\cdot CN$ and *m*-$NO_2\cdot C_6H_4\cdot N{:}CH\cdot C_6H_5$.

The new data are to be found in Table I. For comparison, the ratios of *m*- to *o*- + *p*-substitution determined in Part VIII are recapitulated in Table II.

Discussion of Results.

Application of the Theory of Varying Affinity Demand.—(1) *Relative polar effects of* Cl, CO_2Et, *and* CN. These can be ascertained (compare J., 1909, **95**, 726) from the influence on the dissociation constants of benzoic acid and aniline exercised by these substituents when they occupy the *m*- or *p*-positions. The steric effect from these

positions is negligible, and the alternating effect can be eliminated by averaging the changes in the dissociation constant which a substituent produces when it occupies the *m*-position on the one hand and the *p*-position on the other. It is at present uncertain whether the average change should be calculated by the arithmetical function, polar effect $= (K_m + K_p)/2K_u$, or by the geometrical function, polar effect $= \sqrt{K_m K_p}/K_u$, where K_m, K_p, and K_u are the constants for the *m*- and *p*-derivatives and for the unsubstituted acid (or base) respectively, but the choice of function does not affect the relative order of the polar effects of the above substituents. In connexion with these, the following constants are available:

	K.		*K*.
m-Chlorobenzoic acid	$1{\cdot}59 \times 10^{-4}$	Ethyl *p*-aminobenzoate	$2{\cdot}4 \times 10^{-12}$
p- „ „	$7{\cdot}8 \times 10^{-5}$	Methyl *p*-aminobenzoate	$2{\cdot}9 \times 10^{-12}$
Methyl hydrogen *iso*phthalate	$1{\cdot}28 \times 10^{-4}$	„ *m*-aminobenzoate	$4{\cdot}4 \times 10^{-11}$
m-Cyanobenzoic acid	$1{\cdot}99 \times 10^{-4}$	*m*-Chloroaniline	$3{\cdot}45 \times 10^{-11}$
Benzoic acid	$6{\cdot}0 \times 10^{-5}$	*p*- „	$9{\cdot}9 \times 10^{-11}$
		Aniline	$4{\cdot}6 \times 10^{-10}$

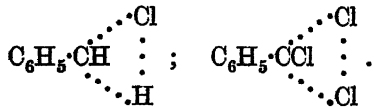
The constants for ethyl and methyl *p*-aminobenzoate show that ethyl has a slightly greater effect than methyl; and a comparison of methyl *p*- and *m*-aminobenzoates, also of *p*- and *m*-nitrobenzoic acids and of *p*- and *m*-nitroanilines, proves that the effect of *m*-directive substituents is greater in the *p*- than in the *m*-position. Taking this into account, the following polar effects are obtained:

	On benzoic acid.		On aniline.	
	Arithmetical mean.	Geometrical mean.	Arithmetical mean.	Geometrical mean.
m- and *p*-Cl	1·975	1·87	0·145	0·13
m- and *p*-CO_2Me	>2·13	>2·13	0·05	0·025
m- and *p*-CO_2Et	>2·13	>2·13	<0·05	<0·025
m- and *p*-CN	>3·32	>3·32	—	—

The sequence of "negative" polarity is therefore, quite conclusively, CN>CO_2Et>Cl, in so far as the effect on the benzene ring is concerned.

(2) *Relative alternating* ("*quantitative*") *effects of* Cl, CO_2Et, *and* CN. The affinity demand of methyl-carbon is approximately equal to that of hydrogen, but when it is linked to an atom with higher affinity demand (*e.g.*, in toluene), then an equilibrium is established resulting in an affinity content of the bond between the two which is somewhat greater than in a bond between hydrogen and either of the two atoms; for instance, $C_6H_5{-}\dot{C}\cdot\cdot H\cdot\cdot$ (compare *Chem. and Ind.*, 1925, **44**, 249, and previous papers). Chlorine has a moderate affinity demand, intermediate between those of hydrogen and hydroxyl; when it is attached to an α-methyl carbon atom, it

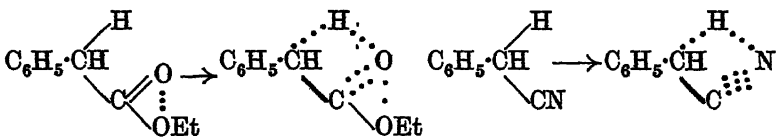
therefore reduces the affinity content of the bond between the latter and the nuclear carbon atom, but only very *moderately* (see below). Conversely, CO_2Et has an affinity demand only slightly inferior to that of hydrogen (see below); when CO_2Et is attached to α-methyl carbon, the affinity content of the bond between the latter and nuclear carbon is therefore *slightly* raised. Since affinity demand is at its maximum in tervalent nitrogen, the bond between CN and α-methyl carbon has a lower affinity content than the corresponding bonds in either of the other cases, and the affinity content of the bond between methyl and nuclear carbon is correspondingly higher.



(3) *Resulting directive effects of* Cl, CO_2Et, *and* CN. It follows that the polar factor should cause *m*-substitution in the order $C_6H_5\cdot CH_2\cdot CN > C_6H_5\cdot CH_2\cdot CO_2Et > C_6H_5\cdot CH_2Cl$, and the quantitative factor in the reverse order. In accordance with this, the degree of *m*-substitution has been found to be practically identical in all three cases. On the other hand, when the above substituents are directly attached to the nucleus, *both* factors cause *m*-substitution in the order $C_6H_5\cdot CN > C_6H_5\cdot CO_2Et > C_6H_5Cl$. For the last two compounds this sequence is, of course, a commonplace, but it has now been definitely proved to hold equally for benzonitrile, for which the value obtained by Baker, Cooper, and Ingold (*loc. cit.*) was found to be too low.

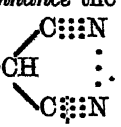
(4) *The effects of lateral subsidiary bonds.* A suggestion due to Brühl (*Ber.*, 1907, **40**, 897; compare also Smedley, J., 1909, **95**, 232), according to which there is an exchange of residual affinity (subsidiary bond) between the oxygen atoms of a carboxyl group, appears to have found general acceptance. It explains why the two oxygen atoms in ethyl benzoate—although bivalent and therefore possessed of a marked affinity demand—are barely able to reduce the affinity content of the bond between α- and nuclear carbon to a level below the content of the hydrogen bond in benzene, as shown by the fact that ethyl benzoate still yields about 30% of *o*-, *p*-nitro-derivatives, notwithstanding that its *m*-substitution is also favoured by the polar effect. Brühl's conception, already extended by Smedley (*loc. cit.*) to a subsidiary N–O bond in amides, must logically apply to all cases where two (or more) atoms possess appreciable amounts of residual affinity,* provided, of course, that the partial mutual saturation is not prevented by the spatial factor (distance). The idea explains, for instance, why tellurium hexafluoride is so much less stable than sulphur hexafluoride, since the

* The effect of such residual bonds on aromatic substitution was first recognised in connexion with the lowering of the affinity demand of NH_2 and OH brought about by acetylation (Flürscheim, J., 1909, **95**, 726, footnote).



greater distance between the fluorine atoms in the former, due to the greater size of the central atom, involves a lower affinity content in the residual bonds between them. When residual bonds between atoms forming part of α-substituents in toluene are considered in relation to their effects on affinity distribution (and thereby on substitution), it becomes necessary to distinguish between three distinct cases:

(*a*) Cases where residual bonds *lower* the total affinity demand on the α-carbon atom, *e.g.*,



The formulæ show immediately why the alternating effect of the α-chlorine atom is substantially less marked than in the case of nuclear chlorine. Even three α-chlorine atoms can only produce preponderating, but nothing like exclusive, *m*-substitution.

(*b*) Cases where residual bonds *do not affect* the total affinity demand on the α-carbon atom, *e.g.*,

It is seen that in the measure in which the content of the bond between the α-carbon atom and another atom is reduced (broken lines) the affinity content of the bond between the α-carbon and a third atom is increased (thick lines) by the formation of a residual bond.

(*c*) Cases where residual bonds *enhance* the total affinity demand on the α-carbon atom; *e.g.*, 

The observation that, whereas nitration of $C_6H_5 \cdot CH_2 \cdot CN$ and $C_6H_5 \cdot CH_2 \cdot CO_2Et$ yields practically the same $m/(o+p)$-ratio, $C_6H_5 \cdot CH(CN)_2$ and $C_6H_5 \cdot CH(CO_2Et)_2$ yield, respectively, ratios of 211·8% and 34·05%, is at first sight puzzling, but is now seen to be a necessary consequence of the theory. The residual bond is here N . . . N and not N . . . H, since the tervalent nitrogen has a much greater residual affinity than the hydrogen atom. Bivalent oxygen has, *ceteris paribus*, always less residual affinity than tervalent nitrogen, and when the carboxyl is compared with the cyano-group, this difference is accentuated by the residual neutralisation of

affinity *within* the former group. In $C_6H_5 \cdot CH(CO_2Et)_2$ a residual bond between the two carboxyl groups can therefore not have a marked effect; but in $C_6H_5 \cdot CH(CN)(CO_2Et)$, where a nitrogen atom tends to saturate its residual affinity, the equilibrium principle postulates a more pronounced effect than in the dicarbethoxy-compound, although to a smaller degree than in the dinitrile, and the observed ratio (59·2) is in accordance with this.

It might be thought that the high *m*-ratio from the dinitrile could be due to a primary replacement of the mobile α-hydrogen atom by NO_2, with subsequent migration of the latter into the *m*-position. This possibility has been excluded by nitration of $C_6H_5 \cdot C(CN)_2(CO_2Et)$, resulting in a *m*-ratio of 698·4. This compound and $C_6H_5 \cdot C(CN)(CO_2Et)_2$, both new compounds, constitute two further cases of the examination of directive effects in toluene derivatives in which *all* the α-hydrogen atoms are replaced by substituents which, in direct linking with the nucleus, would be *m*-directive, the first such case investigated having been the nitration of $C_6H_5 \cdot C(CO_2Et)_3$, described in Part VIII.

(5) *Directive effect of* R·N=. It appeared desirable to examine the directive effect of an α-substituent which, in contrast to those already discussed, would combine *weak polarity* with a *high affinity demand*. Such a substituent is to be found in benzylidene-*m*-nitroaniline, which, unlike benzylamine, would even in concentrated acid preserve its nitrogen chiefly in the tervalent state and would not, in contrast to acetylbenzylamine, have the residual affinity of its nitrogen largely neutralised by a subsidiary bond. The group R·N= would obviously exercise a smaller polar effect than O=; if, notwithstanding this, the *m*-ratio were found to be higher for benzylidene-*m*-nitroaniline than for benzaldehyde, the expected effect of the postulated higher affinity demand of tervalent nitrogen would be established. Benzaldehyde, according to Brady and Harris (J., 1923, **123**, 484), in mixed acid yields 81% of *m*-nitro-derivative [$m/(o + p) = 426{\cdot}3\%$], a value with which our own determinations [78·65% *m*-nitration; $m/(o + p) = 368{\cdot}4\%$] are in good agreement, allowing for the difference of method. Schwalbe (*Z. Farb. Textilchem.*, 1902, **1**, 628) obtained essentially *m*-nitrobenzaldehyde from benzylidene-*m*-nitroaniline in mixed acid, but he neither determined the proportions of the isomerides formed, nor showed whether or not hydrolysis to the aldehyde *preceded* nitration.

Our own experiments prove that in the absence of hydrolysis, in a still stronger acid than Schwalbe's, the *m*-percentage 87·5 [$m/(o + p) = 703\%$] is obtained (nitration No. 13); that the compound during nitration is largely present as the *free* anhydro-base,

as shown by the intensely yellow colour of its solution in concentrated sulphuric acid, compared with its colourless *hydrochloride* obtained by precipitating the base with dry hydrogen chloride; and that the high *m*-ratio is not attributable to nitration of the *m*-directive cation (compare Part V) of the sulphate of the anhydro-base. This last fact was established by testing the effect of added ammonium sulphate on the *m*-ratio, since *m*-nitration of the cation would thereby be appreciably reduced by what Pollard and Robinson (J., 1927, 2770) have named the "Flürscheim effect." A comparison of nitrations Nos. 13 and 14 with Nos. 7 and 8 of Part V (J., 1926, 1569) shows that in the present case, notwithstanding a slightly higher concentration of ammonium sulphate, this effect is very much less marked than with diethylbenzylamine. This is what would be expected since, on the basis of *any* theory, even that relatively small portion of the very weak base benzylidene-*m*-nitroaniline which may be present as salt will be less *m*-directive (according to us, less electrolytically dissociated) than the diethylbenzylammonium salt, and since even the latter, at similar concentration, is chiefly *o*-, *p*-directive. Obviously, the presence of any benzylidene-*m*-nitroaniline as sulphate would therefore *lower* the *m*-ratio, and the value for the latter found in nitration No. 14 must be regarded as a lower limit for the free anhydro-base. *The greater affinity demand of nitrogen in this compound thus clearly outweighs the higher polarity of oxygen in benzaldehyde.*

Conclusion.

The theory of varying affinity demand, relying on one single mechanism, provides a consistent interpretation of our observations. When we examine the results recorded in this paper in the light of the electronic theory of valency, we find that our remarks in Part VIII (this vol., p. 1609, last sentence of section 3) appear to apply with even greater force. It is, however, by considering the effect of substituents on *equilibria* (electrolytic and thermal dissociation) that we hope to obtain a clear-cut decision between these ideas, since the effect of a passing phase (conjugation) on a permanent equilibrium must be negligible, so that one of the two alternative electronic mechanisms can be eliminated.

EXPERIMENTAL.

Preparation of Materials.—(*a*) *Ethyl phenylcyanomalonate.* 15 G. of ethyl phenylacetate and 1·5 g. of sodium wire in 50 c.c. of dry ether were left over-night, and 10 c.c. of ethyl chloroformate were then added. On shaking, the white crystalline sodium salt gradually changed to a jelly-like mass. After the suspension had been shaken

for 7 hours and kept over-night, water was added, and the ethereal layer dried and distilled; 15 g. of a thick oil were obtained which, on redistillation, boiled at 140—141°/1 mm. (Found: C, 64·4; H, 5·8; N, 5·3. $C_{14}H_{15}O_4N$ requires C, 64·4; H, 5·8; N, 5·4%).

(*b*) *Ethyl phenyldicyanoacetate.* 4 G. of phenylmalonitrile and 0·8 g. of sodium in 75 c.c. of dry absolute ether were left for 20 hours. Evolution of hydrogen was slow. After filtration, the white sodium salt was separated mechanically from unchanged sodium, introduced into 40 c.c. of sodium-dried benzene, and 5 c.c. of ethyl chloroformate were added. After 7 hours' shaking and standing over-night, a gelatinous mass had formed. The whole was then shaken with water, the benzene layer separated, and the benzene removed at reduced pressure. On recrystallising the residue from alcohol, 4·9 g., m. p. 58—59°, were obtained, showing after further recrystallisation the constant m. p. 60° (mixed m. p. depression with phenylmalononitrile) (Found: C, 67·2; H, 4·9; N, 13·3. $C_{12}H_{10}O_2N_2$ requires C, 67·3; H, 4·7; N, 13·1%).

(*c*) Phenylmalononitrile was prepared according to Hessler (*Amer. Chem. J.*, 1904, **32**, 119), who obtained it from dilute alcohol with m. p. 68—69°. By using absolute alcohol, we found m. p. 70—71°. Benzylidene-*m*-nitroaniline had m. p. 72·5—73°; benzyl cyanide, b. p. 229—230°; benzonitrile, b. p. 190—191°; mandelonitrile solidified at 5°, m. p. 13° (clear); ethyl phenylcyanoacetate, b. p. 125—126°/1 mm.; α-chlorobenzyl cyanide, b. p. 135—136°/40 mm.

Methods.—(*a*) *Nitration.* The experimental conditions and yields for each nitration are given in Table III. Apart from the nitrations of benzylidene-*m*-nitroaniline (see below), where hydrolysis on subsequent dilution withdrew most of the aniline portion of the anhydro-base from the weighings, the yields were excellent in all cases.

(*b*) *Determination of the isomerides.* Oxidation of the products of nitration to the acids was carried out as described in Part VIII. Ethyl phenylcyanomalonate, however, like ethyl phenylmethanetricarboxylate, had to be treated differently (see below). Our remark (this vol., p. 449) that our modification of the permanganate method had not failed in a single instance must therefore, in the light of our subsequent experience, be qualified in the sense that compounds which—owing to steric inhibition—are exceptionally resistant to lateral oxidation are prone to nuclear destruction by permanganate. It appears that, in such cases, Baker and Ingold's modification of the nitric acid method, *followed* by the application of our modification of the permanganate method, gives trustworthy results. The composition of the acids obtained was in all cases determined by our method described in Part VI.

Details of Nitrations.—The conditions and actual weighings in connexion with the nitrations are to be found in Table III, in which the numbers in column 1 correspond with those in column 1 of Table I. The following additional information appears desirable.

Benzonitrile (No. 1). By pouring the nitration product on ice, 11·521 g. of precipitate, m. p. 108—111°, were obtained, and by extracting the filtrate with ether a further 1·621 g. were recovered which solidified on standing. By recrystallising the 11·521 g. twice from water, 8·440 g. of pure *m*-nitrobenzonitrile (m. p. 117·5°) were obtained. The mother-liquors together with the above 1·621 g. were in this case not oxidised, but hydrolysed to the acids by boiling 1 part for 8 hours with 9 parts of 15% hydrochloric acid, and completing the hydrolysis by boiling with 0·15 part of permanganate and a little potassium hydroxide in 15 parts of water for 1½ hours.

Ethyl phenylcyanoacetate (No. 3). Nitration in acetic anhydride reduced the *m*-percentage in this case as in phenylmalononitrile, but not nearly to the same extent, no doubt on account of the less pronounced reactivity of the side-chain. Two nitrations in acetic anhydride (one shown in parentheses) gave, from 1·000 (0·700) g. of oxidation acids, 1·000 (0·865) g. of tribromoaniline and 0·640 (0·514) g. of tribromoaminobenzoic acid.

Phenylmalonitrile (Nos. 4—6). That nuclear nitration was practically complete, followed from the results of the reduction and bromination of the acids. To eliminate the possibility that the high *m*-percentage might in part have been due to another nitro-group having become attached to the α-carbon atom prior to nuclear nitration, experiment No. 4 was repeated and the freshly prepared nitration *product* brought to constant weight in a vacuum over caustic potash (Found: C, 56·5; H, 2·6. $C_9H_5O_2N_3$ requires C, 57·7; H, 2·7%). The product therefore contained only *one* nitro-group. In nitrations Nos. 5 and 6, the product of nitration was extracted with benzene before being extracted with ether as usual. The upper figures in the column headed "Yield" in Table III are the weights of the benzene extracts, the lower figures being those of the ether extracts for these two nitrations. Nitration of phenylmalononitrile in the presence of acetic anhydride appeared to be preceded by some side-chain reaction, since the preponderating *m*-nitration observed in its absence was completely reversed. Thus 7·9 g. of phenylmalononitrile in 7·9 c.c. of acetic anhydride, to which a mixture of 8 g. of acetic anhydride and 8 g. of nitric acid (*d* 1·52) was added at 15—20° during 20 minutes, with subsequent standing for 30 minutes, yielded 10·35 g. of a whitish, solid mass. This gave the following results on oxidation (those of a second oxidation are added in parentheses): 2·14 (2·45) g. of nitration product gave 1·123

(1·325) g. of acids; 1·000 (1·000) g. of these gave 0·203 (0·193) g. of benzoic acid, 1·392 (1·412) g. of tribromoaniline, and 0·102 (0·110) g. of tribromo-*m*-aminobenzoic acid, thus indicating almost exclusive *o*-, *p*-substitution.

Ethyl phenylcyanomalonate (No. 7). On adding this substance to the nitrating acid, a pale red colour was produced, which gradually changed to green. Oxidation by permanganate yielded only 0·2 g. of acids from 2·3 g. of nitration product, but when 3·775 g. of the latter were boiled for 4 hours with 40 c.c. of nitric acid (*d* 1·125) and then successively with 2 g. and 1 g. of permanganate, a yield of 1·348 g. of acids (nearly 70% of the theoretical) was obtained.

Ethyl phenyldicyanoacetate (No. 8). A cyano-group being smaller than a carbethoxyl group, oxidation by permanganate succeeded in this case, but the yields were still not quite as good as usual. The nitration product, *ethyl* m-*nitrophenyldicyanoacetate*, a pale yellow solid, gave a deep red colour in alcohol, and in dilute acetone. It crystallised from alcohol in white crystals, m. p. 130—133·5°, from chloroform with m. p. 133—134·5°, and from benzene with m. p. 132—134°. In all three cases the fused specimens were *red*, and lost this colour on solidification; they were soluble in cold alcohol or acetone with a strong reddish-orange colour, which deepened on adding water, but the solution in benzene or chloroform was colourless (Found: N, 16·68. $C_{12}H_9O_4N_3$ requires N, 16·22%).

α-Chlorobenzyl cyanide (Nos. 9 and 10). Nitration in acetic anhydride at 15° only took place to the extent of about 1·5%. Since, moreover, other α-cyano-compounds behaved abnormally in this medium, it became necessary to operate in nitric acid (*d* 1·52) alone, although appreciable hydrolysis could not be avoided. In No. 9 the spent acid gave 1·2401 g. AgCl, corresponding to 16·9% of hydrolysis, and in No. 10, where exposure to the acid was shorter, 0·3306 g. AgCl (hydrolysis = 10·0%). The calculated *m*-figures (marked ‡) in Table I have therefore been based on No. 10 alone. Since No. 9, with greater hydrolysis, gave a higher *m*-percentage than No. 10, whereas mandelonitrile yielded a lower *m*-percentage than No. 10, it is obvious that a product other than mandelonitrile is initially formed by hydrolysis, and nitrated. This can only be mandelonitrile nitrate. This result is entirely in agreement with the high *m*-percentage observed in the nitration of benzyl bromide in nitric acid alone (see Part VIII); in this case benzyl nitrate must have been the initial product of hydrolysis, since benzyl alcohol would obviously lead to even less *m*-derivative than mandelonitrile. On adding α-chlorobenzyl cyanide to nitric acid, a red colour was observed, which disappeared on shaking.

Benzylidene-m-*nitroaniline* (Nos. 12, 13, and 14). The yields

given in Table III were obtained by pouring the acid, without cooling, into water in order to hydrolyse most of the anhydro-base and leave the aniline portion in solution. The aldehyde portion was extracted with benzene. The fact that no appreciable hydrolysis occurred during nitration, even in No. 12 where only 4% SO_3 was present as against 5% in Nos. 13 and 14, was proved by pouring exactly one-half of the acid from No. 12 on a mixture of ice and excess of bicarbonate, whereupon 7·044 g., m. p. 142—143°, were precipitated. From 1 g. of this ochre-coloured product, recrystallised from petrol (b. p. 100—120°), 0·710 g. of almost pure *m*-nitrobenzylidene-*m*-nitroaniline, m. p. 148—154°, mixed m. p. higher, was obtained. A synthetic sample prepared by us had m. p. 160° (literature 153°). The yield given in No. 12 is double the amount recovered from the remaining half of the acid by pouring it into water. The proportion of nitric acid used in Nos. 13 and 14 was only one-half of that in No. 12. That no appreciable portion of the anhydro-base would be sulphonated in our conditions appeared probable from the stringent conditions which Schwalbe (*loc. cit.*) had to resort to for its sulphonation. We have confirmed this by leaving the base (5·5 g.) in 5% oleum (30 g.) for 2 hours at room temperature, then pouring it into 50 c.c. of water, whereby 2·313 g. of benzaldehyde were recovered.

In order to prove that the tendency to salt formation in benzylidene-*m*-nitroaniline is even less than in *m*-nitroaniline (which in turn is already millions of times weaker than diethylbenzylamine, the salt solution of which is still chiefly *o*-, *p*-directive under similar conditions), a comparison was made of the relative thermal stabilities of the *hydrochloride* of benzylidene-*m*-nitroaniline with that of *m*-nitroaniline. The former salt was obtained by passing dry hydrogen chloride through a solution of 1 g. of the base in 30 c.c. of dry benzene, and keeping the filtered salt for 48 hours in a desiccator over potassium hydroxide [Found : Cl (Carius), 13·5. $C_{13}H_{11}O_2N_2Cl$ requires Cl, 13·5%]; this salt is colourless. Carbon dioxide (purified by passage successively through water, silver nitrate solution, and concentrated sulphuric acid) was passed through flasks containing the two hydrochlorides, which were immersed side by side in an oil-bath. Until the temperature of the bath reached 110° no silver chloride was deposited in 2 hours in silver nitrate solutions through which the carbon dioxide passed on leaving the flasks. At 120° the benzylidene-*m*-nitroaniline salt began to give off hydrogen chloride, whereas the *m*-nitroaniline hydrochloride was still stable at 145°, and only began to yield a deposit at 150°. The anhydro-base could be recovered mostly unchanged by shaking 0·200 g. of the salt with benzene and potassium bicarbonate solution until

everything was dissolved. The dried benzene solution left 0·174 g. of the base (m. p. 55—57·5°, mixed m. p. 57—59·5°).

We desire to express our indebtedness to the Advisory Council of the Department of Scientific Research, and to the Government Grant Committee of the Royal Society, for grants to one of us (E. L. H.); also to Sir W. H. Bragg and the Royal Institution, who have placed at our disposal the facilities of the Davy Faraday Laboratory, where the work was carried out.

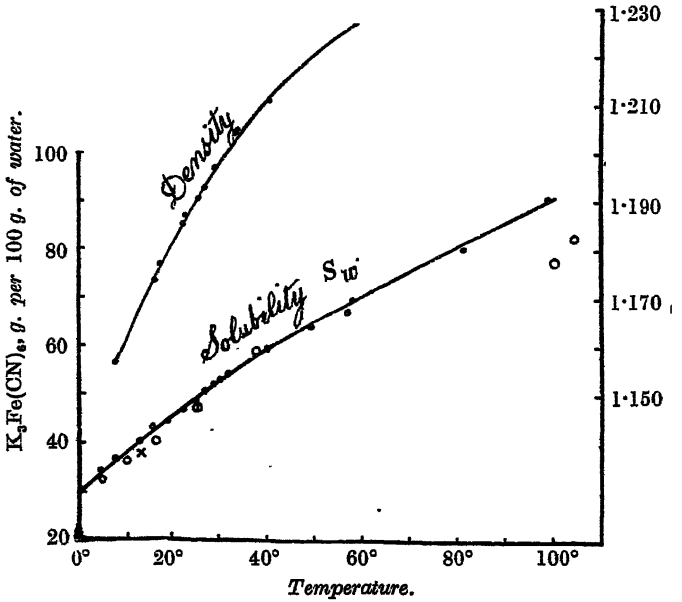
[*Received, June 22nd,* 1928.]

CCXCI.—*The Solubility of Potassium Ferricyanide in Water between* 0° *and* 100°.

By JOHN ALBERT NEWTON FRIEND and WILLIAM NELSON SMIRLES.

VALLANCE (J., 1927, 1328) found a break in the solubility curve of potassium ferrocyanide in water at approximately 18°. This did not appear to be connected with any change in hydration of the solid phase, and is of particular interest in view of the long-admitted possibility of the existence of two stereoisomeric forms of the salt (Briggs, J., 1911, **99**, 1019; 1920, **117**, 1026; Bennett, 1917, **111**, 490).

When the solubility curve of potassium ferricyanide is drawn from the six results of Wallace (J., 1855, **7**, 80) and the one datum of Schiff (*Annalen*, 1860, **113**, 150) for 13°, a break would appear to occur between 20° and 40°. The solution-density curve likewise suggests a break. In view of the alleged isomerism of the salt (Locke and Edwards, *Amer. Chem.* J., 1899, **21**, 193, 413; but see Bellucci and Sabatini, *Atti R. Accad. Lincei*, 1911, **20**, 1; Piutti, *Ber.*, 1912, **45**, 1830; Hauser and Biesalski, *Ber.*, 1912, **45**, 2516; Wells, *Amer. Chem. J.*, 1913, **49**, 205; Briggs, J., 1920, **117**, 1026), a further investigation of this point appeared to be desirable.



EXPERIMENTAL.

Pure potassium ferricyanide was recrystallised, and its iron content was estimated by decomposing about 0·5 g. with concentrated sulphuric acid in a platinum dish, heating until the colour that developed had disappeared, adding a small quantity of concentrated nitric acid, and again heating until sulphuric acid fumes were freely evolved. After cooling, the residue was dissolved in dilute hydrochloric acid, diluted to approximately 400 c.c., and the ferric hydroxide precipitated with ammonia, filtered, re-dissolved, repre-

cipitated, ignited, and weighed [Found: Fe, (i) 17·08, (ii) 17·01. Calc.: Fe, 16·96%].

Determination of Solubility.—The method employed in preparing a saturated solution was similar to that described by Lumsden (J., 1902, **81**, 350). The solution was stirred continuously in contact with the finely crushed salt for about 6 hours, a portion being withdrawn by suction from the saturation bottle through glass wool into a receiving flask, the usual precautions for submersion

FIG. 1.

Solubility and density curves of $K_3Fe(CN)_6$.

○ Wallace's data.

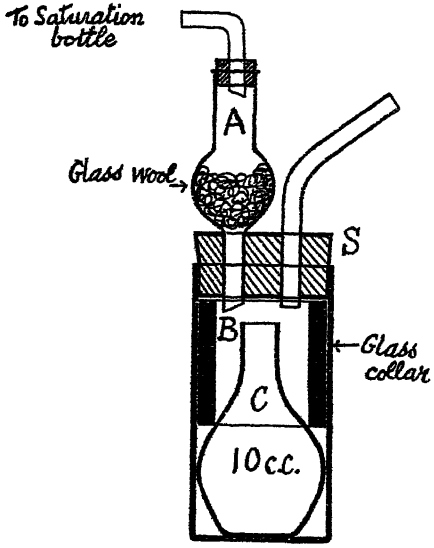
① Grube's result (*Z. Elektrochem.*, 1914, **20**, 342).



in the thermostat being observed to ensure complete uniformity of temperature. A measured volume of the filtered solution was diluted to 250 c.c., and 25 c.c. were evaporated to dryness; from the iron content, determined as indicated above, the amount of ferricyanide was calculated.

The results are given in Fig. 1 and Table I, where S_w and S_s represent g. of anhydrous salt per 100 g. of water and of solution respectively.

Determination of Density.—For the determination of the density of the saturated solution, the apparatus shown in Fig. 2 was attached to the saturation bottle, and the liquid sucked over. The apparatus

consisted of a 10 c.c. glass density bottle, C, standing inside a closely fitting cylindrical bottle, and kept in position either with a glass rod through the rubber stopper S, or by a loose glass collar as shown in the figure. The volume of C and its variation with temperature had previously been ascertained. The end B of the filter tube A was adjusted not to pour direct into C but outside it, and then to flow into it as the containing bottle filled up. The rubber stopper was now removed, and the glass stopper inserted in the density bottle, which was then washed and set aside to cool, being covered with a small tube to prevent evaporation through the capillary.

FIG. 2.

After a density determination the solution was frequently used for a solubility determination so that both data were obtained from the one sample. The results (in air) are given in Table I.

TABLE I.

25·3	—	—	1·1905	99·0	90·83	47·60	
26·3	50·74	33·66	1·1928				

Discussion.—The density and solubility data (S_w) are shown in Fig. 1. The curves are regular, giving no indication of a break. The solubility curve conforms to the equation

$$S_w = 30{\cdot}4 + 0{\cdot}80t - 0{\cdot}0020t^2.$$

With the exception of the value at 37·8°, Wallace's figures are lower than ours, particularly that at 100°, probably owing to the fact that he

estimated his ferricyanide volumetrically by reduction with stannous chloride, a method that is less accurate than the gravimetric. The very low results at 100° and above may possibly be in part due to hydrolysis. Even warm solutions smell of hydrocyanic acid, and at 100° the odour is very marked. Hydrolysis would be likely to affect the volumetric method more seriously than the gravimetric. In order to reduce the disturbing effect of any such change we were careful to use fresh solutions for each of our determinations. Schiff's result is a little low. Grube states that one litre saturated at 25° contains 385·5 g. of salt, and if our mean value (1·1905) be adopted for the density at this temperature, S_w is 47·89, a value slightly lower than ours, *viz.*, 48·80.

CCXCII.—*Lithium Sulphite and some Derivatives.*

By JOHN ALBERT NEWTON FRIEND and DONALD WHITWORTH POUNDER.

PUBLISHED data concerning lithium sulphite are both scanty and unsatisfactory. Danson (J., 1848, **2**, 207) appears to have been the first to prepare the hydrated salt. He passed sulphur dioxide into an aqueous suspension of lithium carbonate until a colourless solution was obtained, and precipitated the hydrated sulphite either by addition of alcohol or by boiling to expel excess of sulphur dioxide. He noticed its ready oxidisability.

Apparently the only other investigator was Röhrig (*J. pr. Chem.*, 1888, **37**, 225), who believed he had isolated both a mono- and di-hydrate, the former by methods similar to those of Danson, the latter by precipitation with alcohol from strongly acid solution. Röhrig's research is the one usually quoted, and there can be no doubt that he obtained a hydrate of lithium sulphite, but the inadequate nature of his analyses appears to have escaped observation. The lithia was correctly estimated as sulphate, but the sulphur dioxide content was calculated after oxidation to sulphate and weighing as barium or lead sulphate. The amount of oxidising agent required was not ascertained, and no tests are recorded to prove the absence of sulphate. In view of the ready oxidation of the salt, this was a singular omission, for it is evident that the ratio $Li_2O : SO_2$, as calculated by the above method, would be the same for the known *sulphates*, Li_2SO_4 and Li_2SO_4,H_2O, as for the supposed *sulphites*. Further, since the water was calculated by difference, the analyses were insufficiently complete to distinguish between

Li_2SO_4 and Li_2SO_3,H_2O, on the one hand, and between Li_2SO_4,H_2O and $Li_2SO_3,2H_2O$, on the other. Moreover, since the higher hydrate was alleged to be formed from the more strongly acid solution, we deemed it desirable to re-investigate the subject.

We have confirmed the existence of the monohydrate, but have obtained no clear evidence of a dihydrate : it is possible that Röhrig's salt was the monohydrate imperfectly freed from water and/or alcohol, for it retains these substances very tenaciously. We have also prepared the pure anhydrous salt for the first time, and, although we have not been able to isolate the hydrogen sulphite, we have prepared its *compounds* with aldehydes and ketones.

Experimental.

The *monohydrate*, Li_2SO_3,H_2O, is readily prepared by making lithium carbonate into a very thin cream with water and passing a mixture of sulphur dioxide and purified hydrogen through it at room temperature with shaking, access of air being prevented with water seals. The object of the hydrogen is to avoid inrush of air during absorption of sulphur dioxide and passage of the liquid up the delivery tube when the supply of the latter gas is cut off. Passage of the sulphur dioxide is continued until the whole of the lithium carbonate has passed into solution and effervescence has ceased, but too great excess should be avoided. The sulphite may be separated in one of the following ways :

1. Evaporation on the water-bath, care being taken to minimise oxidation (see analysis *a*). Unless pure sulphite is required this is a rapid and convenient method of preparation.

2. Evaporation over concentrated sulphuric acid in a vacuum; this is tedious, but yields a very pure, crystalline product (see analyses *b* and *c*).

3. Pouring the solution into excess of alcohol, whereby a white precipitate is obtained which is somewhat difficult to filter, particularly when excess of sulphur dioxide is present. The precipitate is washed with alcohol and ether, and may be dried at 100° or preferably at room temperature in a vacuum desiccator over sulphuric acid : with care, the latter procedure gives a white powder entirely free from sulphate (analysis *d*).

As obtained by the above methods, the monohydrate is readily soluble in water. When exposed to water vapour in the absence of air the salt steadily increases in weight and finally deliquesces to a colourless solution. Exposed to air, it slowly oxidises to sulphate, even in a desiccator. Thus, a specimen of the pure salt after keeping for 8 days contained only 46·20% SO_2, and this fell, after a further 7 days, to 36·76% (Calc. for Li_2SO_3,H_2O, 57·22%).

In dilute solution, the salt oxidises rapidly; an $M/10$-solution exposed to air oxidised somewhat less rapidly than equivalent solutions of the sodium and potassium salts.

The monohydrate retains its water over sulphuric acid at room temperature, but becomes anhydrous at 180°, undergoing slight oxidation to sulphate if exposed to air during heating. Numerous analyses of the different batches of salts have been made, the lithium being estimated as sulphate, and the sulphur dioxide iodometrically. The water is usually calculated by difference. Typical analyses are as follows:

	a.	*b.*	*c.*	*d.*	Theory.
Li_2O (%)	27·42	25·37	26·28	27·29	26·69
SO_2 (%)	56·85	54·39	56·35	57·66	57·22
H_2O (by diff.) (%)	15·73	20·24	17·37	14·90	16·09
Ratio Li_2O/SO_2	0·4823	0·4664	0·4664	0·4733	0·4664

Salt *b* was quite free from sulphate, but retained some adsorbed moisture. Salt *c* contained a trace of sulphate but less adsorbed water, having been kept in a vacuum desiccator for a longer period than the preceding salt. Salt *d* was prepared by the third method, sulphur dioxide being present in only very slight excess. While in the vacuum desiccator, it was repeatedly "rinsed" with air until it ceased to smell of ether. It was entirely free from sulphate but contained 0·15% of iron, calculated as Fe_2O_3.

Following Röhrig's procedure for the preparation of the supposed dihydrate, sulphur dioxide and hydrogen were passed into an aqueous suspension of lithium carbonate until a yellow, acid solution was obtained, the yellow colour indicating the presence of acid sulphite in solution. This was poured into excess of alcohol, and the precipitated salt filtered off (with difficulty) at the pump. A portion was analysed immediately and contained 72·02% of alcohol plus water. Had it not contained alcohol, this would have corresponded to $Li_2SO_3,14H_2O$, which requires H_2O, 72·86%. It was not a definite compound and lost weight rapidly in the balance case. The remainder, when placed on a clock glass in a vacuum desiccator over sulphuric acid, continuously lost weight for 24 hours, but then remained practically constant and was analysed. All the alcohol had evaporated, and the salt consisted of lithium sulphate monohydrate with a trace of sulphate (Found: H_2O, 15·71. Calc.: 16·09%).

Anhydrous lithium sulphite, Li_2SO_3, is conveniently prepared in a pure state by passing a mixture of sulphur dioxide and purified hydrogen into a cream of lithium carbonate and water until effervescence ceases. The flask is then heated to 180—200° in an oil-bath, dry hydrogen being passed through until the salt is anhydrous.

Thus obtained, lithium sulphite is a dull white powder, more stable than the monohydrate. A sample kept in a desiccator for a month was free from all but a trace of sulphate (Found: Li_2O, 31·84; SO_2, 67·72; H_2O, 0·38; total, 99·94; $Li_2O:SO_2$, 0·4702. Li_2SO_3 requires Li_2O, 31·81; SO_2, 68·19%; $Li_2O:SO_2$, 0·4664).

The salt melts at approximately 455° and undergoes partial decomposition, yielding a brown, green, or blue mass according to circumstances. If air is excluded, some lithium sulphide appears to be formed, for the product smells of hydrogen sulphide. This was observed by Röhrig, who suggested the reaction: $4Li_2SO_3 = 3Li_2SO_4 + Li_2S$. An analogous reaction has since been shown to take place on heating sodium sulphite at 700° in a vacuum (Picon, *Compt. rend.*, 1924, **178**, 1548).

Organic Derivatives of Lithium Hydrogen Sulphite.

Acetone. A thin cream of lithium carbonate and water was covered with acetone in a flask, and sulphur dioxide diluted with hydrogen passed through. The temperature rose slightly and after all the carbonate had decomposed a white, crystalline derivative formed. This was washed with acetone and ether. The lithium content was determined by heating with concentrated sulphuric acid and weighing as sulphate (Found: Li_2O, 9·03. $LiHSO_3,C_3H_6O$ requires Li_2O, 9·11%). The acetone was estimated iodometrically; the method did not appear to be very accurate, but sufficed to show that at least 93% of the theoretical quantity of acetone was present. After two months in a stoppered bottle, analysis gave Li_2O, 9·12%; but in another sample that had been less securely stoppered, the percentage of Li_2O rose in a few weeks to 13·57, and the residue smelt of sulphur dioxide, indicating appreciable decomposition.

Benzaldehyde. This derivative was obtained in a similar manner as a beautifully white product; it smelled strongly of benzaldehyde, which was rapidly evolved on warming (Found, for two specimens: Li_2O, 7·14, 8·61. Li_2HSO_3,C_7H_6O requires Li_2O, 7·70%).

Acetaldehyde gave a white product, not analysed. Acetophenone did not react.

CCXCIII.—*The Nature of the Alternating Effect in Carbon Chains. Part XXVIII. The Preparation and some Properties of Benzyl Fluoride.*

By CHRISTOPHER KELK INGOLD and EDITH HILDA INGOLD.

ALTHOUGH benzyl chloride, bromide, and iodide are familiar substances, the preparation of benzyl fluoride has not yet been described, and, in view of the importance of the benzyl halides for the study of serial relationships in the electrochemical behaviour of the halogen elements in organic chemistry, we attempted to devise a satisfactory method for the formation of the missing member of the series. Recent imperfectly successful attempts have been recorded by Tronov (*J. Russ. Phys. Chem. Soc.*, 1926, **58**, 1270), who treated benzyl chloride with silver fluoride and obtained only toluene, and by Swarts (*Bull. Soc. chim.*, 1924, **35**, 1533), who, by some method not stated, obtained "with great difficulty" a small quantity of a liquid which was neither purified nor analysed, and quickly decomposed.

In their study of the decomposition of quaternary ammonium salts, Hanhart and Ingold (J., 1927, 997) showed that under structural conditions antagonistic to the formation of an olefin, the alkyl radical most tolerant to a positive charge is ejected and subsequently combines with the anion of the salt. The order of toleration given included the inequality $C_6H_5{\cdot}CH_2 > CH_3$, and the present application is that the distillation of a quaternary ammonium fluoride such as benzyltrimethylammonium fluoride, containing only benzyl and methyl groups, should yield a predominating proportion of benzyl fluoride. We have prepared benzyl fluoride from several salts of this type (yields about 60% after complete rectification) and have taken the opportunity to study its properties.

Benzyl fluoride is a colourless liquid with an odour which is quite unlike that of its analogues, and rather resembles that of benzene. The m. p. is $-35°$, and the b. p. 139·9°/760 mm. is of interest in relation to those of toluene, benzal fluoride, and benzotrifluoride. The series $C_6H_5{\cdot}CH_3$(110·8°), $C_6H_5{\cdot}CH_2F$(139·9°), $C_6H_5{\cdot}CHF_2$(133·5°), $C_6H_5{\cdot}CF_3$(103·5°) shows a maximum at the boiling point of benzyl fluoride, and this is noteworthy in relation to Arkel and de Boer's theory respecting the boiling points of organic compounds (*Physica, Nederlandsch Tijdsch. Natuurkunde*, 1924, **4**, 392; 1925, **5**, 134; *Rec. trav. chim.*, 1925, **44**, 675). According to these authors, the boiling points of halogenohydrocarbons are additive in the sense that they can be expressed as a simple function of the sum of a number of terms ("$\sqrt{\alpha}$-values") corre-

sponding to the contributions of the atoms to the external molecular field and hence to the internal pressure of the liquid. For compounds belonging to the same hydrocarbon type the $\sqrt{\alpha}$-values of the halogens are constant; *e.g.*, for methane derivatives the values are F 23, Cl 47·5, Br 60·8, I 81·3. On the other hand, the $\sqrt{\alpha}$-value for hydrogen is variable and depends upon the degree of incipient ionisation induced by the halogen atoms attached to the same carbon atom. The degree of incipient ionisation produced by different halogens is substantially the same, and therefore the main factor which determines the $\sqrt{\alpha}$-value for hydrogen is the number of halogen atoms attached to the carbon atom to which it is linked. The following $\sqrt{\alpha}$-values for hydrogen illustrate this (X = halogen): CH_4 16·2, CH_3X 21·4, CH_2X_2 25·2, CHX_3 26·1. The peculiarity of fluorine is that its $\sqrt{\alpha}$-value lies within the range of values which hydrogen may assume, and hence the possibility arises that whilst the replacement of one hydrogen atom in a hydrocarbon by fluorine may cause an increase in $\Sigma\sqrt{\alpha}$ and thus an increase in boiling point, the replacement of succeeding hydrogen atoms attached to the same carbon atom may lead to a decrease both in $\Sigma\sqrt{\alpha}$ and in the b. p. The series of b. p.'s given above forms a striking illustration of this deduction, and is the first complete series of the kind. As already stated, the $\sqrt{\alpha}$-values vary slightly from type to type, and it must be assumed that the value for side-chain hydrogen crosses the fluorine figure on passing from toluene to benzyl fluoride, thus producing a maximum b. p. at this member of the series.

We have studied the refraction and the dispersion of benzyl fluoride, both because these data will ultimately be required for the calculation of the molecular dipole moment of this substance, and also because the effect of the substituent (F) on the optical dispersion of a substance forms a partial measure of its effect on the rigidity of the electrons in the molecule. To facilitate an accurate comparison of the refraction constants of fluorine relative to those of hydrogen, the densities and refractive indices of highly purified toluene have been measured with the same apparatus. The data are in the following table, in which the bottom row contains the differences between $[R_L]$ for benzyl fluoride and for toluene:

	λ 6563.	λ 5893.	λ 5461.	λ 4861.	λ 4358.	λ 4340.
Benzyl fluoride $n^{25\cdot3^\circ}$	1·48481	1·48919	1·49294	1·50014	1·50927	1·50967
$d_4^{25\cdot3^\circ}$ 1·02278 $[R_L]$	30·829	31·067	31·269	31·656	32·144	32·165
Toluene $n^{23\cdot9^\circ}$	1·48876	1·49331	1·49720	1·50454	1·51402	1·51436
$d_4^{23\cdot9^\circ}$ 0·86140 $[R_L]$	30·833	31·077	31·285	31·676	32·177	32·195
(F) − (H)	−0·004	−0·010	−0·016	−0·020	−0·033	−0·030

Eisenlohr's (1910) values for the refraction constant of hydrogen being used, the contributions to the molecular refractions attributable to fluorine in benzyl fluoride are in the following table, in which Eisenlohr's values for the other halogens are included for comparison:

	H_α.	D.	H_β.	H_γ.	$H_\beta - H_\alpha$.	$H_\gamma - H_\iota$
F(BzF)	1·088	1·090	1·095	1·092	0·007	0·004
Cl	5·933	5·967	6·043	6·101	0·110	0·168
Br	8·803	8·865	8·999	9·152	0·196	0·349
I	13·757	13·900	14·224	14·521	0·467	0·764

It will be seen that fluorine has by far the lowest refraction values and that it differs sharply from the other halogens in contributing practically nothing to dispersion, and we conclude that amongst the four benzyl halides the halogen in benzyl fluoride exerts the strongest positive field over the aromatic nucleus. For *o*-, *m*-, and *p*-fluorotoluene Swarts (*J. Chim. phys.*, 1922, **20**, 30) obtained results which, when reduced in the same way, give — 0·034 (mean) for the contribution by fluorine to the dispersion (H_γ—H_α). For fluorobenzene the corresponding figure was — 0·045, and the marked contrast between these figures and that now derived (+ 0·004) for benzyl fluoride shows that the introduction of a fluorine atom into the aromatic nucleus causes a larger restraint on the electrons and hence a larger increase in the frequency governing dispersion than that produced by the entrance of a fluorine atom into the side chain.

Further evidence pointing in a similar direction was obtained by a study of the ultra-violet absorption of the substance, and the results are of interest in connexion with the parallelism which appears to subsist between the selective absorption of simply constituted aromatic compounds and their nuclear reactivity. It is known (Baly and Collie, J., 1903, **87**, 1332) that the conversion of aniline into a salt causes the selective absorption to be displaced in the direction of shorter wave-lengths, and this effect, manifestly connected with the increased electronic restraints produced by the positive charge, may be correlated with the inhibited nuclear reactivity and tendency to *m*-orientation of the salt. The opposite influence of a negative charge is displayed when phenol is converted into a salt, and the displacement of the selective absorption to a region of greater wave-lengths finds its counterpart in largely increased nuclear reactivity and very strong *op*-orientation. Spectrographic studies with benzene, toluene, ethylbenzene, and the three xylenes in alcoholic solution (Baly and Collie, *loc. cit.*) have shown that the introduction of alkyl groups into the aromatic nucleus displaces the absorption maximum towards the red, and quantitative data are available in the case of *p*-xylene (Henri, " Études de

Photochimie," 1919); the effect corresponds to *op*-orientation associated with increased nuclear reactivity (Ingold and Shaw's "Case I," J., 1927, 2918). If, however, the side-chain hydrogen atoms of toluene are replaced by atoms which attract electrons strongly, the circumstances of Ingold and Shaw's "Case I" pass into those of their "Case II," and continuously decreasing nuclear reactivity is associated with increasing *m*-orientation. Benzyl

FIG. 1.

fluoride, benzaldehyde, and benzoic acid represent progressive stages in this process, and it is therefore of interest to compare the positions and intensities of the principal ultra-violet absorption maxima of these substances with those of benzene and *p*-xylene. The curve representing the extinction coefficients for benzyl fluoride in *M*/100- to *M*/1600-ethyl-alcoholic solution is shown in the diagram, and a comparison of the wave-length of the maximum with those recorded by Henri (*loc. cit.*) for the other substances

shows that benzyl fluoride falls into place as a somewhat feebly *m*-orienting member of the series. The trend of the ε-values (minimum at benzene) suggests that electrical dissymmetry in the molecule favours photoelectronic excitation.

	p-Xylene.	Benzene.	Benzyl fluoride.	Benz-aldehyde.	Benzoic acid.
λ	2684	*2547*	2508	2,440	2,302
ε	750	*210*	508	16,260	44,700

It is not to be expected that the basis here indicated for the correlation of colour with constitution will be capable of a more general application until it has been considerably elaborated, and a more extended discussion of the effect of polar influences on colour must await further experimental studies.

The above reference to the *m*-orienting power of the fluoromethyl group is based on our observation that on nitration in acetic anhydride solution benzyl fluoride yields mononitro-derivatives in the following proportions: ortho- 28·1, meta- 17·5, para- 54·4%. Comparison of these figures with those which have been obtained by Miss F. R. Shaw in these laboratories for the nitration of benzyl chloride, namely, ortho- 32·0, meta- 15·5, para- 52·5%, shows that there is more *m*-substitution in the former case, and that therefore the electron-attraction (inductive + direct effects, $-I$ $-D$) of the halogen in benzyl fluoride is greater than in benzyl chloride.

According to Ingold and Vass (this vol., p. 417; see also Lapworth and Robinson, *Mem. Manchester Phil. Soc.*, 1928, **72**, No. 4) the direct effect is one of the main factors controlling the ortho/para ratio in aromatic substitution, and conversely this ratio, or the related ratio para/½ortho, may be taken to indicate the relative intensities of the external fields of the halogen atoms in the above cases, provided that the possibility of complications arising from steric hindrance is not disregarded. The ratios for benzyl fluoride and chloride are 3·89 and 3·28 respectively, showing that the direct effect of fluorine is stronger than that of chlorine, since steric hindrance should produce a difference in the opposite direction. This is confirmed by the halogenobenzene ratios (Holleman), namely, PhF 13·76, PhCl 4·64, PhBr 3·30, PhI 2·85, which indicate that the complete sequence is $D_F > D_{Cl} > D_{Br} > D_I$. It is natural that the ratios for the phenyl compounds should be greater than for the corresponding benzyl compounds, because not only will the field over the nucleus be stronger in the former case owing to the proximity of the halogen atom, but also the difference between the distances of the ortho- and para-positions from the directing atom will be relatively greater. The fact that the difference between the values for fluorobenzene and chlorobenzene is greater

than that between the values for benzyl fluoride and benzyl chloride can be similarly explained, and it may also be a contributing circumstance that in the phenyl compounds a tendency towards sharing additional electrons with the nucleus (residuum of the tautomeric effect + T) in the order Cl>F increases the disparity between the external fields produced by these atoms.

These considerations, combined with conclusions previously reached on other grounds (Ingold and Shaw, *loc. cit.*; Ingold and Vass, *loc. cit.*), show that, whereas in regard to the tautomeric effect the halogens are in the order I>Br>Cl>F, they stand in the reverse order with respect to both their inductive and direct effects, and one of the most interesting problems in the chemistry of the benzyl halides arises in connexion with the reconciliation of the above analysis of their nuclear reactivity with the available data relating to their side-chain transformations. According to Ingold and Rothstein (this vol., p. 1217) the side-chain substitutions of benzene derivatives are of four types, which, for the benzyl halides, may be exemplified by the reactions with (1) amines, water, and alcohols, (2) halogens (high temperatures), (3) reducing agents, (4) powerful alkalis. These types are divisible into two groups, since the mechanism of the reactions of which (2) is an example may be regarded as a variant of that of the reactions of category (1): the latter involve the ionisation $C_6H_5\cdot\overset{+}{C}H_2\}\overset{-}{X}$ (X = halogen). Similarly, reactions of type (4) proceed by a mechanism closely allied to that which obtains in class (3), and these reactions involve the opposite process $C_6H_5\cdot\overset{-}{C}H_2\}\overset{+}{X}$. Now, if the above considerations relating to the inductive and direct effects produced by halogens be taken as indicating the electrical states of these atoms, then the sequence F>Cl>Br>I should connote the order of negativity of halogen substituents in corresponding compounds, that is, the degree of pre-formation of the halide anions. It follows that the relative ease of reactions involving the separation of the halide anions should accord with the above sequence, and the facility of those which require the separation of a real or potential halous kation should follow the opposite order. There exists much evidence indicating that the latter statement corresponds to reality so far as concerns the three previously-known benzyl halides and we have shown that benzyl fluoride falls into the sequence, since, under conditions in which benzyl chloride is reduced [reaction (3)], the fluoride remains unaffected, and furthermore, the conversion of the fluoride into benzyl ethyl ether by treatment with sodium ethoxide [reaction (4)] is much more difficult to bring about than is the corresponding reaction of the chloride. On the other hand,

general experience shows that benzyl iodide and bromide are *more* reactive towards tertiary bases and acid hydrolytic and alcoholytic agents than is the chloride, and we have shown that benzyl fluoride reacts with trimethylamine and with ethyl alcohol much less readily than does benzyl chloride. Thus it appears that in reactions requiring the separation of a halide anion, the reactivities of the benzyl halides are in the opposite order to that which might be expected from a consideration of the influences of halogens on nuclear aromatic substitutions, and we are therefore compelled to suppose that the primary condition affecting the reactivity of the halogen substituents themselves is not so much the average or actual electrical condition of these atoms, but rather the extent to which they *are capable* of temporary electrical polarisation by the external fields of reagent molecules;* in other words, the fundamental condition is the magnitude of the restoring forces brought into play when the electrons of the carbon–halogen linking are displaced in either direction; or, again, the matter might be expressed in terms of energy relations, since the restoring force (f) referred to will be connected, through the integral $\int_0^\infty f dx$, to the critical energy increment of ionisation. It seems a reasonable assumption that the relative displaceability of the shared electrons of the four halogens in corresponding halides will run parallel with that of the unshared halogen electrons, and there is an accumulation of evidence that whilst the unshared electrons which combine most readily with a positive charge are those of iodine (example: formation of iodinium salts), the electrons of the outer shell of iodine are also those which are most easily displaced by a combining anion (example: hydrolysis of *p*-iodoxynitrobenzene). Combining this evidence with facts such as those underlying Fajan's theory of covalency formation and Sidgwick's theory of the production of higher groups of valency electrons, it is but a short step to the inference that the shared halogen electrons in corresponding halogenohydrocarbons are most easily displaced *in both directions* in the case of the iodo-derivative and least easily in the case of the fluoride. Thus the probable order of decreasing restoring forces is F, Cl, Br, I, and this is the sequence required to account for the observations referred to above relating to the side-chain reactivity of the benzyl halides.

One consequence of the assumption that it is the external molecular fields of adjacent reagent molecules which polarise the carbon–halogen linking sufficiently to lead to side-chain substitutions of benzyl halides is that reagents of many kinds, including

* This statement may be expected to apply with a considerable degree of generality to substituents in carbon compounds.

those which are employed for nuclear substitutions, must (since they will also possess external molecular fields) bring about similar, if smaller, temporary electron displacements in the side chain. Concerning the effect of these side-chain polarisations on the result of nuclear substitution, it will be obvious that everything must depend on their duration, and the fact that a change of reagent has little influence on the proportions of the nuclear substitution products (provided that covalency formation does not take place between the side chain and the reagent) shows that the duration of the side-chain polarisations must be small. Nevertheless we believe that the cause here indicated is one of the principal factors which contribute to the small differences which have been observed in the proportions of nuclear substitutions by different reagents, and we deduce that the nuclear substitution of an iodo-compound should be more sensitive to a change of reagent than that of the corresponding bromo-derivative, and so forth (I>Br>Cl>F). Thus the interesting distinction between the state of polarisation and the polarisability of the halogens and other substituents should be capable of independent investigation along these lines.

EXPERIMENTAL.

Preparation of Benzyl Fluoride.—Benzyl chloride (60 c.c.) and a 33% solution of trimethylamine in ethyl alcohol (120 c.c.) were mixed in an open flask at the ordinary temperature and the mixture was shaken and cooled externally as long as was necessary to prevent the temperature from rising above 40° (about 15 mins.). A further 60 c.c. of benzyl chloride and 120 c.c. of trimethylamine solution were then added and the action was regulated as before. The flask was thereafter closed with a drying tube, kept for 1 hour, and heated at 45° for several hours (usually over-night) to complete the reaction. About 2 l. of dry ether were added and the hygroscopic benzyltrimethylammonium chloride was rapidly collected, washed with ether, and dissolved in water. The solution was treated (stirring) with a suspension of excess of silver oxide and filtered. The combined filtrate and washings were neutralised with 20% hydrofluoric acid and evaporated on the steam-bath to a viscous syrup. A third of the syrup thus obtained was distilled in a water-pump vacuum from a water-bath until the crystals of benzyltrimethylammonium fluoride, at first transparent, had dried and become opaque through efflorescence, and then with a free flame (the better to control frothing), through an ice-water condenser, into 400 c.c. of 10% hydrochloric acid cooled below 0°, in which the benzyl fluoride collected as an oil. A tower containing a small amount of hydrochloric acid cooled below 0° served to scrub a

further small quantity of benzyl fluoride from the methyl fluoride which passed into the pump. After the remainder of the syrup had been similarly distilled in two portions into the same receiver, the oil in this and the scrubber was extracted with ether, and the extract washed three times with 10% hydrochloric acid and twice with aqueous sodium hydrogen carbonate, and dried with sodium sulphate. The residue which remained after removal of the ether gave (*a*) 4 g. of distillate, b. p. up to 69°/65 mm.; (*b*) 54 g., b. p. 69—71°/65—66 mm.; (*c*) 4 g., b. p. 71—77°/65—66 mm.; and (*d*) about 4 g. of a yellow, less volatile residue. Redistillation of fractions (*a*) and (*c*) augmented (*b*) to 60 g. The hydrochloric acid solution was evaporated to a paste, which was distilled with concentrated aqueous potassium hydroxide to expel the trimethylamine; this was dried, collected in alcohol, and used again. The benzyldimethylamine which remained as an oil was also recovered for use in the following method.

The recovered benzyldimethylamine was treated with the theoretical quantity of benzyl bromide, about half of which was introduced slowly with shaking and external cooling. Just before the mass became inconveniently viscous the remainder was added quickly, the reaction then proceeding rapidly to completion with a large evolution of heat. The crystalline dibenzyldimethylammonium bromide was, without purification, converted into the hydroxide and thence into the fluoride, which was decomposed by distillation as in the first method (yield, about 60%). The recovered bases consisted of benzyldimethylamine and dibenzylmethylamine. The former on treatment with benzyl bromide, and the latter on treatment with methyl iodide, yielded quaternary salts from which a further stock of dibenzyldimethylammonium fluoride, and thence of benzyl fluoride, was obtained.

Gram-molecular quantities of tribenzylamine and methyl iodide were kept in a sealed flask at 45° (in a thermostat) for 10 days. The sparingly soluble tribenzylmethylammonium iodide was finely ground and well-stirred for 16 hours with 4·5 l. of an aqueous suspension of silver oxide at 80—90°. The hydroxide was converted into the fluoride, which was decomposed in the usual way, yielding 35 g. of benzyl fluoride. Dibenzylmethylamine and some tribenzylamine were recovered and used again.

Physical properties. The *benzyl fluoride* (Found: C, 76·3; H, 6·3. C_7H_7F requires C, 76·4; H, 6·4%) prepared by these methods is a colourless mobile liquid, which does not fume in air and is not lachrymatory. On cooling, it sets to a mass of white needles, m. p. — 36° (uncorr.), and the b. p.'s observed during the preparation were 40—40·5°/14 mm., 55—56°/30—30·5 mm., 70—71°/

66 mm., 85—86°/118—119 mm., 100—100·5°/244—246 mm., 139—140°/ordinary pressure (all uncorr.). For more precise physical characterisation a sample boiling within a range of 1° was further purified by distillation, controlled by m. p. determinations. After the first distillation the m. p.'s were as follows: first, 20%, — 36·5°; middle, 60%, — 35·5°; last, 20%, — 37·5°. The middle fraction, on redistillation, gave a head fraction, m. p. — 35°, a main fraction, m. p. — 35°, and a tail fraction, m. p. — 36°. The main fraction on distillation gave only fractions having m. p. — 35° (corr.). The b. p. was 139·8°/753 mm. (corr.), which corresponds to 139·9°/760 mm. (corr.) if the small correction to standard pressure is made by means of the approximate vapour-pressure observations recorded above. The purified sample was used for the determinations of density and refractive index recorded on p. 2250, and for tracing the curve of extinction coefficients shown in the diagram. The toluene required for the former observations was carefully purified by freezing. The absorption curve is plotted from about 50 comparison photographs taken with a polarisation-photometer by Bellingham and Stanley, Ltd., and a spectrometer giving a dispersion at the plate of 80 Å.U. per cm. at λ 2500.

Action of Sulphuric Acid, Hydrofluoric Acid, and Certain Kinds of Glass.—Benzyl fluoride readily loses hydrogen fluoride under certain conditions and passes into a hydrocarbon, or mixture of hydrocarbons $(C_7H_6)_x$. When the liquid is touched with a rod moistened with concentrated sulphuric acid, a violent reaction sets in and rapidly spreads throughout the mass, much heat being generated and hydrogen fluoride copiously evolved. The product is an opaque white glass. It is sparingly soluble in alcohol and moderately easily soluble in benzene; but it could neither be distilled nor crystallised. It contained not more than a trace of fluorine, and analysis indicated the empirical composition C_7H_6, although the molecular weight is undoubtedly high. A similar product is obtained when benzyl fluoride is left in contact with concentrated hydrofluoric acid in a platinum vessel, but hydrochloric and nitric acids do not appear to induce the decomposition.

An identical, or closely similar, product, also giving analytical results in accordance with the formula $(C_7H_6)_x$, is obtained when benzyl fluoride decomposes spontaneously in glass vessels. The reaction, which may develop with almost explosive violence, appears also to commence at the glass surface. In the earlier experiments it frequently occurred during distillation, commencing in the side tube, with etching of the glass, and spreading backwards into the distilling flask. The action seems to be autocatalytic, and when the pure stable liquid is deliberately contaminated with a trace of

a decomposing specimen the whole decomposes even in platinum. The kind of glass is an important factor, and no losses have so far occurred when Jena glass vessels have been used for distillation. For storage, moulded bottles of uncertain history are to be avoided; the pure fluoride has, however, been kept for months without any sign of deterioration in Wood Bros.' flasks and Parkes' test-tubes.

Action of Potassium Carbonate.—Benzyl fluoride (11 g.) was boiled for 6 hours with 400 c.c. of 10% potassium carbonate solution; the product on distillation yielded 4·4 g. of recovered benzyl fluoride, b. p. 137—142°, 3·4 g. of benzyl alcohol, b. p. 200—208°, and an intermediate fraction containing both. Benzyl chloride (12·5 g.), treated similarly, yielded only benzyl alcohol.

Action of Zinc and Alcohol.—According to Tommasi (*Ber.*, 1874, 7, 826) benzyl chloride, on boiling with zinc dust and ethyl alcohol, is reduced to toluene. We have confirmed this, but find that benzyl ethyl ether is also formed. Benzyl fluoride (11 g.) on similar treatment yielded neither toluene nor benzyl ethyl ether in significant quantities, and over 90% was recovered unaltered.

Action of Alcoholic Trimethylamine.—Benzyl chloride readily reacts with 33% ethyl-alcoholic trimethylamine and combination is complete when a mixture of the theoretical quantities has been kept at about 45° for 3 hours. A mixture of benzyl fluoride and 33% alcoholic trimethylamine in the correct proportion was kept at 44° for 20 hours. The product, on being poured into water and extracted with ligroin, gave back 80% of the original benzyl fluoride, b. p. 138—140°. The aqueous solution was evaporated until it was neutral; the quaternary base was then precipitated as its picrate (m. p. and mixed m. p. with genuine benzyltrimethylammonium picrate, 169—170°). The yield was 5%, and since the picrate is very sparingly soluble, it is probable that this approximately represents the proportion of quaternary salt formed under the conditions used.

Action of Sodium Ethoxide.—Benzyl chloride and sodium ethoxide react quantitatively and immediately at the boiling point of alcohol. Benzyl fluoride (11 g.) was boiled for 1 hour with a solution of sodium ethoxide prepared from 2·3 g. of sodium and 24 g. of ethyl alcohol. The product yielded unaltered benzyl fluoride (3·1 g., b. p. 139—144°), benzyl ethyl ether (2·2 g., b. p. 185—190°), and an intermediate fraction which contained a considerable amount of benzyl fluoride (sulphuric acid test).

Nitration.—Freshly distilled, absolute nitric acid (6·3 g.), freed from nitrous acid, was slowly mixed with acetic anhydride (16 g.) at 5°. After warming the solution to 25°, benzyl fluoride (11·0 g.) was added. Nitration proceeded at a convenient velocity, between

25° and 30°, and was controlled by cooling the mixture to 25° as often as the temperature mounted to 30°. When this ceased to occur, the flask was placed in a thermostat at 25° for 6 hours, after which its contents were shaken with ice and water to destroy the acetic anhydride. The straw-coloured oil was extracted with benzene, washed six times with water, which removed a trace of yellow dye, and once with aqueous sodium hydrogen carbonate, and dried with sodium sulphate. The benzene and any excess of benzyl fluoride were removed at 40—50°/14 mm. by a slow stream of dry air, and the nitration product was distilled under about 0·1 mm.; only an insignificant residue remained. The distillate (Expt. 1) had $n_D^{25°}$ 1·5385 (Found: C, 54·3; H, 3·8. Calc.: C, 54·2; H, 3·8%). The last few drops, collected separately, had $n_D^{25°}$ 1·5390, proving the absence of dinitration products. The corresponding figures for the product of Expt. 2 were $n_D^{25°}$ 1·5382; C, 54·2; H, 3·9%; and for the last drops of the distillate, $n_D^{25°}$ 1·5388.

These products partly crystallised at 0° and appeared to be wholly solid at − 33°. That obtained from Expt. 1 was filtered off at the temperature of ice (solid = A_1), again at that of liquid sulphur dioxide (solid = B_1), and again in an ice–salt mixture (solid = C_1; liquid = D_1). The product of Expt. 2 was similarly treated, the filtration at 0°, however, being omitted (fractions B_2, C_2, D_2). Fractions A_1, B_1, and B_2 remained solid at the ordinary temperature and on crystallisation from ether–ligroin below 0° yielded long, colourless needles, m. p. 38·5°, of pure p-*nitrobenzyl fluoride* (Found: C, 54·4; H, 3·9. $C_7H_6O_2NF$ requires C, 54·2; H, 3·8%), since oxidation with alkaline permanganate under the standard conditions described below yielded *p*-nitrobenzoic acid (m. p. 230—233° unpurified, mixed m. p. 233—234°). Fractions C_1 and D_1, which were liquid at the ordinary temperature, were drained on porcelain at the temperature of liquid ammonia (C_1' and D_1'); and fractions C_2 and D_2 were crystallised from ligroin containing a trace of ether at about − 40°, whereby, as was shown by oxidation, the *o*-nitro-compound was concentrated in the former (C_2') and the *m*-derivative in the latter (D_2'), so that these isomerides, although they could not be completely purified, were obviously produced in significant quantities.

For the estimation of the isomerides the mixed mononitro-derivatives were converted into the nitrobenzoic acids, which were estimated by separation (Baker and Ingold, J., 1926, 2462) and also by Baker's adaptation (J., 1927, 565) of Holleman's solubility method. Both methods were again standardised by application to artificial mixtures. The method of oxidation was different from those formerly employed, which proved unsatisfactory; the new

method depended on the formation of nitrobenzyl alcohols which were rapidly oxidised with permanganate of low concentration. Conversions of about 90%, reproducible to 1%, were obtained, and deviations in the conversions of the individual isomerides were corrected for (Ingold, Ingold, and Shaw, J., 1927, 813).

The nitration product (Expt. 3 : $n_D^{25°}$ 1·5387; C, 54·3; H, 3·9%) was boiled with 50 parts of 10% aqueous potassium carbonate, and an equal volume of the same solution containing 3% of potassium permanganate was added in 75 equal parts at such a rate as to keep pace with the decolorisation as exactly as possible. The acids were isolated in 89·4% yield in the usual way (*M* by titration, 167·2; benzoic acid by sublimation, nil), and on separation gave 55·0% of *p*-nitrobenzoic acid, m. p. 234—235° unpurified, mixed m. p. 235—236°, and 17·6% of *m*-nitrobenzoic acid, m. p. 133—137°, mixed m. p. 138—140°, the recorded yields being corrected for the solubility of the *p*-acid in chloroform and of the *m*-barium salt in water. The yield of crude *o*-acid, m. p. 130—140° (containing *m*-acid), brought the total recovery to 99·7%. For the determination of the *m*-isomeride (18·0%) by solubility it was necessary to extend the reference curve given by Baker (*loc. cit.*) and the following additional determinations were made :

Meta added (mg.)	70·1	107·1	133·9	162·3	164·9
Meta found (mg.)	74·7	125·0	168·7	190·8	191·8

Fraction C_1' oxidised under the standard conditions gave nitrobenzoic acids in 89·0% yield (*M* by titration, 166·7; benzoic acid, nil), which on separation yielded 42·3% of *p*-nitrobenzoic acid, m. p. 231—234°, mixed m. p. 234—235°. The proportion of *m*-acid was determined by the solubility method to be 2·7%. Fraction C_2' yielded 88·8% of mixed nitrobenzoic acids, which on separation gave 29·2% of *p*-nitrobenzoic acid; the proportion of *m*-nitrobenzoic acid, determined by solubility, was zero. Fraction D_1' gave 90·9% of mixed acids (*M*, 167·3; benzoic acid, nil), which on separation yielded 14·5% of *p*-nitrobenzoic acid, m. p. 230—232°, mixed m. p. 232—234°, and 47·8% of *m*-nitrobenzoic acid, m. p. 131—136°, mixed m. p. 136—139°; the figure 47·8% was also obtained by the solubility method. Fraction D_2' yielded 91·2% of mixed acids, which on separation gave 8·0% of *p*-nitrobenzoic acid, m. p. 229—233°, mixed m. p. 230—234°; the proportion of *m*-nitrobenzoic acid was found by the solubility method to be 65·1%. *p*-Nitrobenzyl fluoride gave nitrobenzoic acid in 89·6, 90·0% yields. The mean conversions are calculated to be ortho 88·4%, meta 92·9%, para 89·8%, and hence the proportions of *o*-, *m*-, and *p*-nitrobenzyl fluorides are : ortho 27·9%, meta 17·1%, para 55·0% (separation), meta 17·5% (solubility). Expts. 4, 5,

and 6 were carried out in like manner and the results are included in the following table:

		Nitrobenzoic acids.			Nitrobenzyl fluorides.

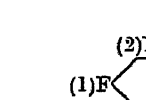
Distillation of o-, m-, *and* p-*Nitrobenzyltrimethylammonium Fluorides.*—*p*-Nitrobenzyltrimethylammonium fluoride, which was prepared from *p*-nitrobenzyl chloride and trimethylamine *via* the quaternary chloride and hydroxide, yielded a crystalline neutral distillate when a water-pump was used, and a solid, together with an oil which contained combined fluorine, when the distillation was conducted with an oil-pump-backed two-stage diffusion pump and a charcoal–liquid-air trap. In each case the solid proved to be *p*-nitrobenzaldehyde (Found: C, 55·8; H, 3·6. Calc.: C, 55·6; H, 3·3%). In the vacuum of the diffusion pump the *o*- and *m*-nitrosalts gave oily distillates, from which aqueous semicarbazide acetate at once precipitated the semicarbazones of *o*- and *m*-nitrobenzaldehydes. In each case a very small amount of an oil containing fluorine was obtained by washing the crude semicarbazones with a mixture of equal parts of ether and ligroin. Energetic decomposition with charring occurred under all conditions and effective control could not be maintained.

THE UNIVERSITY, LEEDS. [*Received, June 13th*, 1928.]

CCXCIV.—*The Nature of the Alternating Effect in Carbon Chains. Part XXIX. Further Experiments bearing on the Problem of the Ortho-Para Ratio in Aromatic Substitution.*

BY CHRISTOPHER KELK INGOLD and CHARLES CYRIL NORREY VASS.

IN a previous paper (this vol., p. 417) we developed the hypothesis that the principal polar orienting influence determining the ortho-para ratio in aromatic substitution arises from the external field of the substituent or substituents already present (direct effect, *D*), although steric inhibition and the occurrence of special



mechanisms may modify the situation in certain cases (*Ann. Reports*, 1926, **23**, 140). The experimental test then applied consisted in a comparison of the orienting effects of fluorine and chlorine in *p*-fluorochlorobenzene and *o*-fluorochlorobenzene; for the (negative) direct effects due to fluorine and chlorine are expected to be large and in the order F>Cl. It followed that, whereas in the *p*-compound, in which the direct effect assists the other polar factors, the relative control of nitration by the two halogens should follow the order Cl > F (Found: Direction by Cl/Direction by F = 72%/28%), in the case of the *o*-compound, in which the direct effect acts in opposition to the other influences, the order might be reversed (Found: Direction by Cl/Direction by F = 21%/79%).

Since the difference between the direct effects of fluorine and bromine should be greater than that between fluorine and chlorine, our attention was attracted (*loc. cit.*, footnote) to some recent papers by Hove (*Bull. Acad. roy. Belg.*, 1926, **12**, 801, 823; *Bull. Soc. chim. Belg.*, 1927, 361) in which it is shown that *p*-fluorobromobenzene on nitration in a large excess of sulphuric acid or in fuming sulphuric acid gave (although not in good yield) a product containing more than 40% of the *o*-fluoronitro-isomeride. In spite of the unsatisfactory yields this proportion appears to be definitely too high to be adequately accounted for on the lines indicated in our previous paper; but, having regard to the conditions employed by Hove in his nitrations, the considerations advanced by Ingold and Ingold (preceding paper) relating to the influence of media on orienting effects appeared to offer a possible basis for the explanation of Hove's result. According to this view, the external fields of reagent and solvent molecules are assumed to effect some degree of polarisation of the directing atom, and, if the *o*-*p*-substitution of the halogenobenzenes be regarded as evidence of the affinity of the unshared halogen electrons for a positive charge (tautomeric effect, + *T*), there can be little doubt that it would be the positive ends of dipolar solvent molecules which would be oriented towards the halogen. It need not be supposed, even when concentrated sulphuric acid is in contact with a halogen compound, that the formation of a real salt takes place, for Baker has shown in an independent series of observations (this vol., p. 1586) that it is possible experimentally to draw a clear distinction between the electrostriction of acids by weak bases and actual salt-formation involving co-ordination of the proton; at the same time he has proved that the polarising effect of the condition which may be described as *incipient* salt-formation is very considerable. Furthermore, turning again to the tautomeric effect in the substitution of the halogenobenzenes and to the indications afforded by Ingold

and Shaw's investigation of the relative velocity of these reactions (J., 1927, 2918), it is to be expected that the affinity of the unshared halogen electrons for a positive field will be in the order I>Br>Cl>F, and, *ceteris paribus*, that this order will therefore represent the effect of strong acids in polarising, and thus diminishing the *op*-orienting power of, halogen atoms. Finally, analogy with the nitration of acetanilide, in which the addition of sulphuric acid leads to the formation of appreciable quantities of the *m*-derivative, and also causes a marked rise in the ratio para/½ortho (Noelting and Collin, *Ber.*, 1884, **17**, 262; Holleman, Hartogs, and van der Linden, *Ber.*, 1911, **44**, 704), suggests that sulphuric acid produces particularly powerful medium-effects in substitutions oriented by substituent atoms containing unshared valency electrons.

Thus in Hove's experiments all the conditions calculated to produce an anomalous result are present, but it appeared impossible directly to test this view of the situation by further study of the nitration of *p*-fluorobromobenzene because Hove was unable to establish satisfactory conditions for this reaction in the absence of an excess of sulphuric acid. We have therefore sought for evidence of the medium-effect in the analogous case of *p*-fluorochlorobenzene and have studied the effect of varying quantities of sulphuric and fuming sulphuric acids on the proportions in which the isomerides are formed. In the nitration of this substance the effect of the medium would be expected to be smaller than in *p*-fluorobromobenzene; nevertheless, it should be in the same direction and the addition of excess of acid should increase the proportion of the *o*-fluoronitro-compound (Cl>F).

That this is indeed the case is evident from the following figures:

	Mols. H_2SO_4 per mol. HNO_3.					Mols. "free" SO_3 per mol. H_2SO_4.		
 (%)	0·00	0·67	0·86	3·00	6·00	0·33	0·64	1·87
	20·8	24·1	24·5	25·0	25·5	27·8	28·9	30·0
$\frac{1:2:4\text{-isomeride}}{1:3:4\text{-isomeride}} \times 100$	26·2	31·8	32·5	33·3	34·2	38·4	40·6	42·9

It will be seen that by the addition of sulphuric acid the proportion of 1 : 2 : 4-compound relatively to its isomeride has been increased by 31%, and that the addition of fuming sulphuric acid caused an increase of 64%. These results not only furnish a sufficient explanation of Hove's observations, but also suggest that in the nitration of the monohalogenobenzenes the addition of sulphuric acid should increase the ratio para/½ortho, and that this combined illustration of the operation of the direct effect and the polarising

influence of solvent molecules should become increasingly marked with increasing atomic weight of the halogen. It is proposed to test these deductions.

EXPERIMENTAL.

p-*Fluorochlorobenzene and its Nitro-derivatives.*—*p*-Fluoroaniline (25 g.), prepared from *p*-fluoronitrobenzene (Ingold and Vass, *loc. cit.*), was diazotised at — 5° to 0° in solution in hydrochloric acid (175 c.c. of *d* 1·15; ice, 50 g.) with a concentrated solution of sodium nitrite. The solution was saturated with hydrogen chloride at 0°, treated with precipitated copper (20 g.) under reflux, and distilled in steam. The *p*-fluorochlorobenzene (yield, 66%), which was extracted with ether from the basified distillate and dried with phosphoric oxide, had b. p. 129—130° (compare Swarts, *Rec. trav. chim.*, 1915, **36**, 131).

2-Fluoro-5-chloronitrobenzene was prepared from *p*-fluoroaniline by nitration in sulphuric acid solution (Holleman, *Rec. trav. chim.*, 1905, **24**, 29) and subsequent replacement of the amino-group by chlorine (Swarts, *loc. cit.*). 5-Fluoro-2-chloronitrobenzene was prepared by an analogous series of reactions from *p*-fluoroacetanilide (Swarts, *loc. cit.*).

Nitration of p-*fluorochlorobenzene.* The nitration of this substance in nitric acid alone was studied by Swarts, whose quantitative results differ to some extent from those obtained by us. Swarts analysed his nitration product by two methods. First, ordinary thermal analysis indicated the presence of 27·75% of the *o*-fluoronitro-compound (Found by us, 20·8%); but a re-plot of Swarts's data connecting the f. p.'s of mixtures of the isomerides shows a marked deflexion in the neighbourhood of the composition of the nitration mixture. Since this deflexion depends only on one observation by Swarts, and since, furthermore, we have been quite unable to confirm it, it is probable that Swarts's figures require revision. Secondly, Swarts treated his nitration mixture with sodium methoxide under conditions in which, according to his observations, the *o*-fluoronitro-compound reacts completely and the *o*-chloronitro-compound is unaffected; the figure obtained by this method, namely, 27·78% of *o*-fluoronitro-compound, is in remarkably good agreement with the result of thermoanalysis. Our observations show, on the contrary, that neither under the conditions described by Swarts nor under any others that we have been able to discover is it possible to obtain a quantitative decomposition of one isomeride and a complete absence of any decomposition of the other; *e.g.*, under the conditions described by Swarts, 5-fluoro-2-chloronitrobenzene underwent hydrolysis to the

extent of 11·6—12·3% (see Table IV). From these observations it appears that it is impossible to analyse the nitration product by this method, and that the agreement obtained by Swarts was fortuitous.

The conditions under which the various nitrations were carried out are recorded in Table I. In all experiments the temperature was — 15° to —10°. The isolation of the product was effected by the method previously described for *o*-fluorochlorobenzene (Ingold and Vass, *loc. cit.*). The synthesised isomerides were isolated and purified by a similar process. The freezing points recorded in Tables I, II, and III are uncorrected, but were determined under identical conditions with the same apparatus. In order to control possible changes of composition during isolation, the material, after the f.-p. determination, was redissolved in nitric acid and the isolation repeated, with the result that the f. p. remained unaltered to within 0·1°. Furthermore, as a check on the binary character of the nitration products, some of these were mixed with known proportions of the pure isomerides and the f. p.'s of the mixtures were compared with the f. p.–composition curve.

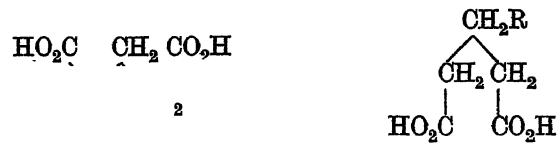
CCXCV.—*Electrometric Titration Curves of Dibasic Acids. Part II. β-Substituted Glutaric Acids.*

By RICHARD GANE and CHRISTOPHER KELK INGOLD.

IN Part I (this vol., p. 1594) we described a preliminary examination into the possibility of obtaining approximate measurements of the distance between the carboxyl groups of dibasic acids by utilising hydrogen-ion activity determinations, during neutralisation with a strong base, in conjunction with Bjerrum's theory respecting the effect of the external field of a pole on the degree of dissociation of another ionising centre situated in the same molecule. It was shown that the results obtained by this method for the distances

between the carboxyl groups of normal dibasic acids, are subject to various disturbances, of which probably the most important are the following: (1) the influence of solvation and electrostriction, which, although it interferes with quantitative accuracy, should not, and apparently does not, alter the order of a given series of related substances in respect of the dimension considered; (2) the effect of internally propagated polar influences, which gives rise to larger anomalies the shorter the carbon chain between the carboxyl groups. It was found, furthermore, that the disturbances attributable to internal influences, although large in malonic acid and considerable in succinic acid, became small in glutaric acid and its higher normal homologues, and it was therefore decided to examine a series of substituted glutaric acids in order to ascertain whether the hypothesis of valency deflexion, which has hitherto been successful mainly in explaining chemical relationships, would receive support from physical measurements.*



We have examined glutaric acid, two β-alkylglutaric acids, three ββ-dialkylglutaric acids, and three related ring compounds. The values of the first and second electrometric dissociation constants and the calculated value of the apparent distance r (in Ångström units) between the carboxyl groups are shown in the following table:

Substance.	k_1.	k_2.	r.
Glutaric acid	$4{\cdot}60 \times 10^{-5}$	$5{\cdot}34 \times 10^{-6}$	9·22
β-Methylglutaric acid	$5{\cdot}77 \times 10^{-5}$	$6{\cdot}28 \times 10^{-7}$	2·27
β-*n*-Propylglutaric acid	$4{\cdot}97 \times 10^{-5}$	$4{\cdot}32 \times 10^{-7}$	2·12
ββ-Dimethylglutaric acid	$2{\cdot}03 \times 10^{-4}$	$5{\cdot}51 \times 10^{-7}$	1·57
ββ-Diethylglutaric acid	$3{\cdot}40 \times 10^{-4}$	$7{\cdot}85 \times 10^{-8}$	1·02
ββ-Di-*n*-propylglutaric acid	$2{\cdot}03 \times 10^{-4}$	$5{\cdot}42 \times 10^{-8}$	1·01
*cyclo*Pentane-1 : 1-diacetic acid	$1{\cdot}68 \times 10^{-4}$	$2{\cdot}63 \times 10^{-7}$	1·40
*cyclo*Hexane-1 : 1-diacetic acid	$3{\cdot}36 \times 10^{-4}$	$1{\cdot}02 \times 10^{-7}$	1·04
*cyclo*Heptane-1 : 1-diacetic acid	$2{\cdot}78 \times 10^{-4}$	$1{\cdot}09 \times 10^{-7}$	1·10

The most remarkable feature presented by these data is the fact that the value for r for glutaric acid is so very much greater than for any of the substituted acids. In Part I, it was shown that the normal (unsubstituted) dibasic acids tend to a straight (zig-zag), and not a coiled, configuration, since the apparent distance between the carboxyl groups increases regularly by 1·73 Å.U. for each methylene group in this series of homologues. The value 9·2 Å.U. for glutaric acid is in keeping with this conception, and there appears to be no other way of explaining the much smaller values given by

* Spiers and Thorpe (J., 1925, **127**, 538) pointed out the close parallelism between the first dissociation constants (conductivity) of substituted glutaric acids and the tendency to ring-closure of corresponding derivatives, and this, therefore, is the first indication that valency-deflexion may manifest itself in physical properties.

the substitution products than to suppose that the presence of a β-substituent causes the molecule to assume the coiled configuration:

Apart from this unexpected result, the data are in general agreement with the valency-deflexion hypothesis in regard to both the sequence of the compounds and the relative magnitude of the differences in respect of the property under discussion. Thus the value for the β-propyl acid is less than that for the β-methyl derivative; the value for β-ethylglutaric acid was not determined, but it would be expected to approximate closely to the figure for the propyl compound. The distance for the *gem*-dimethyl acid is, however, considerably less than for either of the mono-substituted acids, and this is in conformity both with the spatial theory of valency-deflexion and with the chemical evidence relating to these examples which has been adduced in support of it (Ingold, J., 1921, **119**, 305; 1922, **121**, 2676). Again, both on theoretical grounds and also by analogy with chemical evidence (Deshapande and Thorpe, J., 1922, **121**, 1430; Bains and Thorpe, 1923, **123**, 1206), it would be expected that the distance for the ββ-diethyl acid should be substantially less than for the dimethyl compound, whilst the value for the ββ-di-*n*-propyl derivative should be only very slightly less than for its diethyl analogue. It will be seen that the measurements bear out both these expectations, although the small recorded difference (0·01 Å.U.) between the distances for the diethyl and dipropyl acids cannot be regarded as possessing quantitative significance.

According to the elementary form of the deflexion hypothesis, the distance *r* for *cyclo*pentanediacetic acid would be expected to be slightly greater than that for the *gem*-dimethyl analogue; chemical evidence, however, indicates that it might be slightly smaller (Becker and Thorpe, J., 1920, **117**, 1579), and it would be possible to reconcile this discrepancy by means of a minor modification of the theory, provided that the value for the *cyclo*pentane acid is definitely greater than that for its open-chain analogue having the same number of carbon atoms, *viz.*, the diethyl acid. The data now recorded show that the distance for the *cyclo*pentane acid is actually slightly less than that for the *gem*-dimethyl acid, in agreement with the chemical indications, and is considerably greater than that for the *gem*-diethyl acid as theory requires. The distance for the

*cyclo*hexane acid should, of course, be less than for either the *gem*-dimethyl or the *cyclo*pentane acid (Beesley, Ingold, and Thorpe, J., 1915, **107**, 1080), and the measurements illustrate this. Finally, according to Baker and Ingold's conception (J., 1923, **123**, 122) of the influence of large rings in producing valency-deflexion, the value for *cyclo*heptanediacetic acid should be between the values for the *cyclo*hexane and *cyclo*pentane acids, since the maximum deflexion occurs with *cyclo*hexane. This also is shown by the data now submitted, and corresponds with the evidence already obtained by the study of *spiro*-compounds (*idem, ibid.*; Baker, J., 1925, **127**, 1678).

In conclusion, then, it may be stated that the measurements here recorded justify the suggestion of Ingold and Thorpe (this vol., p. 1318) that a study of the dissociation constants of β-substituted glutaric acids would confirm all the main features of the hypothesis of valency-deflexion by means of which for some 13 years past they have interpreted chemical relationships. Furthermore, it will be seen that where unexpected chemical observations have suggested modifications of the original hypothesis, the physical measurements confirm the modifications.

EXPERIMENTAL.

The substituted glutaric acids were prepared by known methods and carefully purified * by repeated crystallisations before use. The hydrogen potential measurements were carried out and standardised and the results calculated exactly as described in Part I, and in this connexion we have again to thank Messrs. W. R. Atkin and F. C. Thompson for the loan of their apparatus. The temperature was in all cases 25°.

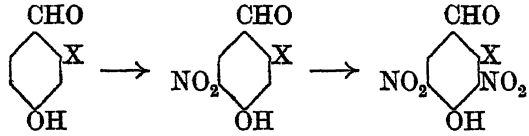
THE UNIVERSITY, LEEDS. [*Received, June 13th,* 1928.]



CCXCVI.—*Nitration of 4-Halogeno-2-hydroxy- and 2-Halogeno-4-hydroxy-benzaldehydes.*

By HERBERT HENRY HODGSON and THOMAS ALFRED JENKINSON.

THE mononitration of the 4-halogenosalicylaldehydes, hitherto not studied, produces only one series of nitro-derivatives, although dinitration is readily accomplished. The first nitro-group appears to enter position 5, since bromination of the products (I) affords the compounds (II) obtained by nitrating the 3-bromo-4-halogeno-salicylaldehydes (III). Since, however, the 4-halogenomononitro-2-hydroxybenzaldehydes were sufficiently volatile in steam to indicate that nitration might have taken place in the 3-position, the products (IV) were prepared for comparison. The sodium salts of (I) and (II) are yellow, whereas those of (IV) are bright red, indicating para- and ortho-nitrophenolic structures respectively. Dinitration of the 4-halogenosalicylaldehydes gives products which, for the same reasons, must be 3 : 5-dinitro-derivatives (V).

The 2-halogeno-4-hydroxybenzaldehydes are similarly converted into the 5-nitro- and 3 : 5-dinitro-compounds :

The brown colours produced by alkalis on the phenylhydrazones of certain of these substituted *m*-nitrobenzaldehydes are in accord with the observations of Chattaway and Clemo (J., 1923, **123**, 3043).

EXPERIMENTAL.

Nitration of 4-Chloro-2-hydroxybenzaldehyde.—(*a*) *Mononitration.* 4-Chloro-2-hydroxybenzaldehyde (2 g.), dissolved in glacial acetic acid (5 c.c.), was nitrated at 18° by addition of fuming nitric acid (0·5 c.c.) during 3 minutes, and kept for 8 hours at 60° with stirring. On pouring into water, a yellow, oily liquid separated which was steam-distilled, two fractions (150 c.c. each) being collected. The first contained unchanged aldehyde (0·2 g.) with a little nitro-product. From the second fraction (0·2 g.), *4-chloro-5-nitro-2-hydroxybenzaldehyde* (0·3 g.) was obtained, which crystallised from alcohol in small pale yellow needles, m. p. 116° (Found : Cl, 17·6. $C_7H_4O_4NCl$ requires Cl, 17·6%), sparingly soluble in water and light petroleum, but readily soluble in the usual solvents; the product does not reduce ammoniacal silver nitrate or Fehling's solution or react with bromine water. The *phenylhydrazone* crystallises from alcohol in small light orange-yellow needles, m. p. 188° (decomp.) (Found : Cl, 12·0. $C_{13}H_{10}O_3N_3Cl$ requires Cl, 12·2%), which give golden-brown solutions with caustic alkalis. The *p-nitrophenylhydrazone* crystallises from alcohol or glacial acetic acid in bright yellow micro-needles, m. p. 294° (decomp.) (Found : Cl, 10·5. $C_{13}H_9O_5N_4Cl$ requires Cl, 10·5%), which give cherry-red colours with concentrated alkalis, turning bluer on dilution. The *semicarbazone* crystallises from dilute acetic acid in very pale yellow micro-needles, which decompose above 300° (Found : Cl, 13·5. $C_8H_7O_4N_4Cl$ requires Cl, 13·7%).

(*b*) *Dinitration.* The aldehyde (0·75 g.) dissolved in glacial acetic acid (8 c.c.) is added all at once to nitric acid (8 c.c.; 91%) and, after the violent reaction has abated, the mixture is warmed at 100° for 5 minutes, kept for 15 minutes, poured into water, and steam-distilled to remove volatile mononitro-product. *4-Chloro-3 : 5-dinitro-2-hydroxybenzaldehyde* (1 g.) crystallises from water in slender, pale golden-yellow needles, m. p. 153° (Found : Cl, 14·5.

$C_7H_3O_6N_2Cl$ requires Cl, 14·4%), which neither reduce Fehling's solution nor give a precipitate with bromine water. The *phenylhydrazone* crystallised from alcohol in light brown micro-crystals, m. p. 219° (Found: Cl, 10·3. $C_{13}H_9O_5N_4Cl$ requires Cl, 10·55%), and gives a golden-brown colour with alkalis. The p-*nitrophenylhydrazone* crystallises from dilute acetic acid in light brown micro-crystals, m. p. 286° (decomp.) (Found: Cl, 9·1. $C_{13}H_8O_7N_5Cl$ requires Cl, 9·3%), and with aqueous and alcoholic sodium hydroxide gives a cherry-red colour which turns a bluer shade on dilution. The *semicarbazone* separates from dilute acetic acid in light yellow micro-crystals, m. p. 225° (decomp.) (Found: Cl, 11·5. $C_8H_6O_6N_5Cl$ requires Cl, 11·7%).

Nitration of 2-Chloro-4-hydroxybenzaldehyde.—(*a*) *Mononitration.* The aldehyde (3 g.), dissolved in glacial acetic acid (15 c.c.), was nitrated by the gradual addition of nitric acid (3 g.; 63%), the mixture then being kept at 35—40° for 2 hours. The *2-chloro-5-nitro-4-hydroxybenzaldehyde* was removed by steam-distillation and crystallised from alcohol in colourless needles, m. p. 125° (Found: Cl, 17·6. $C_7H_4O_4NCl$ requires Cl, 17·6%), only slightly soluble in water and less soluble in the usual solvents than the initial aldehyde. The *phenylhydrazone* crystallised from alcohol in silky, dark purple needles, m. p. 166° (slight decomp.) (Found: Cl, 12·1%), which gave no colour with aqueous but a red with alcoholic alkalis. The p-*nitrophenylhydrazone* crystallised from glacial acetic acid in small, silky, deep orange needles, m. p. 266° (decomp.) (Found: Cl, 10·4%), which gave a violet-red colour with aqueous and alcoholic alkalis, turning bluer on dilution. The *semicarbazone* crystallised from dilute acetic acid in light orange micro-needles, m. p. 266° (decomp.) (Found: Cl, 13·6%).

(*b*) *Dinitration.* The aldehyde (3 g.), dissolved in glacial acetic acid (10—15 c.c.), was added gradually (10 minutes) to nitric acid (6 g.; 63%); the mixture was kept at 60° for 2 hours, poured into water, and steam-distilled. The non-volatile *2-chloro-3 : 5-dinitro-4-hydroxybenzaldehyde* crystallised from water in pale yellow, massive, prismatic crystals, m. p. 93° (Found: Cl, 14·3%), sparingly soluble in cold but readily soluble in hot water. The *phenylhydrazone* crystallised from alcohol in small, lustrous, brownish-purple needles, m. p. 210° (decomp.) (Found: Cl, 10·4%), which give a red colour with aqueous-alcoholic alkalis. The p-*nitrophenylhydrazone* crystallised from dilute acetic acid in reddish-brown micro-needles, m. p. 267° (decomp.) (Found: Cl, 9·1%), which gave a violet-red colour with alkalis, changing to a fine violet on dilution. The *semicarbazone* crystallised from dilute acetic acid in light brown micro-needles, m. p. 192° (decomp.) (Found: Cl, 11·5%).

Reimer–Tiemann Reaction with 3-Chloro-2-bromo- and 2 : 3-Di-bromo-phenols.—The procedure employed was that in the authors' previous paper (J., 1927, 1740), but the yields were only moderate. *4-Chloro-3-bromo-2-hydroxybenzaldehyde* forms colourless needles, m. p. 124° (0·1000 g. gave 0·1390 g. of AgX.* Calc.: 0·1407 g.), having a faint sweet odour, slowly volatile in steam, sparingly soluble in water but readily soluble in the usual organic solvents; the *phenylhydrazone*, colourless needles, m. p. 204° (0·1000 g. gave 0·1010 g. AgX. Calc.: 0·1018 g.), gave a pale yellow solution with aqueous-alcoholic alkalis; the p-*nitrophenylhydrazone*, orange micro-needles, m. p. 298° (decomp.), gave a ruby-red colour with aqueous alkalis. *3-Chloro-2-bromo-4-hydroxybenzaldehyde*, colourless needles, m. p. 177° (0·1000 g. gave 0·1415 g. AgX. Calc.: 0·1407 g.), is very slowly volatile in steam and resembles its isomeride in solubilities; the p-*nitrophenylhydrazone*, dark crimson micro-needles, m. p. 253° (decomp.) (0·1000 g. gave 0·0900 g. AgX. Calc.: 0·0895 g.), gave a deep purplish-red colour with aqueous alkalis. *3 : 4-Dibromo-2-hydroxybenzaldehyde* forms colourless needles, m. p. 129° (Found: Br, 56·9. $C_7H_4O_2Br_2$ requires Br, 57·1%), volatile in steam, and having a faint sweet odour. The p-*nitrophenylhydrazone*, orange micro-needles, decomp. above 220° (Found: Br, 38·3. $C_{13}H_9O_3N_3Br_2$ requires Br, 38·55%), gives a ruby-red colour with alkalis, becoming bluer on dilution.

2 : 3-Dibromo-4-hydroxybenzaldehyde, colourless needles, m. p. 192° (Found: Br, 57·0%), is only very slightly volatile in steam and odourless. The p-*nitrophenylhydrazone*, vermilion-red micro-needles, m. p. 254° (decomp.) (Found: Br, 38·3%), gave a deep red colour with aqueous alkalis.

Nitration of 4-Chloro-3-bromo-2-hydroxybenzaldehyde.—The aldehyde (1·5 g.), dissolved in glacial acetic acid (5 c.c.), was nitrated at 60—65° during 2 hours with nitric acid (0·5 g.; *d* 1·5). The *4-chloro-3-bromo-5-nitro-2-hydroxybenzaldehyde* crystallised from alcohol in yellow prisms, m. p. 137° (Found: Cl + Br, 40·8. Calc.: 41·2%). The *phenylhydrazone* crystallised from alcohol in bright yellow needles, m. p. 229° (decomp.) (Found: Cl + Br, 31·3. Calc.: 31·2%), and gave brown colours with alkalis.

Bromination of 4-Chloro-5-nitro-2-hydroxybenzaldehyde.—The aldehyde (0·5 g.) in glacial acetic acid (2 c.c.) was treated with 3 c.c. of a solution of bromine (2 g.) in the same solvent (10 c.c.), the mixture warmed for 5 minutes on the water-bath, diluted with water until the slight turbidity just disappeared on heating, and allowed to cool slowly; 4-chloro-3-bromo-5-nitro-2-hydroxybenzaldehyde separated in yellow prisms, m. p. 137° (Found: Cl + Br, 40·9%),

* AgX = mixed silver halides.

unaltered when mixed with foregoing product. The yellow *sodium* salt was sparingly soluble in aqueous sodium carbonate. The *phenylhydrazone* crystallised from alcohol in bright yellow needles, m. p. 229° (decomp.) (Found: Cl + Br, 31·4%); a mixed m. p. with the corresponding product above indicated identity.

Preparation of 4-*Chloro*-5-*bromo*-2-*hydroxybenzaldehyde*.—To *m*-chlorophenol (23 g.), dissolved in chloroform (70 c.c.), bromine (9 c.c.) dissolved in chloroform (60 c.c.) was gradually added with shaking. After the free bromine had disappeared, the mixture was refluxed with 20% aqueous sodium hydroxide (200 c.c.) for 4 hours, the chloroform removed by means of steam, the mixture acidified, and again steam-distilled; 4-*chloro*-5-*bromo*-2-*hydroxybenzaldehyde* readily passed over: colourless needles, m. p. 125° (0·0838 g. gave 0·1181 g. AgX. Calc.: 0·1180 g.), from dilute acetic acid. The *phenylhydrazone* crystallised from alcohol in colourless needles, m. p. 200° (Found: Cl + Br, 35·2. Calc.: 35·5%). The p-*nitrophenylhydrazone* crystallised from glacial acetic acid in small, light brown needles, m. p. 280° (decomp.) (Found: Cl + Br, 30·9. Calc.: 31·2%), which gave a blue cherry-red colour with aqueous and alcoholic alkalis.

Nitration of 4-*Chloro*-5-*bromo*-2-*hydroxybenzaldehyde*.—The aldehyde (2 g.) was dissolved in warm acetic anhydride (2 c.c.) and obtained as a paste of fine crystals by chilling; it was then treated gradually with diacetylorthonitric acid (2 c.c.), maintained at 50° for 15 minutes, and kept over-night; 4-*chloro*-5-*bromo*-3-*nitro*-2-*hydroxybenzaldehyde* separated, and crystallised from alcohol in large, pale yellow prisms, m. p. 116° (Found: Cl + Br, 41·3. Calc.: 41·2%), giving a bright red *sodium* salt. The *phenylhydrazone* crystallised from alcohol in small, orange needles, m. p. 241° (decomp.) (Found: Cl + Br, 31·3%). The mixed m. p.'s with the isomerides above were depressed. Orange-red colours were given by aqueous and alcoholic alkalis.

Nitration of 2-*Chloro*-3-*bromo*-4-*hydroxybenzaldehyde*.—This process was carried out with quantities as for 4-chloro-3-bromo-2-hydroxybenzaldehyde, but at 30—40° for one hour. 2-*Chloro*-3-*bromo*-5-*nitro*-4-*hydroxybenzaldehyde* crystallised from glacial acetic acid in long, golden-yellow, silky needles, m. p. 140° (Found: Cl + Br, 40·9%). Bromination as above of the mononitration product of 2-chloro-4-hydroxybenzaldehyde gave an identical product, m. p. and mixed m. p. 140°. The identical *phenylhydrazones* crystallised from alcohol in very deep purple plates, m. p. 205° (decomp.) (Found: Cl + Br, 30·9, 31·0. Calc.: 31·2%), and gave brownish-red colours with aqueous and alcoholic alkalis.

Nitration of 4-*Bromo*-2-*hydroxybenzaldehyde*.—(*a*) *Mononitration.*

The aldehyde (3 g.) was nitrated as for the 2-chloro-4-hydroxy-compound, 6 g. of nitric acid being used. The product, 4-*bromo*-5-*nitro*-2-*hydroxybenzaldehyde*, was entirely volatile in steam and crystallised from alcohol in very pale yellow rosettes, m. p. 128° (Found: Br, 32·3. $C_7H_4O_4NBr$ requires Br, 32·5%), which were slightly soluble in cold, but readily soluble in hot water and in the usual solvents. The *phenylhydrazone* crystallised from alcohol in small, orange needles, m. p. 189° (Found: Br, 23·6. $C_{13}H_{10}O_3N_3Br$ requires Br, 23·8%), its yellow solution being deepened by alkalis. The p-*nitrophenylhydrazone*, yellow micro-needles, m. p. 301° (decomp.) (Found: Br, 21·2. $C_{13}H_9O_5N_4Br$ requires Br, 21·0%), gave a cherry-red colour with alkalis, turning bluer on dilution. The *semicarbazone*, pale yellow micro-needles, decomposed above 210° (Found: Br, 26·2. $C_8H_7O_4N_4Br$ requires Br, 26·4%).

(*b*) *Dinitration.* The aldehyde (2 g.), dissolved in glacial acetic acid (5 c.c.), was nitrated at 0° with fuming nitric acid (3 c.c.), and heated at 100° for 10 minutes; 4-*bromo*-3 : 5-*dinitro*-2-*hydroxybenzaldehyde* was separated from volatile products by steam-distillation and then crystallised from alcohol in colourless plates and from dilute acetic acid in colourless needles, m. p. 143° (Found: Br, 27·3. $C_7H_3O_6N_2Br$ requires Br, 27·5%). The *phenylhydrazone* crystallised from alcohol in small orange needles, m. p. 209° (decomp.) (Found: Br, 20·8. $C_{13}H_9O_5N_4Br$ requires Br, 21·0%), and its yellow solution was turned brown by caustic alkalis. The p-*nitrophenylhydrazone*, light orange micro-needles, m. p. 250° (decomp.) (Found: Br, 18·6. $C_{13}H_8O_7N_5Br$ requires Br, 18·77%), gave a deep red colour in concentrated solution with caustic alkalis, which became bluer on dilution. The *semicarbazone*, light yellow micro-needles, had m. p. 224° (decomp.) (Found: Br, 22·7. $C_8H_6O_6N_5Br$ requires Br, 23·0%).

Nitration of 2-*Bromo*-4-*hydroxybenzaldehyde.*—(*a*) *Mononitration.* Quantities and procedure as for the previous isomeride. 2-*Bromo*-5-*nitro*-4-*hydroxybenzaldehyde* was much more slowly volatile in steam than the chloro-analogue and also more soluble in water; it crystallised from alcohol in pale yellow needles, m. p. 131° (Found: Br, 32·7. $C_7H_4O_4NBr$ requires Br, 32·5%), gave an orange-red *silver* salt and a bright green *copper* salt. The *phenylhydrazone*, fine, silky, purple needles, had m. p. 181° (decomp.) (Found: Br, 23·5. $C_{13}H_{10}O_3N_3Br$ requires Br, 23·8%), and gave a reddish-brown colour with aqueous alkalis. The p-*nitrophenylhydrazone*, orange micro-needles, m. p. 265° (decomp.) (Found: Br, 20·8%), gave violet-red colours with alkalis, turning bluer on dilution. The *semicarbazone*, light orange micro-needles, had m. p. 267° (decomp.) (Found: Br, 26·1%).

(*b*) *Dinitration.* The aldehyde (2 g.), dissolved in glacial acetic acid

(15 c.c.), was nitrated with 63% nitric acid (3 g.) in the cold and then kept at 50° for 3 hours; 2-*bromo*-3 : 5-*dinitro*-4-*hydroxybenzaldehyde* was non-volatile in steam and crystallised from water in massive pale yellow prisms, m. p. 110° (Found: Br, 27·4%), slightly soluble in water; it gave a deep golden-brown colour with ferric chloride, but did not reduce ammoniacal silver nitrate or Fehling's solution. The brown, flocculent *silver* salt was soluble in water. The *phenylhydrazone* crystallised from alcohol in dark purple plates, m. p. 186° (decomp.) (Found: Br, 20·8%), the golden-brown solution being changed to reddish-brown by caustic alkalis. The p-*nitrophenylhydrazone*, brown micro-needles, m. p. 248° (decomp.) (Found: Br, 18·9%), gave violet-red colours with caustic alkalis, turning bluer on dilution. The *semicarbazone*, orange micro-needles, had m. p. 188° (decomp.) (Found: Br, 22·9%).

Nitration of 2 : 3-dibromo-4-hydroxybenzaldehyde gave 2 : 3-*dibromo*-5-*nitro*-4-*hydroxybenzaldehyde*, m. p. 155° (Found: Br, 49·0. $C_7H_3O_4NBr_2$ requires Br, 49·2%), identical with the brominated product from the mono-nitrated 2-bromo-4-hydroxybenzaldehyde, m. p. and mixed m. p. 155°, the procedures being as for the chloro-analogues. Their identical *phenylhydrazones* crystallised from alcohol in deep purple parallelepipeds, m. p. 204° (decomp.) (Found: Br, 38·3, 38·6. $C_{13}H_9O_3N_3Br_2$ requires Br, 38·5%), and gave brownish-red colours with aqueous and alcoholic alkalis.

Nitration of 3 : 4-dibromo-2-hydroxybenzaldehyde gave 3 : 4-*dibromo*-5-*nitro*-2-*hydroxybenzaldehyde*, which crystallised from alcohol in pale yellow needles, m. p. 114° (Found: Br, 48·8%), and did not depress the m. p. of the product obtained by the bromination of the mononitrated 4-bromo-2-hydroxybenzaldehyde (above).

4 : 5-*Dibromo*-2-*hydroxybenzaldehyde*, colourless needles, m. p. 132° (Found: Br, 57·2%), was prepared in the same way as 4-chloro-5-bromo-2-hydroxybenzaldehyde (*loc. cit.*). It gives a yellow *silver* salt. The p-*nitrophenylhydrazone* crystallised from glacial acetic acid in deep orange-brown micro-needles, m. p. 266° (decomp.) (Found: Br, 38·4%), and gave deep bluish-red colours with alkalis. 4 : 5-*Dibromo*-3-*nitro*-2-*hydroxybenzaldehyde* crystallised from alcohol in pale yellow prisms, m. p. 118° (Found: Br, 49·1%). The *silver* salt is deep orange. The *phenylhydrazone* crystallised from alcohol in orange needles, m. p. 236° (decomp.) (Found: Br, 38·4%), and gave a deep red colour with aqueous caustic alkalis.

Nitration of 4-*Iodo*-2-*hydroxybenzaldehyde.*—(*a*) *Mononitration.* The aldehyde (2 g.), dissolved in glacial acetic acid (6 c.c.), was treated with fuming nitric acid (3 g.), kept for 2½ hours, and then heated at 45° for 5 minutes; the mixture was diluted with water, nearly neutralised by alkali, and steam-distilled.

4-*Iodo*-5-*nitro*-2-*hydroxybenzaldehyde* (1·5 g.), which passed over, crystallised from alcohol in small golden-yellow needles, m. p. 118° (Found : I, 42·9. $C_7H_4O_4NI$ requires I, 43·3%). The yellow *silver* salt was only sparingly soluble in water. The *phenylhydrazone*, small, old-gold needles, had m. p. 177° (decomp.) (Found : I, 33·0. $C_{13}H_{10}O_3N_3I$ requires I, 33·2%) and gave a brown colour with alkalis. The p-*nitrophenylhydrazone*, bright yellow micro-needles, m. p. 297° (decomp.) (Found : I, 29·3. $C_{13}H_9O_5N_4I$ requires I, 29·7%), gave violet-red colours with alkalis, turning bluer on dilution. The *semicarbazone*, pale yellow micro-needles, decomposed at 230—240° (Found : I, 35·9. $C_8H_7O_4N_4I$ requires I, 36·2%).

3-*Bromo*-4-*iodo*-5-*nitro*-2-*hydroxybenzaldehyde* crystallised from alcohol in small pale yellow needles, m. p. 145° (Found : Br + I, 55·9. $C_7H_3O_4NBrI$ requires Br + I, 55·6%).

(*b*) *Dinitration.* In the above process the residue (0·5 g.) after steam-distillation was 4-*iodo*-3 : 5-*dinitro*-2-*hydroxybenzaldehyde*, which crystallised from alcohol in small, brown needles, m. p. 160° (Found : I, 37·8. $C_7H_3O_6N_2I$ requires I, 37·6%). The *silver* salt was light orange. The *phenylhydrazone*, small, light brown needles, had m. p. 229° (decomp.) (Found : I, 30·0. $C_{13}H_9O_5N_4I$ requires I, 29·7%) and gave brown colours with alkalis. The p-*nitrophenylhydrazone*, brownish-orange micro-needles, m. p. 257° (decomp.) (Found : I, 26·4. $C_{13}H_8O_7N_5I$ requires I, 26·8%), gave deep violet-red colours with alkalis. The *semicarbazone*, light brownish-yellow micro-needles, decomposed when heated (Found : I, 31·8. $C_8H_6O_6N_5I$ requires I, 32·15%).

5-*Bromo*-4-*iodo*-2-*hydroxybenzaldehyde* is slowly volatile in steam and crystallises from alcohol in very pale yellow needles, m. p. 117° (0·1100 g. gave 0·1428 g. AgX. Calc. : 0·1422 g.), and its rather insoluble *sodium* salt in golden spangles. It gives a yellow *silver* salt. The *phenylhydrazone* crystallises in slender, pale yellow needles, m. p. 151°, and the p-*nitrophenylhydrazone* in orange micro-needles, m. p. 266° (decomp.), which give deep bluish-red colours with aqueous alkalis.

5-*Bromo*-4-*iodo*-3-*nitro*-2-*hydroxybenzaldehyde* crystallises from alcohol in small, golden-yellow prisms, m. p. 153° (0·1042 g. gave 0·1180 g. AgX. Calc. : 0·1185 g.), and gives an orange *silver* salt. The *phenylhydrazone* crystallises from alcohol in deep orange needles, m. p. 245° (decomp.) (0·1000 g. gave 0·0922 g. AgX. Calc. : 0·0915 g.), and gives a deep red colour with aqueous caustic alkalis.

Nitration of 2-*Iodo*-4-*hydroxybenzaldehyde.*—(*a*) *Mononitration.* A method giving better results than the foregoing was to nitrate the aldehyde (4·5 g.), dissolved in acetic anhydride (12 c.c.), with diacetylorthonitric acid (4 c.c.) added in two portions, the temperature

not being allowed to exceed 40—50°. After being kept for 15 minutes at 50°, the mixture was diluted and steam-distilled; *2-iodo-5-nitro-4-hydroxybenzaldehyde*, which passed over, crystallised from alcohol in small, colourless prisms, m. p. 162° (Found: I, 43·5. $C_7H_4O_4NI$ requires I, 43·3%). The orange *silver* salt was sparingly soluble in water. The *phenylhydrazone*, very dark purple needles, had m. p. 204° (decomp.) (Found: I, 33·3%) and gave golden-brown solutions with alcoholic alkalis. The p-*nitrophenylhydrazone*, reddish-brown micro-needles, m. p. 273° (Found: I, 29·8%), gave violet-red colours with alkalis. The *semicarbazone*, light brown micro-needles, had m. p. 211° (decomp.) (Found: I, 36·6%).

3-Bromo-2-iodo-5-nitro-4-hydroxybenzaldehyde crystallises from dilute acetic acid in pale yellow needles, m. p. 178° (Found: Br + I, 55·8%). An authentic specimen had m. p. 178°.

(*b*) *Dinitration.* Procedure as for the analogues. *2-Iodo-3:5-dinitro-4-hydroxybenzaldehyde* crystallised in massive yellow prisms, m. p. 162° (Found: I, 37·5%). The colours of the *silver* and *copper* salts were canary-yellow and bright green, respectively. The *phenylhydrazone*, deep brownish-purple needles, had m. p. 197° (decomp.) (Found: I, 30·0%), and gave a reddish-brown solution with alkalis. The p-*nitrophenylhydrazone*, dark-red micro-needles, m. p. 240° (decomp.) (Found: I, 27·2%), gave a reddish-violet colour with aqueous sodium hydroxide, which changed to reddish-pink on heating. The *semicarbazone*, orange micro-needles, had m. p. 205° (decomp.) (Found: I, 32·4%).

3-Bromo-2-iodo-4-hydroxybenzaldehyde crystallises from alcohol in pale yellow prisms, m. p. 204° (Found: AgX, 129·7. $C_7H_4O_2BrI$ requires AgX, 129·4%).

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD. [*Received, June 16th*, 1928.]

CCXCVII.—*The Quadrivalency of Selenium. Part I. 4-Carboxydiphenyl and* p-*Carboxyphenyl Methyl Selenoxides.*

By WILSON ROBINSON GAYTHWAITE, JOSEPH KENYON, and HENRY PHILLIPS.

THE resolution of 4′-amino-4-methyldiphenyl sulphoxide (I) and *m*-carboxyphenyl methyl sulphoxide (II) into their optically active forms (Harrison, Kenyon, and Phillips, J., 1926, 2079) provided

conclusive experimental evidence that the double bond between sulphur and oxygen in these compounds is unsymmetrical and can

(I.) (II.)

therefore be considered to be a semipolar double bond. In order to obtain evidence as to the nature of the bonds linking the selenium and oxygen atoms of selenoxides, attempts have now been made to resolve *phenyl* p-*tolyl selenoxide* (III), 4-*carboxydiphenyl selenoxide* (IV), and p-*carboxyphenyl methyl selenoxide* (V), but they

(III.) (IV.) (V.)

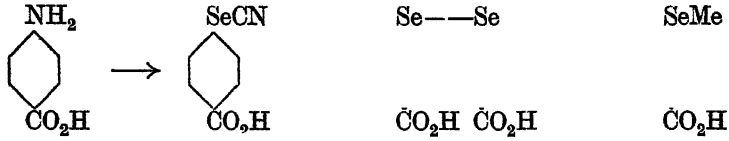
have been unsuccessful. This failure was unexpected since the sulphoxides were resolved without difficulty, and the resolution of *dl*-phenylmethylselenetine *d*-bromocamphorsulphonate by Pope and Neville (J., 1902, **81**, 1552) proves that quadrivalent selenium has a tetrahedral environment.

The chemical evidence at our disposal suggests that the linking between the selenium and oxygen atoms may be partly polar in character. For example, the selenoxides now described, to a greater degree even than the sulphoxides of similar constitution, are much more soluble in acids than in water.

The selenoxides, however, differ from sulphoxides in one important respect. Sulphoxides are so readily oxidised with potassium permanganate to the corresponding sulphones that it is often difficult, even when mild oxidising reagents are used, to arrest the oxidation of a sulphide at the sulphoxide stage. It is noteworthy, therefore, that the selenoxides described could not be oxidised to selenones by potassium permanganate, and also that with the exception of diphenyl selenone (Krafft and Vorster, *Ber.*, 1893, **26**, 2820), which has the properties of a peroxide and hence differs considerably from its inert sulphur analogue, no reference to the isolation of selenones can be found in the literature. This particular reluctance on the part of a selenium atom, linked to two univalent groups and to oxygen, to pass to the sexavalent condition is also illustrated by the crystallisation of benzeneseleninic acid as a nitrate from moderately concentrated nitric acid (which would oxidise benzenesulphinic acid to the sulphonic acid); moreover, although the interaction of ethyl iodide and silver sulphite leads to the formation of the unsymmetrical ethyl ethanesulphonate, yet silver selenite, under the same conditions, yields the symmetrical diethyl selenite (Michaelis and Landmann, *Annalen*, 1887, **241**, 150).

It can therefore be concluded that the linking between the

selenium and oxygen atoms of a selenoxide may be partly polar in character, but at the same time may tend to utilise or render inert the remaining combining capacity of the selenium atom in a manner which suggests that the linking may not be an unsymmetrical semipolar double bond. The partly polar character of the linking might be accounted for by assuming that the oxygen atom is linked to the selenium atom by two semipolar single bonds (Prideaux, *Chem. and Ind.*, 1923, **42**, 672; Sugden, J., 1927, 1173); until the electronic structure of such bonds is precisely defined, however, it is difficult to visualise why two such bonds, when exerted together towards the same atom, should differ from a semipolar double bond, and further, why, by exerting two semipolar single bonds, the selenium atom should lose combining capacity.



These difficulties could be overcome by assuming that two selenium electrons and one oxygen electron are concerned with the formation of each semipolar single bond, but that only one of the electrons—a selenium electron—is shared by both atoms, the remaining selenium electron and oxygen electron of the trio being assumed to be in some way essential for the formation of a semipolar single bond and no longer available for purposes of reaction. By the aid of these assumptions it would be possible to explain, not only the reluctance on the part of the selenium atom to become sexavalent, but also the possible symmetrical disposition of the oxygen atom in space with respect to the remainder of the selenoxide molecule. To determine whether this hypothesis is valid other selenoxides are being prepared and investigated.

Phenyl *p*-tolyl selenoxide was prepared by the action of alkalis on phenyl *p*-tolyl selenide dibromide. On cooling warm solutions of this selenoxide in aqueous solutions of *d*-camphorsulphonic acid, indefinite mixtures of the two separated, and the selenoxide recovered from the mother-liquors was optically inactive; but when equimolecular proportions were mixed in warm, dry ethyl acetate crystals were deposited which, by titration, were found to agree closely in composition with that demanded for the *d*-camphorsulphonate of the selenoxide. The rotatory powers of these " salts " in dry ethyl acetate were, however, identical with the rotatory powers of the solutions obtained by dissolving *d*-camphorsulphonic acid and the selenoxide in ethyl acetate in the same proportions as they occurred in the " salts."

4-Carboxydiphenyl selenoxide was prepared by the oxidation of phenyl *p*-tolyl selenide with an excess of potassium permanganate, and was not contaminated by the corresponding selenone. It gave well-defined, crystalline salts with brucine, *l*-menthylamine, and *d*-α-phenylethylamine, the properties of the salts being un-

changed by repeated crystallisation from various solvents. The selenoxide regenerated from the salts was, in every instance, optically inactive. Although, when free, 4-carboxydiphenyl selenoxide does not form a dihydroxide, its salt with *d*-α-phenylethylamine was carefully examined after it had been in contact with water or wet solvents, in order to make certain that the failure to obtain resolution was not due to the addition of water to the possibly unsymmetrical selenoxide, giving rise to a symmetrical dihydroxide. No evidence for such combination could be obtained, and no change in the rotatory power of a dry specimen of this salt could be produced by recrystallising it from dry ethyl acetate.

p-Carboxyphenyl methyl selenoxide was prepared from the dibromide of the corresponding selenide, which was synthesised according to the following scheme. It gave a brucine salt which furnished no evidence that it was a mixture of stereoisomerides.

EXPERIMENTAL.

Phenyl p-*tolyl selenide* was obtained by the method used by Krafft and Vorster (*loc. cit.*) for the preparation of diphenyl selenide. Phenyl *p*-tolyl sulphone (116 g.), which has m. p. 127—128° and not 124·5° as quoted in the literature, and powdered selenium (40 g.) were heated in a metal-bath until there was an active evolution of sulphur dioxide: after 2—3 hours the temperature was raised, and phenyl *p*-tolyl selenide distilled at 305—312°. By redistillation it was obtained as an almost odourless, pale yellow, mobile liquid, b. p. 175—178°/20 mm.; yield 35 g. (Found: C, 63·2; H, 4·9. $C_{13}H_{12}Se$ requires C, 63·1; H, 4·8%). The *dibromide* was prepared by the addition of bromine (6·5 g.) to a cooled solution of the selenide (10 g.) in carbon disulphide (20 c.c.). After standing for an hour, the crystalline material (14 g., m. p. 143—144°) was removed by filtration and recrystallised from carbon disulphide whereby it was obtained as long, orange-red, glistening needles, m. p. 149—150° (Found: Br, 39·2. $C_{13}H_{12}SeBr_2$ requires Br, 39·4%).

Phenyl p-*tolyl selenoxide* was readily obtained by trituration of the dibromide (7·5 g.) with sodium hydroxide solution (15 c.c. of 15%) until the reddish-brown paste became converted into a white, granular powder; this was filtered off, washed, dried, and crystallised from benzene, from which it separated in clusters of feathery needles,

m. p. 131—133°; yield 4 g. The selenoxide was also prepared directly from the selenide by the action of a boiling solution of potassium permanganate. When the theoretical amount of potassium permanganate was used the yield of selenoxide was only about 25% because further oxidation of a portion of the material to 4-carboxydiphenyl selenoxide took place and therefore a considerable proportion of the selenide was recovered unchanged. Phenyl *p*-tolyl selenoxide prepared in this way had m. p. 131—133° either alone or when mixed with that prepared from the dibromide (Found: C, 59·7; H, 4·5. $C_{13}H_{12}OSe$ requires C, 59·3; H, 4·5%). The selenoxide, when triturated with saturated aqueous hydrobromic acid, was rapidly transformed into the orange-red dibromide, which after crystallisation from carbon disulphide had m. p. 149—1[illegible]° (decomp.) either alone or when mixed with the dibromide prepa[illegible] directly from the selenide.

Attempted Resolution of Phenyl p-*Tolyl Selenoxide by Mean*[illegible] d-*Camphorsulphonic Acid.*—Phenyl *p*-tolyl selenoxide (1·3 g.) [illegible] added to a solution of *d*-camphorsulphonic acid (3 g.) in water (5 c.c.), and the mixture heated on the steam-bath for a few minutes until solution was almost complete. After cooling, the crystalline material was filtered off and found to consist of almost pure selenoxide which was optically inactive. The recovered selenoxide was therefore dissolved in a solution of *d*-camphorsulphonic acid (2 g.) in ethyl alcohol (12 c.c.), and the solution allowed to crystallise. After decomposition of the filtrate with sodium carbonate, 0·18 g. of selenoxide was obtained which proved to be optically inactive.

The selenoxide (2·6 g.) and *d*-camphorsulphonic acid (2·3 g.) were dissolved in hot, dry ethyl acetate. The crystals which separated on cooling the resulting clear solution had α_{5461} + 0·32° in dry ethyl acetate (c = 1·1175; l = 2·0), whence $[\alpha]_{5461}$ + 14·3°. By titration, 0·2235 g. of the crystals was found to contain 0·0908 g. of *d*-camphorsulphonic acid, whereas if the crystals had been the pure salt of the selenoxide they should have contained 0·1045 g. of the acid. A solution prepared by making up 0·1327 g. of the selenoxide and 0·0908 g. of *d*-camphorsulphonic acid to 20 c.c. with dry ethyl acetate had α_{5461} + 0·33° (l = 2·0) whence $[\alpha]_{5461}$ + 14·7°. Hence it was concluded that no resolution of the selenoxide was taking place. The filtrate from the crystals described above deposited on standing a second crop which had α_{5461} + 0·30° in dry ethyl acetate (c = 1·0725; l = 2·0) whence $[\alpha]_{5461}$ + 13·9°. This second crop contained slightly more than the theoretical quantity of *d*-camphorsulphonic acid, since 0·2847 g. contained 0·1409 g. of acid (theory requires 0·1331 g.).

4-Carboxydiphenyl selenoxide was prepared by boiling an aqueous

suspension of phenyl *p*-tolyl selenide and potassium permanganate for several hours. The manganese mud was dissolved and the 4-carboxydiphenyl selenoxide precipitated by the passage of sulphur dioxide. The reaction mixture was filtered and the insoluble portion macerated with dilute sodium carbonate solution. In this way, the products of the oxidation were separated into phenyl *p*-tolyl selenoxide and 4-carboxydiphenyl selenoxide. On the addition of dilute sulphuric acid to the sodium carbonate extract, 4-carboxydiphenyl selenoxide separated and was obtained, after crystallisation from alcohol, as a microcrystalline powder, m. p. 253—255° (decomp.) (Found : C, 53·5; H, 3·4; equiv., by titration, 292. $C_{13}H_{10}O_3Se$ requires C, 53·2; H, 3·4%; equiv., 293).

4-*Carboxydiphenyl selenide* was prepared by warming a mixture of 4-carboxydiphenyl selenoxide (0·5 g.), acetic acid (15 c.c.), and zinc dust (0·3 g.) on a steam-bath for 3 hours. The hot filtered solution was diluted with water and the selenide (0·25 g.) separated as pale yellow, glistening leaflets, m. p. 182—184° (without decomp.) (Found : equiv., by titration, 279. $C_{13}H_{10}O_2Se$ requires equiv., 277).

4-*Carboxydiphenyl selenide dibromide* was prepared (*a*) by the addition of aqueous hydrobromic acid to a warm solution of 4-carboxydiphenyl selenoxide (0·5 g.) in acetic acid, from which it separated as yellow, microcrystalline needles (0·6 g.), which turn deep red and soften between 180—190° and melt at 208—210°; (*b*) by the addition of a solution of bromine (0·13 g.) in carbon tetrachloride (1 c.c.) to a warm solution of 4-carboxydiphenyl selenide (0·21 g.) in the same solvent (50 c.c.). The dibromide (0·28 g.), m. p. 205—207°, crystallised on cooling the mixed solutions (0·1534 g. neutralised 0·0560 g. KOH on decomposition. Calc.: 0·0588 g.).

Attempted Resolution of 4-Carboxydiphenyl Selenoxide.—The *brucine* salt of 4-carboxydiphenyl selenoxide was prepared in warm acetone solution, from which it separated on cooling as very small needles, m. p. 130° (decomp.). The *strychnine* salt was too unstable to be of service. The l-*menthylamine* salt crystallised from alcohol in needles, m. p. 220—222° (decomp.). Its rotatory power, $[\alpha]_{5461}$ — 16·4° ($c = 0{\cdot}8415$ in ethyl alcohol; $l = 2{\cdot}0$), and m. p. remained unchanged after repeated crystallisation from alcohol. The d-*α-phenylethylamine* salt was prepared in aqueous solution, from which it separated in clusters of feathery needles, m. p. 194—195° (decomp.). Recrystallisation from alcohol, water, or ethyl acetate caused no change in either its m. p. or its rotatory power, which was $[\alpha]_{5461}$ — 12·7° ($c = 1{\cdot}139$ in pyridine; $l = 2{\cdot}0$). This salt was also heated at 98°/15 mm., but such treatment did not cause it to lose weight or to change in rotatory power.

4 : 4′-*Dicarboxydiphenyl diselenide* was prepared by the method used by Bauer (*Ber.*, 1913, **46**, 92) for the preparation of analogous compounds. To a vigorously stirred, cooled solution of *p*-aminobenzoic acid (46 g.) in water (750 c.c.) and concentrated hydrochloric acid (83 c.c.), sodium nitrite solution (230 c.c. of 10%) was added. After 30 minutes, the solution was made alkaline to Congo-red by the addition of potassium acetate, and a solution of potassium selenocyanate (96 c.c. of 50%) was then gradually added. After the mixture had been stirred for 3 hours, the light brown, insoluble material was removed by filtration; it consisted mainly of an inseparable mixture of *p*-carboxyphenyl selenocyanate contaminated with 4 : 4′-dicarboxydiphenyl diselenide. In order to convert the selenocyanate into the diselenide, the mixture was dissolved in 2*N*-sodium hydroxide solution, and the solution boiled for an hour, cooled, filtered and acidified. The precipitated 4 : 4′-dicarboxydiphenyl diselenide (32 g.) separated from methyl alcohol as a pale yellow, microcrystalline powder, m. p. 297° (Found: C, 42·1; H, 2·5. $C_{14}H_{10}O_4Se_2$ requires C, 42·0; H, 2·5%).

p-*Carboxyphenyl methyl selenide*. To a gently boiling solution of 4 : 4′-dicarboxydiphenyl diselenide (40 g.) in aqueous sodium hydroxide (240 c.c. of 10%), sodium hydrosulphite (80 g.) (or zinc dust, 12 g.) was gradually added. To the filtered and cooled solution, methyl sulphate (13 c.c.) was added in small portions with agitation, and after 1 hour the crude p-*carboxyphenyl methyl selenide* was precipitated by the addition of acid. When dry, it was extracted with benzene, in which the chief impurity, the diselenide, is insoluble; 20 g. separated from hot benzene as a pale yellow, microcrystalline powder, m. p. 174° (Found: C, 44·8; H, 3·8. $C_8H_8O_2Se$ requires C, 44·6; H, 3·7%). The *dibromide* was prepared by the addition of a solution of bromine (9·6 g.) in acetic acid (50 c.c.) to a slightly warm solution of the selenide (12·80 g.) in acetic acid (200 c.c.). The addition compound (22·4 g.) rapidly separated as small orange-red needles, which, after washing with acetic acid, turned a deep red above 170° and had m. p. 198—199° (Found: Br, 42·3. $C_8H_8O_2SeBr_2$ requires Br, 42·7%).

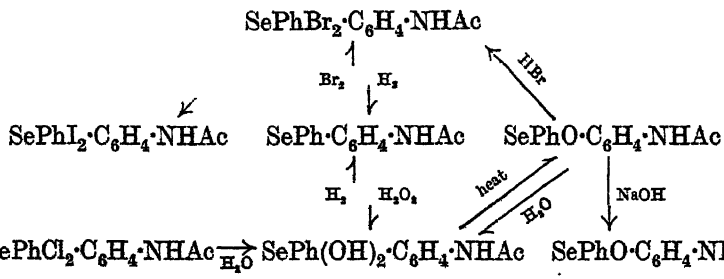
p-*Carboxyphenyl methyl selenoxide* was obtained (*a*) by triturating the dibromide (22·4 g.) with water (60 c.c.) and a few c.c. of 3*N*-sodium hydroxide solution until the suspension had turned completely white, the liquor being acid to Congo-red, removing the selenoxide (9·80 g.) by filtration, washing with water and drying, m. p. 170° (indef.); (*b*) by the addition of hydrogen peroxide (5 c.c. of 30%) to a solution of *p*-carboxyphenyl methyl selenide (10·2 g.) in methyl alcohol (300 c.c.), and filtering the crystals (10 g.) of *p*-carboxyphenyl methyl selenoxide which separated over-night.

It crystallised from alcohol in small, hard, irregular prisms, m. p. 183—184° (decomp.) (Found: C, 41·2; H, 3·7. $C_8H_8O_3Se$ requires C, 41·6; H, 3·5%), and the molten product rapidly set to a yellow solid which remelted about 250°.

The *brucine* salt of *p*-carboxyphenyl methyl selenoxide had m. p. 105—110° (see below); it was very soluble in cold alcohol, and when recrystallised from a hot mixture of alcohol and acetone was obtained with m. p. 151—153°. On investigation, it was found that during the recrystallisation the selenoxide had become partly reduced to the selenide and that the alkaloidal salt (m. p. 151—153°) was a mixture of the brucine salts of the selenoxide and the selenide. Accordingly the brucine salt was prepared in cold absolute ethyl alcohol and the solution allowed to concentrate in a desiccator until a suitable amount (m. p. 105—110°, decomp.) had separated. From this salt the selenoxide (m. p. 183—184°, decomp.) could be obtained by decomposition with alkalis and acidification of the alkaline extract with acetic acid. Similarly, by the addition of dilute sodium carbonate solution to the filtrate from the brucine salt, aqueous solutions of the sodium salt of *p*-carboxyphenyl methyl selenoxide were prepared. These solutions after repeated extraction with chloroform to remove dissolved brucine were found to be either optically inactive or in some cases to give a rotation of the order α_{5461} + 0·02°—0·04°, *i.e.*, within the limits of experimental error. The various solutions of the sodium salt yielded *p*-carboxyphenyl methyl selenoxide (as shown by its m. p., and by conversion into the dibromide by means of hydrobromic acid) which was optically inactive in either aqueous or ethyl-alcoholic solution. The brucine salt of *p*-carboxyphenyl methyl selenoxide is optically inactive to light of λ_{5461} and has $[\alpha]_{5870}$ + 2·5° (l = 2·0; c = 0·9864 in ethyl alcohol).

BATTERSEA POLYTECHNIC, S.W. 11. [*Received, June 18th*, 1928.]

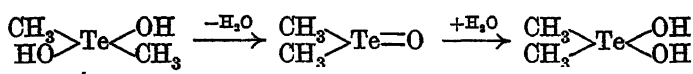
CCXCVIII.—*The Quadrivalency of Selenium. Part II. The Simple Halogen Derivatives and the Dihydroxide of 4-Acetamidodiphenyl Selenide.*



By WILSON ROBINSON GAYTHWAITE, JOSEPH KENYON, and HENRY PHILLIPS.

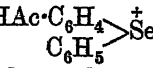
THE primary object of this investigation was to prepare and attempt the resolution of 4-*aminodiphenyl selenoxide*. This selenoxide can be prepared indirectly from 4-*aminodiphenyl selenide*, which is formed by the interaction of benzeneseleninic acid with aniline;

but it proved to be unstable in the presence of acids and hence its resolution could not be attempted. 4-*Acetamidodiphenyl selenide*, however, reacts with halogens in acetic acid solution to give well-defined, highly coloured, crystalline dihalogen derivatives, the chemical properties of which have been studied in order to compare and contrast them with those of the dihalogen derivatives of semi-aromatic and aliphatic selenides. When heated, the *dichloride* and also the *dibromide* are converted into selenides with halogenated aromatic nuclei. The corresponding *di-iodide*, however, under the same treatment evolves iodine and, indeed, even when exposed to the air at the ordinary temperature, gradually reverts to the selenide.



An aqueous solution of potassium bromide converts the dichloride into the dibromide, and this with an aqueous solution of 2 mols. of potassium iodide yields the di-iodide. Each of the three dihalogen compounds can be recrystallised from glacial acetic acid, but only the di-iodide is sufficiently soluble in ethyl alcohol to be recrystallised from this solvent. When the di-iodide is treated with a suitable amount of dry ether, a less highly coloured substance remains undissolved, which proves to be the selenide. Similarly, the selenide is deposited when an ethereal solution of the di-iodide is concentrated. The di-iodide in ethereal solution therefore dissociates into iodine and the selenide.

Water, or more rapidly dilute alkalis, converts the dichloride and dibromide into the *dihydroxide*. Boiling water, however, is without action on the di-iodide which with sodium hydroxide yields its parent selenide. By the action of moist silver oxide, the di-iodide can be made to yield the dihydroxide, which is nevertheless contaminated with some selenide, the latter being the sole product when the di-iodide is treated with warm aqueous solutions of either potassium iodide or sodium thiosulphate. These reactions can be summarised as follows :



4-Acetamidodiphenyl selenide dihydroxide can also be obtained by the action of hydrogen peroxide on the selenide, and can be recrystallised from hot water. On fusion (147—148°) it loses water,

and the corresponding selenoxide is formed, which, when heated more strongly, darkens, suddenly evolves oxygen, and leaves a fluid mass of pure 4-acetamidodiphenyl selenide. This behaviour is in marked contrast to that of 4-amino-4′-methyldiphenyl sulphoxide which can be heated well above its m. p. without showing any sign of decomposition. At a lower temperature and pressure, 4-acetamidodiphenyl selenide dihydroxide loses water in a manner which is strongly reminiscent of the conversion of α-dimethyltelluronium dihydroxide into a telluroxide (Vernon, J., 1920, **117**, 86, 889). By the action of the halogen acids on aqueous solutions of this telluroxide, Vernon obtained dimethyltelluronium dihalides, which differed in chemical and physical properties from the corresponding dihalogen compounds obtained from aqueous solutions of the β-dimethyltelluronium dihydroxide; he concluded that the four groups of the isomeric dimethyltelluronium dihydroxides were in the same plane as the central tellurium atom, and that the α-base was the *trans*-isomeride, whilst the telluroxide after recombination with water gave the *cis*-isomeride.

α-trans.

No analogous change occurs, however, when 4-acetamidodiphenyl selenide dihydroxide loses water, since the same dihalogen compounds were obtained from the dihydroxide as from the selenoxide. These dihalogen compounds were also identical with those prepared from 4-acetamidodiphenyl selenide by the direct addition of halogen.

The behaviour of the dihalogen derivatives and dihydroxide of 4-acetamidodiphenyl selenide is therefore consistent with a constitution such as  .

It may be pointed out, however, that during all the reactions described, the selenide molecule remains intact and in no instance is a carbon–selenium bond broken. The ease with which 4-acetamidodiphenyl selenoxide loses oxygen is noteworthy as suggesting, but in no way proving, that oxygen may be linked to selenium by a linking weaker than a semipolar double bond.

Experimental.

4-Aminodiphenyl selenide was prepared by heating a mixture of benzeneseleninic acid (20 g.) and aniline (80 c.c.) at 110—115° for 6 hours. After removal of the unchanged aniline in a current of steam, the dark-coloured residue was extracted with hot dilute hydrochloric acid. On addition of sodium carbonate to the acid

extract, the selenide was precipitated as a pink, microcrystalline powder (yield, 12—15 g.). 4-Aminodiphenyl selenide separates from aqueous alcohol (norit) in clusters of almost colourless, prismatic needles, m. p. 93—94° (Found : N, 5·7. $C_{12}H_{11}NSe$ requires N, 5·6%). The base is readily soluble in hot dilute hydrochloric acid, and on cooling, the *hydrochloride* separates as small, feathery needles, m. p. 159° (Found : HCl, by titration, 13·0. $C_{12}H_{12}NSeCl$ requires HCl, 12·9%). Addition of sodium carbonate solution to the hydrochloride regenerates the pure base.

By the interaction of aniline and benzenesulphinic acid, Hinsberg (*Ber.*, 1908, **41**, 113) obtained 4-aminodiphenyl sulphoxide. The foregoing reaction of benzeneseleninic acid doubtless proceeds by the same mechanism, but the selenoxide produced is reduced to the selenide by the excess of aniline.

4-*Acetamidodiphenyl selenide* was prepared by warming together 4-aminodiphenyl selenide (3·8 g). and acetic anhydride (4 c.c.). The product (4·2 g.) separated from aqueous alcohol in glistening leaflets, m. p. 169—170° (Found : C, 58·2; H, 5·0; N, 4·8. $C_{14}H_{13}ONSe$ requires C, 57·9; H, 4·4; N, 4·8%). 4-Acetamidodiphenyl selenide decomposes when heated with mineral acids. It undergoes hydrolysis smoothly, however, under the following conditions : A solution of the selenide (2 g.) in alcohol (10 c.c.) was heated under reflux with 3*N*-sodium hydroxide solution (10 c.c.) for 6 hours; on cooling, the regenerated base (1·65 g.) crystallised from the reaction mixture, and after crystallisation from alcohol, had m. p. 93—94°.

4-*Acetamidodiphenyl Selenide Dihydroxide.*—To a cooled mixture of 4-acetamidodiphenyl selenide (5·8 g.) and glacial acetic acid (10 c.c.), perhydrol (4 c.c.) was gradually added; the *dihydroxide* (5·7 g.) separated from the resulting clear solution on standing, and after crystallisation from boiling water (700 c.c.) had m. p. 147—148° (decomp.) (Found : C, 51·9; H, 5·0; N, 4·3. $C_{14}H_{15}O_3NSe$ requires C, 51·9; H, 4·6; N, 4·3%). When a large excess of perhydrol was used the same compound was obtained, and no trace of the corresponding selenone could be detected. When heated for a few minutes with zinc dust and glacial acetic acid 4-acetamidodiphenyl selenide dihydroxide was quantitatively reduced to the corresponding selenide. It dissolved in warm *N*/2-hydrochloric acid, and when the solution was heated on the steam-bath for an hour glistening leaflets of 4-acetamidodiphenyl selenide separated. Some of the dissolved dihydroxide reappeared as tarry material and the solution possessed oxidising properties, consistent with the view that it contained hypochlorous acid which had resulted from the dissociation of a selenide hydroxychloride. 4-Acetamidodiphenyl

selenide dihydroxide was melted over a small flame and the colourless liquid heated until there was no further loss of moisture (Found: H_2O, 5·56. Calc.: 5·55%). When the horny mass thus obtained was heated more strongly, it darkened, suddenly evolved a gas, and the residual fluid became crystalline on cooling. By recrystallisation from alcohol, this residue was obtained as colourless leaflets (1·0 g.), m. p. 166—168°, either alone or when mixed with 4-acetamidodiphenyl selenide.

4-*Acetamidodiphenyl Selenoxide*.—4-Acetamidodiphenyl selenide dihydroxide (4 g.) when heated under a pressure of 20 mm. effervesced vigorously at 120—130° and became fluid. After 20 minutes, the effervescence ceased and the liquid crystallised although its temperature was 130°. The solid, *4-acetamidodiphenyl selenoxide*, was recrystallised from dry chloroform and obtained as small, ill-defined crystals, m. p. 144—146° (Found: C, 54·8; H, 4·6; N, 4·6. $C_{14}H_{13}O_2NSe$ requires C, 54·9; H, 4·3; N, 4·6%). Unlike the original dihydroxy-compound, the selenoxide does not decompose on melting: the m. p. of the dihydroxy-compound is really the temperature at which it loses water at ordinary pressure.

When a hot aqueous-alcoholic solution of 4-acetamidodiphenyl selenoxide was cooled, crystals of the corresponding dihydroxide, m. p. 147—148° (decomp.), were deposited. The dihalides, obtained in quantitative yields by the addition of concentrated solutions of hydrochloric, hydrobromic, or hydriodic acid to a warm solution of the selenoxide in glacial acetic acid, were identical with the dihalides obtained in a similar manner from the corresponding dihydroxide.

4-*Aminodiphenyl selenoxide* was prepared by heating a solution of 4-acetamidodiphenyl selenide dihydroxide (1·7 g.) in alcohol (15 c.c.) with sodium hydroxide solution (10 c.c. of 3*N*) for 6 hours; on cooling, the selenoxide (1·3 g.) separated as glistening needles, m. p. 188—189° (decomp.) (Found: C, 54·4; H, 4·1; N, 5·4; Se, 30·4. $C_{12}H_{11}ONSe$ requires C, 54·6; H, 4·2; N, 5·3; Se, 30·0%). This compound was also prepared from 4-aminodiphenyl selenide as follows: The selenide (7·5 g.), dissolved in acetone (30 c.c.), was mixed with perhydrol (4·5 c.c.), and the crystals (5·2 g.) which separated on standing were filtered off and washed with acetone (m. p. 180—181°). They were recrystallised, together with a second crop (0·6 g.) obtained from the filtrate, from methyl alcohol, and then had m. p. 187—189° either alone or when mixed with the selenoxide prepared from 4-acetamidodiphenyl selenide dihydroxide as described above. 4-Aminodiphenyl selenoxide was quantitatively reduced to the corresponding selenide by treatment with zinc dust and a solution of sodium hydroxide.

Reaction with dilute hydrochloric acid. The finely-powdered

selenoxide (1 g.) was triturated with dilute hydrochloric acid (50 c.c. of $N/2$). The reaction mixture was filtered, and from the acid filtrate 4-aminodiphenyl selenide (0·2 g.), m. p. 93—94°, was precipitated by the addition of sodium bicarbonate. No crystalline product could be isolated from the tarry, insoluble material.

4-Acetamidodiphenyl selenide dichloride was prepared by the addition of a mixture of concentrated aqueous hydrochloric acid (2 c.c.) and acetic acid (3 c.c.) to a warm solution of the dihydroxide (1·53 g.) in glacial acetic acid (4 c.c.); the dichloride which separated crystallised from acetic acid (30 c.c.) as almost colourless, bulky, feathery needles (1·6 g.), which turned yellow about 125° and had m. p. 131—132° (Found: Cl, 19·6. $C_{14}H_{13}ONCl_2Se$ requires Cl, 19·6%). When chlorine was passed into a solution of 4-acetamidodiphenyl selenide in acetic acid, a white, crystalline compound was precipitated, m. p. 186—187°, which contained chlorine not displaceable by the action of aqueous sodium hydroxide. Even when the equivalent amount of chlorine, dissolved in acetic acid, was added to an acetic acid solution of the selenide, the product obtained melted indefinitely at 110—120°. Thus chlorine, in contradistinction to bromine and iodine, appears to react with the acetamido-group. By treatment either with much water or with dilute sodium hydroxide solution, the dichloride was converted quantitatively into the dihydroxide, whilst when triturated with a cold, concentrated, aqueous solution of potassium bromide (2 mols.), it was rapidly and quantitatively converted into the brightly coloured dibromide.

4-Acetamidodiphenyl selenide dibromide was prepared by mixing solutions of bromine (1·8 g.) and 4-acetamidodiphenyl selenide (3·5 g.) in acetic acid (95 c.c. in all); hemispherical clusters of small red needles (5·05 g.) separated rapidly. After recrystallisation from warm glacial acetic acid, the dibromide turned bright red at 100° and melted to a deep red liquid at 135—136° (Found: C, 37·2; H, 3·9; N, 3·1; Br, 35·1. $C_{14}H_{13}ONBr_2Se$ requires C, 37·3; H, 2·9; N, 3·1; Br, 35·4%). When zinc dust was added to a suspension of the dibromide in acetic acid, 4-acetamidodiphenyl selenide was obtained. On grinding with sodium hydroxide solution (35 c.c. of $3N$), the highly coloured dibromide (17·6 g.) was converted into the colourless dihydroxide (10 g.), m. p. 147—148°, with evolution of steam. The same reaction was effected, only more slowly, by the use of cold water. Hydrobromic acid was evolved when 4-acetamidodiphenyl selenide dibromide was heated at its m. p. for ½ hour; the resulting deep red paste was washed with ether, and the insoluble grey powder was crystallised from alcohol, from which it separates as colourless, glistening needles, m. p. 167°.

This *compound* contains bromine but gives no precipitate when heated with alcoholic silver nitrate solution (Found: Br, 34·7. $C_{14}H_{11}ONBr_2Se$ requires Br, 35·2%); the bromine had therefore migrated from the selenium atom to one of the benzene nuclei, producing, probably, 3 : 5-dibromo-4-acetamidodiphenyl selenide.

4-*Acetamidodiphenyl selenide di-iodide.* (*a*) A solution of iodine (1·3 g.) in warm acetic acid (29 c.c.) was added to a solution of 4-acetamidodiphenyl selenide (1·45 g.) in acetic acid (30 c.c.); after a few minutes, the *di-iodide* separated in bulky rosettes of fine needles (2·3 g.), m. p. 144—145° (decomp.) (Found: I, by titration, 46·6. $C_{14}H_{13}ONI_2Se$ requires I, 46·7%). (*b*) Concentrated aqueous hydriodic acid (10 c.c.) was added to a warm solution of the dihydroxide (0·8 g.) in acetic acid (10 c.c.), and the di-iodide (1·0 g.), m. p. 144—145° (decomp.) either alone or when mixed with the compound prepared as described under (*a*) or (*c*), was obtained. Furthermore, when 4-acetamidodiphenyl selenoxide was used in the above experiment in place of the dihydroxide, an identical di-iodide was obtained. (*c*) The dibromide (1·12 g.) was triturated with a solution of potassium iodide (0·83 g.; 2 mols.) in water (1 c.c.) during 20 minutes; the orange dibromide gradually changed to the chocolate-brown di-iodide, which was washed with water and recrystallised from alcohol or acetic acid.

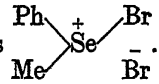
4-Acetamidodiphenyl selenide di-iodide, when heated at its m. p. for an hour, gave a copious sublimate of iodine, whilst the residue, after crystallisation from aqueous alcohol, had m. p. 93—94° either alone or when mixed with 4-acetamidodiphenyl selenide. This change proceeds slowly at ordinary temperatures: a specimen of the di-iodide exposed to the air was found to have changed completely to the selenide after 10 days.

BATTERSEA POLYTECHNIC, S.W. 11. [*Received, June 18th,* 1928.]

CCXCIX.—*The Quadrivalency of Selenium. Part III. The Instability of the Compounds of Quadrivalent Selenium derived from Phenyl Methyl and Phenyl Ethyl Selenides and Phenyl- and* p-*Tolyl-selenoglycollic Acids.*

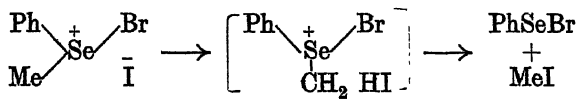
By OWEN KEMPSTER EDWARDS, WILSON ROBINSON GAYTHWAITE, JOSEPH KENYON, and HENRY PHILLIPS.

OWING to their instability, much difficulty has been experienced in the preparation of selenoxides containing an alkyl group attached to the selenium atom. Such selenoxides have been found to decom-



pose on heating mainly as indicated by the equation $SeRO{\cdot}CH_2R = SeRH + O{:}CHR$. They differ widely in this respect from purely aromatic selenoxides, such as 4-acetamidodiphenyl selenoxide, which, as described in the preceding communication, decomposes on heating into the corresponding selenide and oxygen.

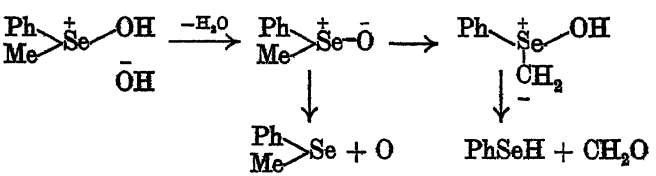
Sulphoxides containing an alkyl group attached to the sulphur atom are known to undergo a similar change. For example, Fromm and Achert (*Ber.*, 1903, **36**, 534) obtained benzaldehyde by heating benzyl sulphoxide; Smythe (J., 1909, **95**, 349) showed that during the interaction of this sulphoxide with hydrogen chloride in various solvents, benzaldehyde, benzyl mercaptan, dibenzyl disulphide, and benzyl chloride were produced. Similarly, Fichter and Sjöstedt (*Ber.*, 1910, **43**, 3422) and Fichter and Wenk (*Ber.*, 1912, **45**, 1373) showed that the controlled electrochemical oxidation of phenyl ethyl sulphide yielded phenyl mercaptan and acetaldehyde. Pummerer (*Ber.*, 1909, **42**, 2282; 1910, **43**, 1404), who investigated the conversion of phenyl- and *p*-tolyl-sulphoxyacetic acids into glyoxylic acid and the corresponding aromatic thiols (by the agency of heat or traces of mineral acids), was led to suggest, as the underlying cause, the tendency on the part of such sulphoxides to assume an isomeric form by a process analogous to the keto-enol change. On the electronic conceptions of valency, Pummerer's formulation of the initial step in the decomposition could be written



$$R{\cdot}\overset{+}{S}(\overset{-}{O}){\cdot}CH_2R \longrightarrow R{\cdot}\overset{+}{S}(\overset{-}{O}H){\cdot}CHR.$$

Since we find that selenoxides of analogous constitution to the sulphoxides mentioned decompose in a similar fashion, it is possible that selenoxides also may undergo an isomeric change of this nature. The following compounds of quadrivalent selenium have therefore been investigated in order to obtain evidence as to whether the migration of hydrogen is an initial phase of their decomposition.

Phenyl methyl selenide dibromide, prepared by the addition of bromide to phenyl methyl selenide, is a well-defined, bright red crystalline substance. On heating at about 100° it decomposed quantitatively into methyl bromide and bromoselenobenzene. When triturated at 40° with a concentrated solution of potassium iodide, the dibromide was converted into the *di-iodide*; if, however, the dibromide was treated with a cold solution of potassium iodide of the same concentration, a *bromo-iodide* was obtained in theoretical yield. This compound, on heating, decomposed quantitatively to give methyl iodide and bromoselenobenzene. These results clearly

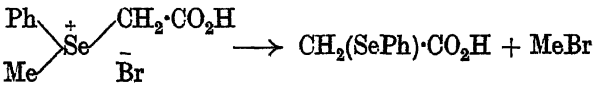


indicate that the bromine atoms of phenyl methyl selenide dibromide are not linked in the same manner to the selenium atom, and hence agree with a formula such as  .

The facility with which the dibromide and the bromo-iodide decompose into alkyl halogen compounds and bromoselenobenzene is most marked, and that the presence of the methyl group is in some way responsible is evident, since diphenyl selenide dibromide (Krafft and Lyons, *Ber.*, 1894, **27**, 1761) has been found to decompose into bromodiphenyl selenide and hydrobromic acid, whilst 4-acetamidodiphenyl selenide dibromide yields 3 : 5-(?)dibromo-4-acetamidodiphenyl selenide and hydrobromic acid (preceding communication). The mode of decomposition of phenyl methyl selenide bromo-iodide is therefore not inconsistent with the view that such decompositions pass through a preliminary phase, as indicated below, which involves the loss of a proton by the methyl group and causes this group to become less firmly attached to the selenium atom.

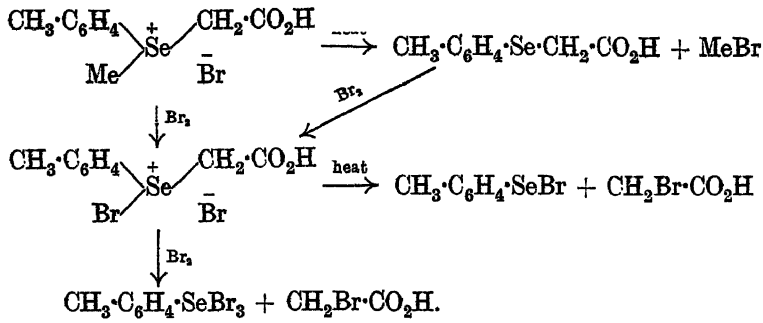
Phenyl ethyl selenide dibromide was also found to decompose quantitatively when heated at 130° into ethyl bromide and bromoselenobenzene.

Phenyl methyl selenide dihydroxide, prepared by treating a solution of the dibromide in water with silver oxide, and concentrating the filtrate in a vacuum, was obtained as a viscous oil, which, when heated at 100°/15 mm. or at 170°/760 mm., decomposed yielding phenyl methyl selenide, diphenyl diselenide, and formaldehyde. The phenyl methyl selenide may have been produced by the reduction of the dihydroxide or selenoxide by the other products of the decomposition. The formation of formaldehyde is in agreement with the view that phenyl methyl selenoxide may exist in two isomeric forms which, being unstable, decompose thus :



Unsuccessful attempts were made under various experimental

conditions to cause phenyl methyl selenide dihydroxide to lose water and yield a selenoxide. These experiments led to the conclusion that the selenoxide, when formed, immediately decomposed, and they were therefore abandoned.



Phenyl ethyl selenide dihydroxide, prepared from the dibromide by similar methods, was found to be less stable than its lower homologue, and decomposed yielding mainly diphenyl diselenide, even when left in a vacuum desiccator containing sulphuric acid.

Phenyl- and p-*Tolyl-methylselenetine Bromides.*—Phenylmethylselenetine bromide, prepared by the method of Pope and Neville (J., 1902, **81**, 1552), was found to decompose smoothly and quantitatively at its m. p. into methyl bromide and phenylselenoglycollic acid :

Similarly, *phenylselenoglycollic acid dibromide* decomposed when heated, yielding bromoselenobenzene and bromoacetic acid. Attempts were made to prepare phenylethylselenetine bromide by the interaction of phenyl ethyl selenide and bromoacetic acid; phenylselenoglycollic acid was, however, the only product isolated, owing, presumably, to the ease with which the selenetine bromide produced decomposed.

p-*Tolylmethylselenetine bromide* was also prepared from *p*-tolyl methyl selenide and bromoacetic acid. On heating, it softened at 85—88°, turned more definitely crystalline, and finally became molten at 96—97°, the m. p. of *p*-tolylselenoglycollic acid (Morgan and Porritt, J., 1925, **127**, 1758). When treated with a molecular proportion of bromine in cold carbon tetrachloride solution, *p*-tolylmethylselenetine bromide was converted into *p*-tolylselenoglycollic acid dibromide which, on heating, decomposed smoothly into *p*-bromoselenotoluene and bromoacetic acid. The replacement of the methyl group of *p*-tolylmethylselenetine bromide by means of bromine occurs with great readiness. This possibly explains why we were unable to obtain *p*-tolylselenoglycollic acid tetrabromide by the action of excess of bromine on *p*-tolylselenoglycollic acid, as described by Morgan and Porritt (*loc. cit.*). We found, in agreement with the results of our other experiments, that the dibromide produced as an initial stage of the reaction was converted by the excess of bromine into *p*-bromoselenotoluene dibromide and bromoacetic acid. The results of the experiments with these compounds can be summarised as follows :

All the decomposition reactions which have been described support the contention that the withdrawal of aliphatic groups from their combination with quadrivalent selenium may be facilitated by their ability to provide a proton. The most striking example is the decomposition of *p*-tolylselenoglycollic acid dibromide, which does not decompose into *p*-tolylselenoglycollic acid and bromine, as might be expected (compare Morgan and Porritt, *loc. cit.*), but into bromoselenotoluene and bromoacetic acid.

EXPERIMENTAL.

The Action of Heat on Phenylmethylselenetine Bromide.—Phenylmethylselenetine bromide was prepared by the method of Pope and Neville (*loc. cit.*). Equimolecular amounts of phenyl methyl selenide (8·6 g.) and bromoacetic acid (7·0 g.) were gently warmed until molten and allowed to stand over-night; dry ether was then added to the reaction mixture from which a mass of crystals had separated. The white, additive compound (7·6 g.) removed by filtration had m. p. 110—111°, with evolution of a gas. After recrystallisation from a mixture of alcohol and ether, the phenylmethylselenetine bromide had m. p. 111° as recorded by Pope and Neville.

0·4665 G. of this bromide was heated at about 110° until the evolution of gas had ceased; the gas was passed into an aqueous-alcoholic solution of silver nitrate and produced a copious precipitate of silver bromide. The residual product when cold weighed 0·3256 g., the loss being 30·2% (Calc. for loss of CH_3Br, 30·6%). The residual product was an acid (Found: equiv., 230. Phenylselenoglycollic acid, $C_6H_5{\cdot}Se{\cdot}CH_2{\cdot}CO_2H$, requires equiv., 215). The acid thus obtained in another experiment was seeded with phenylselenoglycollic acid and set to a mass of colourless crystals, m. p. 36—37°, either alone or when mixed with phenylselenoglycollic acid prepared by the method of Morgan and Porritt (*loc. cit.*). (Although the acid was obtained as described by these authors, yet the physical constants recorded by them, b. p. 160°/750 mm., m. p.

40°, are considerably different from those now found, *viz.*, b. p. 197—198°/10 mm., m. p. 36—37°.)

It was not found possible to synthesise phenylmethylselenetine bromide from phenylselenoglycollic acid and methyl bromide. A dry ethereal solution of these two substances was kept in a stoppered bottle for 50 days, but did not deposit crystals of the insoluble selenetine bromide. Further, phenylmethylselenetine bromide was heated in a sealed tube at 110° until completely molten; after 24 hours, the tube (the contents of which were still fluid) was opened and found to be under considerable pressure, which was due to the presence of methyl bromide, since the still molten contents of the tube crystallised when inoculated with a crystal of phenylselenoglycollic acid.

Phenylselenoglycollic acid dibromide was prepared by the addition of a solution of bromine (8 g.) in warm carbon tetrachloride (50 c.c.) to a hot solution of phenylselenoglycollic acid (10·75 g.) in carbon tetrachloride (500 c.c.). The additive compound (18·3 g.; yield 97%) separated in very small, yellow, ill-defined needles, which melted at 126° to a deep red liquid (Found: Br, 42·3. $C_8H_8O_2Br_2Se$ requires Br, 42·7%), and were almost insoluble in carbon tetrachloride, chloroform, benzene, or carbon disulphide; they dissolved in about 10 times their weight of hot glacial acetic acid, but on cooling, the solution deposited deep red crystals of bromoselenobenzene, m. p. 61°, in almost theoretical amount (Found: Br, 33·9. Calc.: Br, 33·9%).

Action of Heat on Phenylselenoglycollic Acid Dibromide.—(*a*) When this dibromide (3·7 g.) was heated, the products of decomposition distilled at 100—102°/12 mm. and set to a brownish-red, crystalline mass. When about two-thirds of the material had distilled, the temperature began to rise and the distillation was stopped. The distillate was separated by light petroleum into brownish-red crystals of bromoselenobenzene (m. p. 61°) and very hygroscopic, colourless plates, m. p. 46° (see below). The undistilled residue was separated by means of warm light petroleum into bromoselenobenzene and diphenyl diselenide (m. p. 63°). (*b*) Phenylselenoglycollic acid dibromide (3·7 g.) was melted and the cooled melt extracted several times with cold light petroleum; the residue consisted of almost colourless crystals which separated from hot light petroleum in transparent, colourless leaflets, m. p. 46—47°, either alone or when mixed with bromoacetic acid. The extracts on evaporation gave bromoselenobenzene together with a small amount of diphenyl diselenide. It is therefore evident that phenylselenoglycollic acid dibromide decomposes at its m. p. mainly thus: $CH_2(SeBr_2Ph)\cdot CO_2H = PhSeBr + CH_2Br\cdot CO_2H$.

p-*Tolylmethylselenetine Bromide.*—A cold liquid mixture of *p*-tolylmethyl selenide (3·7 g.) and bromoacetic acid (2·8 g.), after standing over-night, set to a mass of long, glistening needles, which, when separated from the admixed oil by means of porous earthenware, weighed 3·7 g. A portion (0·2 g.) of this *p*-tolylmethylselenetine bromide was placed in a test tube and plunged into boiling water; the compound slowly melted, without visible effervescence, but a strong odour of methyl bromide was developed. The resulting oil immediately set to a crystalline mass, m. p. 96—97°, either alone or when mixed with *p*-tolylselenoglycollic acid (Morgan and Porritt, *loc. cit.*). 0·1964 G., heated until completely molten, lost 0·0582 g. (Found: loss, 29·7. Calc. for CH_3Br, 29·3%).

p-Tolylselenoglycollic acid dibromide (compare Morgan and Porritt, *loc. cit.*) was prepared by two methods. (*a*) A solution of bromine (1·4 g.) in carbon tetrachloride (25 c.c.) was added to a hot solution of *p*-tolylselenoglycollic acid (1·8 g.) in the same solvent (100 c.c.); the yellow needles of the additive compound (3·1 g.) melted at 103—104° to a deep red liquid. (*b*) A solution of bromine (0·4 g.) in carbon tetrachloride (25 c.c.) was added to a cold solution of *p*-tolylmethylselenetine bromide (0·65 g.) in carbon tetrachloride (300 c.c.); the yellow needles (0·8 g.), which began to separate immediately, had m. p. 100—101°, either alone or when mixed with the dibromide prepared as in (*a*).

Action of heat on p-*tolylselenoglycollic acid dibromide.* This compound (1·5 g.) was heated at its m. p. for a few minutes, and the deep red liquid, which set to a semicrystalline mass on cooling, was extracted several times with small amounts of cold light petroleum; the insoluble residue (0·43 g.) consisted of colourless, hygroscopic leaflets, m. p. 48—49° either alone or when mixed with bromoacetic acid. The extracts, on evaporation at the ordinary temperature, gave a reddish-brown oil which could not be induced to crystallise; that it is *p*-bromoselenotoluene is rendered highly probable by its ready reduction with aluminium amalgam in moist ethereal solution to di-*p*-tolyl diselenide, m. p. 47°; aluminium bromide was obtained on washing the ethereal solution with water.

p-*Bromoselenotoluene dibromide* was prepared by three methods. (*a*) *p*-Tolueneseleninic acid (1·02 g.) was triturated with concentrated aqueous hydrobromic acid (6 c.c.), and the orange-red powder (2 g., m. p. 80—90°) which separated was recrystallised from chloroform; red needles, m. p. 113—114° (decomp.). (*b*) A solution of bromine (0·5 g., 3 mols.) in carbon tetrachloride (15 c.c.) was added to a warm solution of di-*p*-tolyl diselenide (0·34 g.) in warm carbon tetrachloride (25 c.c.); on cooling, orange-red leaflets

(0·6 g.) separated, m. p. 114—115° (decomp.). (*c*) Solutions of bromine (0·9 g., 2 mols.) and of *p*-tolylselenoglycollic acid (0·57 g.) in chloroform (20 c.c. in all) were mixed and became warm; on cooling, deep red needles were deposited, m. p. 113—114° (decomp.) either alone or when mixed with the compound prepared as described under (*a*) or (*b*). There can be no doubt therefore that this compound is actually *p*-bromoselenotoluene dibromide, and not *p*-tolylselenoglycollic acid tetrabromide as supposed by Morgan and Porritt (*loc. cit.*). *p*-Bromoselenotoluene dibromide dissolves in hot water and the resulting colourless solution on cooling deposits colourless needles, m. p. 169—170° either alone or when mixed with *p*-tolylseleninic acid.

If preparation (*c*) be attempted in carbon tetrachloride, of which 100 c.c. are necessary to dissolve the acid, the sole product of the reaction is *p*-tolylselenoglycollic acid dibromide.

Phenyl methyl selenide dibromide was prepared by the addition of bromine (33 g.) in carbon disulphide (30 c.c.) to phenyl methyl selenide (35 g.) in the same solvent (120 c.c.). The warm solution deposited the additive compound almost immediately as long, yellow, glistening needles (yield 95%) which turned brown at about 100° and melted at 115—116° (decomp.); it is soluble in water to the extent of about 6%, and the colourless solution is acid to Congo-red and when cooled or concentrated deposits the dibromide unchanged in m. p. (Found: Br, 48·0. $C_7H_8SeBr_2$ requires Br, 48·3%).

Action of heat on phenyl methyl selenide dibromide. The dibromide (1·9940 g.) was heated at 120—130° for about 10 minutes, by which time decomposition had ceased. The evolved gas was passed into an alcoholic solution of silver nitrate and caused the precipitation of silver bromide. The loss in weight was 0·5684 g. or 28·50% (Calc. for loss of CH_3Br, 28·46%). The non-volatile residue set to a brownish-red, crystalline mass, m. p. 60—61°, which separated from light petroleum as deep garnet-red cubes, m. p. 61°, alone or when mixed with bromoselenobenzene.

Phenyl methyl selenide di-iodide was prepared by triturating the dibromide (2 g.) at 40° with a solution of potassium iodide (2 g.; 2 mols.) in water (10 c.c.). The chocolate-coloured powder obtained (2·65 g.; calc., 2·60 g.), after washing and drying had m. p. 67—70°, and crystallised from alcohol in glistening, purple, short prisms, m. p. 69—71° (Found: I, 59·4. $C_7H_8I_2Se$ requires I, 59·8%).

Phenyl methyl selenide bromo-iodide was prepared by triturating phenyl methyl selenide dibromide (3 g.) with a cold solution of potassium iodide (3 g.; 2 mols.) in water (15 c.c.). The bromo-iodide (3·5 g.) was deep red and separated from alcohol in red,

ill-defined, compact crystals (3·1 g.), m. p. 85° (decomp.) (Found: Br + I, 55·5. C_7H_8BrISe requires Br + I, 54·8%). When triturated with a warm solution of potassium iodide it was immediately converted into the di-iodide, m. p. and mixed m. p. 67—70° (decomp.).

The action of heat on phenyl methyl selenide bromo-iodide. 1·0056 G. of the bromo-iodide were heated at 100° and the distillate was collected. The non-volatile residue weighed 0·7636 g. (Found: loss, 34·1. Calc., for MeI, 37·5%; for MeBr, 25·1%), and when crystallised from light petroleum had m. p. 61°, either alone or mixed with bromoselenobenzene. The distillate was a colourless liquid which was non-volatile at the ordinary temperature, contained iodine, and combined with pyridine on warming. Phenyl methyl selenide bromo-iodide therefore decomposes on heating according to the equation SePhMeBrI = SePhBr + MeI.

Phenyl methyl selenide dihydroxide was prepared by the trituration of a mixture of phenyl methyl selenide dibromide (10 g.), silver oxide (12 g.), and water (100 c.c.) until the yellow colour of the dibromide had disappeared. The colourless filtered solution on evaporation and desiccation gave about 8 c.c. of a viscous oil which could not be induced to crystallise. This compound was not analysed since it could not be completely freed from moisture without decomposition, but its identity was established by its immediate conversion into phenyl methyl selenide dibromide, m. p. 115—116°, on the addition of aqueous hydrobromic acid.

Action of heat on phenyl methyl selenide dihydroxide. The above compound (4 c.c.), contained in a small distilling flask, was gradually heated in an oil-bath; at 135—155° (bath temp.) some of the admixed water distilled, and at 175—180° one or two drops of an oily material distilled over and dissolved in the water into which the side-arm of the flask dipped; at 185°, a sudden decomposition ensued and some material distilled. The residue in the flask (about 1 g.) set immediately to a yellow, crystalline mass, m. p. 63—64°, after inoculation with a crystal of diphenyl diselenide. The water into which the products of decomposition had been led contained globules of oil, which was isolated with ether and distilled; the distillate (about 1 g.) had b. p. 202—203° and was identified as phenyl methyl selenide by its complete conversion into the dibromide, m. p. 115—116°. The water, after removal of the oil, gave a silver mirror with ammoniacal silver oxide, restored the colour to Schiff's reagent, gave the characteristic odour of formalin on evaporation, and left a small amount of white, amorphous, insoluble material. There can thus be little doubt that formaldehyde is one of the decomposition products of phenyl methyl selenide dihydroxide. Similar

products were obtained when the decomposition was carried out at 100°/15 mm.

Phenyl ethyl selenide dibromide was prepared by mixing phenyl ethyl selenide (5·55 g.) and a solution of bromine (4·9 g.) in carbon disulphide (20 c.c.). After several hours, the separated crystalline material (10 g.), m. p. 79°, was crystallised from ether and obtained as light red, transparent, stout, prismatic rods melting at 84° to a deep red liquid (Found : Br, 46·4. $C_8H_{10}Br_2Se$ requires Br, 46·4%).

Action of heat on phenyl ethyl selenide dibromide. This compound (2·0044 g.) was heated in a bath at a temperature not exceeding 130° until decomposition was complete (10 mins.). The residue (1·3738 g.) set to a brownish-red, crystalline mass, m. p. 60—61°. The vapour evolved during the decomposition gave a copious precipitate of silver bromide when passed into an aqueous-alcoholic solution of silver nitrate. The decomposition of the dibromide therefore takes place according to the equation $SePhEtBr_2 = SePhBr + EtBr$ (Found : loss, 31·3. Calc. for loss of C_2H_5Br, 31·6%). The solid product of the decomposition separated from light petroleum as deed garnet-red cubes, m. p. 61° either alone or when mixed with bromoselenobenzene.

Interaction of Phenyl Ethyl Selenide and Bromoacetic Acid.—Phenyl ethyl selenide (5·55 g.) and bromoacetic acid (4·17 g.) were mixed and a little dry ether was added to render the mixture homogeneous. After standing for 3 weeks, the product had set to a mass of crystals, which, after draining on porous earthenware, had m. p. 35—36° either alone or when mixed with phenylselenoglycollic acid of m. p. 36—37°.

Action of Heat on Diphenyl Selenide Dibromide.—Diphenyl selenide and diphenyl diselenide were prepared by the method of Krafft and Lyons (*Ber.*, 1894, **27**, 1761). Diphenyl selenide dibromide was obtained in 95% yield by mixing bromine (4·9 g.) and diphenyl selenide (7 g.) each dissolved in 15 c.c. of carbon disulphide. This solvent is preferable to ether, since the m. p. of the diphenyl selenide dibromide (154°, unaltered by recrystallisation) obtained by its use is 14° higher than that recorded by Krafft and Lyons (*loc. cit.*). When heated, diphenyl selenide dibromide (5·0 g.) melted to a deep red liquid which effervesced vigorously owing to the evolution of hydrogen bromide. After 10 minutes, the evolution of gas ceased and the loss in weight was 20% (Calc. for 1HBr, 20·6%). The residue, a semi-solid mixture, was separated by means of light petroleum into an oil and an almost colourless, crystalline solid, which crystallised from hot light petroleum as glistening leaflets (0·5 g.), m. p. 115·5°. This compound is evidently dibromodiphenyl selenide, isolated by Krafft and Lyons (*loc. cit.*). The oil distilled completely at 196—198°/12 mm. to give an almost

colourless liquid which deposited glassy crystals (2·0 g.), m. p. 32—33° (Found: Br, 25·6. $C_{12}H_9BrSe$ requires Br, 25·6%). Since this *compound* was the principal product of the thermal decomposition of diphenyl selenide dibromide, it follows that the main course of the reaction can be represented by the equation $SePh_2Br_2 = Ph{\cdot}Se{\cdot}C_6H_4Br + HBr$, and that the equation given by Krafft and Lyons, *viz.*, $2SePh_2Br_2 = Ph_2Se + (C_6H_4Br)_2Se + 2HBr$, represents a side reaction. These results explain why the attempt made by these authors to isolate diphenyl diselenide from the products of decomposition was unsuccessful.

Diphenyl selenoxide, prepared by the action of sodium hydroxide solution on diphenyl selenide dibromide, after recrystallisation from benzene had m. p. 113—114° (Krafft and Lyons, *loc. cit.*). This compound is more conveniently prepared by the following method: To diphenyl selenide (7 g.), perhydrol (10 c.c.) was added in small portions. The reaction mixture set, on cooling, to a crystalline mass; cold water was added and the product filtered, but as the selenoxide obtained weighed only 6·45 g. (instead of the calculated 7·5 g.), the aqueous filtrate (50 c.c.) was mixed with hydrobromic acid until no further reddish-yellow crystalline precipitate was formed. The latter, filtered and dried (1·75 g.), had m. p. 152—153° either alone or when mixed with diphenyl selenide dibromide. This result shows that diphenyl selenoxide is soluble in cold water to the extent of 2·2%. Diphenyl selenoxide, after crystallisation from benzene, has m. p. 113—114°, either alone or when mixed with the selenoxide prepared by the action of sodium hydroxide on diphenyl selenide dibromide.

The authors desire to express their indebtedness to the Government Grant Committee of the Royal Society for a grant which has helped to defray the cost of these investigations. One of them (W. R. G.) wishes to thank the Department of Scientific and Industrial Research for a maintenance grant which has enabled him to participate in this work.

BATTERSEA POLYTECHNIC, S.W. 11. [*Received, June 18th,* 1928.]

CCC.—*The Use of Toluenesulphonic Esters in Place of Halogen Esters in Malonic Ester Syntheses.*

By DAVID HENRY PEACOCK and PO THA.

ALTHOUGH the esters of *p*-toluenesulphonic acid are readily prepared and have found many applications in syntheses, there appears to be no record of their use in conjunction with sodiomalonic ester;

moreover, since such esters are sometimes more readily accessible than the halogen esters, the reaction appeared worthy of examination. As was to be expected, it took place much more slowly than when the halogen esters are used, but the experiments show that the toluenesulphonates are equally suitable, in spite of a similar tendency to form dialkylmalonic esters from equimolecular proportions of sodiomalonic and toluenesulphonic esters.

The results may prove especially useful in the preparation of substances containing the phenoxyethyl or phenoxypropyl groups, for these derivatives are of value in a number of syntheses. Thus, phenoxyethylmalonic acid is usually prepared from a phenoxyethyl halide (see, *e.g.*, Bently, Haworth, and Perkin, J., 1896, **69**, 169), but the corresponding alcohol is much more readily prepared than the bromide (Kirner, *J. Amer. Chem. Soc.*, 1926, **48**, 2749), and one of us has found that it is readily converted into β-*phenoxyethyl* p-*toluenesulphonate*, an easily purified crystalline substance which reacts smoothly with sodiomalonic ester to give phenoxyethylmalonic ester. The derivatives of phenoxyethylmalonic acid are thus readily accessible by this route.

Experimental.

(1) Ethyl malonate (16 g.), methyl *p*-toluenesulphonate (18·6 g.), sodium (2·3 g.), and absolute alcohol (78 c.c.) were boiled under reflux until the reaction was complete (4 hrs.). The product was worked up in the usual way and 13·9 g. of ester, b. p. 105—110°/30 mm., were obtained; this was converted by the action of strong ammonia into the amide which, after crystallisation from alcohol, had m. p. 209°. Since the m. p. of malonamide is 170°, and that of methylmalonamide is variously given as 206—212°, it is clear that the alkylation had been successful.

(2) Ethyl malonate (80 g.), ethyl *p*-toluenesulphonate (100 g.), sodium (11·5 g.), and absolute alcohol (300 c.c.) were boiled under reflux for 20 hours, and the product was worked up in the usual way, 63 g. (yield 68%) of the ester being obtained; hydrolysis with alcoholic potash gave ethylmalonic acid, m. p. 111—112° (Conrad, *Annalen*, 1880, **204**, 136, gives m. p. 111·8°, and malonic acid has m. p. 132°). The silver salt of the butyric acid prepared from this ethylmalonic acid in the usual way was analysed (Found: Ag, 55·1. Calc.: Ag, 55·3%).

(3) Phenoxyethylmalonic acid was prepared as follows. Phenoxyethyl alcohol was obtained by boiling a mixture of phenol (188 g.), caustic soda (80 g.), ethylene chlorohydrin (120 g.), and water (720 c.c.) under reflux for ½ hour. The product was worked up in the usual way and the yield was 163 g. (79%). This alcohol can be

converted into its *p*-toluenesulphonate by heating with the acid chloride at 110—120°, but this is better prepared as follows (compare Foldi, *Ber.*, 1920, **53**, 1836): To 70 g. of phenoxyethyl alcohol, 100 g. of *p*-toluenesulphonyl chloride and 100 c.c. of caustic soda solution (containing 20 g. NaOH) are added with shaking during ½ hour. At first the mixture is cooled under the tap, but it becomes almost solid when the ester begins to separate and the temperature is therefore allowed to rise. The mixture is finally heated for ½ hour on a steam-bath to complete the reaction. *β-Phenoxyethyl p-toluenesulphonate* separates as an oil which solidifies on being poured into cold water (crude yield, 90%). When crystallised from methylated spirit, it separates in stout prisms, m. p. 80° (Found: C, 61·4; H, 5·4. $C_{15}H_{16}O_4S$ requires C, 61·6; H, 5·5%). The reactions of this ester with ammonia, amines, and *p*-toluenesulphonamide have been examined by one of us and will be communicated later. Ethyl phenoxyethylmalonate was prepared by heating together 1·15 g. of sodium, 8 g. of ethyl malonate, 15 g. of β-phenoxyethyl *p*-toluenesulphonate, and 25 c.c. of absolute alcohol under reflux for 20 hours. On being worked up in the usual way the mixture gave phenoxyethylmalonic acid, which, when crystallised from toluene, had m. p. 134—136° (compare Bently, Haworth, and Perkin, *loc. cit.*) (Found: C, 58·7; H, 5·3. Calc.: C, 58·9; H, 5·35%).

CCCI.—*Dibenzyl Ether as a Cryoscopic Solvent.*

By GEORGE MACDONALD BENNETT and GERVASE HEWITSON WILLIS.

THE observation that dibenzyl ether may be induced to crystallise below 0°, in spite of a marked tendency to supercooling, afforded us the opportunity to add this substance to the list of available cryoscopic solvents. The pure substance melts at +3·60°. The following values of the cryoscopic constant K were found with various solutes: Phenetole 62·6, ethylene dibromide 61·8, dimethylaniline 62·8, naphthalene 63·6. From the mean of these values, *62·7*, the latent heat of fusion of dibenzyl ether is calculated to be 24·4 cals. per g.

A few cryoscopic observations were also made with benzoic and acetic acids and benzyl alcohol as solutes. A tendency for ethers to unite with hydroxylic substances to yield complexes of the type $R_2O \longrightarrow HOR'$ (Sidgwick, "The Electronic Theory of Valency,"

p. 137) should show itself by causing the apparent molecular weight of a substance R'OH to be less in solution in the ether R_2O than in a solvent chemically indifferent to it such as benzene, in which association of the hydroxylic substance is likely to be more pronounced. The only ether previously proposed as a cryoscopic solvent is diphenyl ether (Durand and Rougé, *Bull. Soc. chim.*, 1925, **37**, 697), but it is less suitable than dibenzyl ether for testing the point under discussion on account of the lower donating power which is to be expected in an oxygen atom attached directly to the benzene nucleus.

In Table I our values for the apparent molecular weights (*M*) of the hydroxylic substances examined in dibenzyl ether are compared with the values at corresponding concentrations and closely similar temperatures in benzene solution as recorded in the literature (Beckmann, *Z. physikal. Chem.*, 1888, **2**, 729; Auwers, *ibid.*, 1893, **12**, 689). The values for benzoic and acetic acids are definitely lower in dibenzyl ether than in benzene, but those for benzyl alcohol are not appreciably different in the two solvents. The ebullioscopic measurements of Beckmann (*ibid.*, 1890, **6**, 437) show a similar difference in the direction expected.

TABLE I.

Solute.	Solvent.	Concentration (%).	*M*.
Benzoic acid.	Benzene.	1·44—4·73	228—236
	Dibenzyl ether.	1·1 —5·3	147—177

	Dibenzyl ether.	1·6 —5·0	91·6—109
Benzyl alcohol.	Benzene.	1·57—5·12	116—165
	Dibenzyl ether.	2·0 —4·5	135—140

EXPERIMENTAL.

Preparation and Purification of Dibenzyl Ether.—The ether was conveniently prepared by boiling a mixture of benzyl alcohol (30 g.) and benzyl chloride (25 g.) with potassium hydroxide (25 g.) for 5 hours, and fractionating the product. Repeated distillation under diminished pressure did not eliminate the odour of benzaldehyde. It appears that the ether suffers a slight decomposition in distillation even at temperatures below 200°. After repeated fractional freezing, the substance had b. p. 184°/28 mm., 170°/16 mm., m. p. 3·60°, $d_4^{10\cdot5°}$ (vac.) 1·0504, $d_4^{20°}$ (vac.) 1·0428, and its faint odour was quite distinct from that of benzaldehyde. The liquid often remained for hours in the supercooled state without crystallising spontaneously. Crystallisation could always be induced, however, by vigorous stirring at a temperature below —15°.

Cryoscopic Measurements.—The observations were made with the

Beckmann apparatus, the usual precautions being adopted. Nucleation was always necessary in order to bring about crystallisation of the solvent without undue supercooling. The data obtained with standard substances are recorded in Table II, Δt being the observed depression of the freezing point of dibenzyl ether when w g. of solute were dissolved in 26·10 g. of solvent.

The values with benzil as solute are anomalous. These and the first value for naphthalene have been ignored in taking the mean value of K.

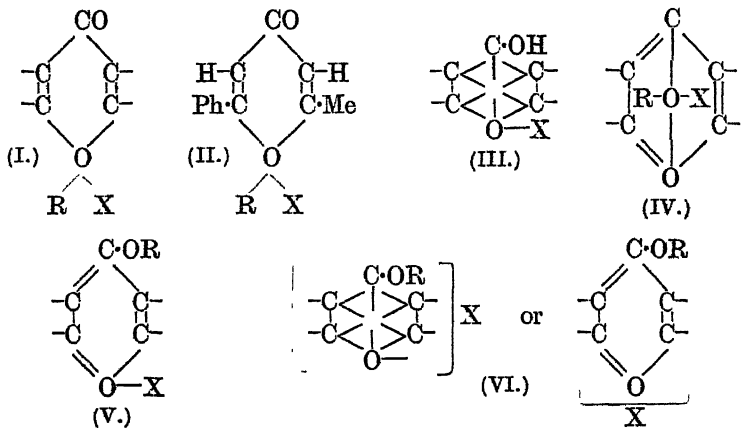
CCCII.—*Derivatives of 2-Phenyl-6-methyl-4-pyrone. The Non-resolution of 2-Phenyl-6-methyl-4-pyrone d-α-Bromocamphor-π-sulphonate.*



By CHARLES STANLEY GIBSON and JOHN LIONEL SIMONSEN.

IN a note published some years ago (P., 1913, **29**, 159), Levy, Holmyard, and Ruhemann described briefly some experiments on the attempted resolution of the relatively stable 2-phenyl-6-methyl-4-pyrone *d*-α-bromocamphor-π-sulphonate into its diastereoisomerides. Subsequently Dr. Levy continued these experiments in this department, but, finding himself unable to devote the necessary time to the work, he suggested that we should complete the investigation.

At the time of publication of the above note, the authors held the view that the salts of the 4-pyrones were true oxonium salts represented by the general formula (I), where R = H and X = acid radicals, and in this case it is obvious that in derivatives such as (II), which are asymmetrical, resolution of the salt into its diastereoisomerides is to be anticipated.

Since Collie and Tickle (J., 1899, **75**, 710) first described the salts of dimethylpyrone and ascribed to them formula (I), the constitution of these salts has been the subject of much discussion. Werner (*Ber.*, 1901, **34**, 3309) suggested the centric formula (III), whilst Collie (J., 1904, **85**, 971) adopted a bridged formula (IV). The

important experiments of Baeyer (*Ber.*, 1910, **43**, 2337) appeared to show beyond question that the correct formulation of the salts was (V). In 1914, Boon, Wilson, and Heilbron (J., **105**, 2176; compare Baly, Collie, and Watson, J., 1909, **95**, 144), from a study of the absorption spectra of a number of arylidene-pyrones and their salts, suggested that although the salts of dimethylpyrone were best represented by the bridged structure (IV), the salts of the arylidene-bases were true oxonium salts (I).

Hantzsch (*Ber.*, 1919, **52**, 1535, 1544), from a comparison of the absorption spectra of the pyrones, thiopyrones, and their salts, concluded that the true salts were co-ordination compounds of the general formula (VI), which is identical with that (III) suggested by Werner (*loc. cit.*). This view was apparently accepted by Arndt, Scholz, and Nachtwey (*Ber.*, 1924, **57**, 1903). The bridged formula of Collie would, however, appear still to have adherents (compare Drew, this vol., p. 518).

The divergent views on the constitution of the salts of the 4-pyrones enhance the importance of a careful repetition of Levy, Holmyard, and Ruhemann's experiments, since if the resolution of 2-phenyl-6-methyl-4-pyrone *d*-α-bromocamphor-π-sulphonate could be effected, it would lend support to a bridged formulation of these salts, as it would be difficult to account for optical isomerism in the case of co-ordinated compounds. We have therefore subjected the pure salt to a prolonged and careful systematic examination. Seventeen fractional crystallisations from pure dry acetone were carried out, but the optical rotatory powers of the six final fractions, when dissolved in pure ethyl alcohol, were all identical, and no sign of resolution was observed. In so far as one is justified in drawing conclusions from negative results, therefore, our experi-

ments would appear to support the co-ordination formulation of these salts.

As it seemed to us possible that a methylated compound might more readily lend itself to resolution, we prepared the *methylmethosulphate* and the *methiodide* of 2-phenyl-6-methyl-4-pyrone. These compounds were, however, found to be unsuitable, being readily hydrolysed.

It has been suggested by Boon, Wilson, and Heilbron (*loc. cit.*) that the salts of the arylidene-pyrones are true oxonium salts (see, however, Heilbron, Barnes, and Morton, J., 1923, **123**, 2564); we therefore prepared *2-phenyl-6-piperonylidenemethyl-4-pyrone*, but this colourless substance yields such intensely coloured salts that the stereochemical investigation of the d-*α-bromocamphor-π-sulphonate* has so far been found to be impossible with the equipment at present available. When the piperonylidene derivative is treated with bromine in chloroform solution a yellow crystalline solid, m. p. 155—157°, is obtained; this was not analysed but probably consisted of the dibromo-derivative (compare Boon, Wilson, and Heilbron, *loc. cit.*). On crystallisation from acetone, hydrogen bromide was eliminated and an ochreous crystalline solid, m. p. 222°, separated. Analysis showed this to be the *monobromopiperonylidene-pyrone* but the position of the bromine atom was not determined.

EXPERIMENTAL.

2-Phenyl-6-methyl-4-pyrone.—The pyrone was prepared by the method of Ruhemann (J., 1908, **93**, 431), except that finely powdered sodamide was used in place of dry sodium ethoxide and the reaction mixture was mechanically stirred during the condensation. By these modifications of the original process the yield was somewhat improved.

The *hydrochloride* was readily obtained by the saturation of an ethereal solution of the pyrone with hydrogen chloride at 0° (Levy, Holmyard, and Ruhemann, *loc. cit.*). The crude salt melted somewhat indefinitely at 161°, and crystallised from a large volume of acetone in fine, glistening prisms, which softened at 105° and melted to a red oil at 165°. It was very readily soluble in water and alcohol, only sparingly soluble in acetone, and insoluble in ether, benzene, and light petroleum (Found: C, 64·7; H, 4·9; HCl, 16·2. $C_{12}H_{11}O_2Cl$ requires C, 64·7; H, 4·9; HCl, 16·4%).

Perchlorate. A warm solution of the pyrone (1 g.) in dilute alcohol (3 c.c.) was treated with an excess of a dilute aqueous solution of perchloric acid. The *perchlorate* separated immediately as an oil which rapidly solidified. It crystallised from dilute alcohol or from much hot water in fine needles, which softened at 135—

137° and melted at 145—147° (Found: C, 61·0, 61·6; H, 4·6; $HClO_4$, by titration, 21·4. $C_{24}H_{21}O_8Cl$ requires C, 61·0; H, 4·5; $HClO_4$, 21·3%).

Sulphate. The pyrone, dissolved in the minimum quantity of methyl alcohol, was treated with the requisite amount of 0·1*N*-sulphuric acid, and the clear solution evaporated to dryness under diminished pressure at room temperature. The crystalline residue after trituration with a little cold acetone had m. p. 165°. It separated from much acetone in iridescent glistening prisms, m. p. 168—169°. It was very soluble in water and methyl alcohol, but insoluble in benzene and ethyl acetate (Found: C, 50·4; H, 4·5. $C_{12}H_{12}O_6S$ requires C, 50·7; H, 4·2%).

Methylmethosulphate. The pyrone, dissolved in the minimum quantity of benzene, was mixed with the calculated amount of freshly distilled methyl sulphate. On standing, the solution, which developed a pink colour, gradually deposited the methylmethosulphate in fine, long needles. After remaining for 48 hours, the crystals were collected, washed with benzene, and dried in a vacuum, m. p. 140—143° with slight previous softening (Found: C, 53·0; H, 5·0. $C_{14}H_{16}O_6S$ requires C, 53·8; H, 5·1%). The *methylmethosulphate* could not be purified by recrystallisation. It was very soluble in water, and in methyl and ethyl alcohols, but insoluble in benzene, ethyl acetate, and light petroleum; it dissolved in a large volume of hot dry acetone, but underwent decomposition. The first fraction which separated on cooling softened at 120° and had m. p. 140—142°, analysis showing it to be a mixture of the methylmethosulphate and the sulphate (Found: C, 51·3; H, 4·9. Calc. for $C_{12}H_{12}O_6S$: C, 50·7; H, 4·2%. Calc. for $C_{14}H_{16}O_6S$: C, 53·8; H, 5·1%). The presence of the sulphate in the solution was confirmed by concentration, whereupon the pure sulphate crystallised in prisms, m. p. 167° (Found: C, 50·2; H, 4·4%). When an aqueous solution of the methylmethosulphate (m. p. 140—143°) was treated with a dilute solution of perchloric acid, the pyrone perchlorate, m. p. 145—147°, was obtained (Found: C, 60·4; H, 4·4; Cl, 7·5. Calc.: C, 61·0; H, 4·5; Cl, 7·5%). The methylmethosulphate did not react with silver *d*-α-bromocamphor-π-sulphonate in alcoholic solution.

Methiodide. When the methylmethosulphate, dissolved in water, was treated with an excess of a dilute solution of potassium iodide, and placed in the ice-chest, the *methiodide* gradually separated. The crystals, which were generally discoloured, decomposed at 105° and were somewhat unstable. Purification was best effected by solution in cold acetone and precipitation by careful addition of light petroleum; colourless needles were deposited, the decom-

position point being unchanged. On keeping, the crystals rapidly become discoloured owing to the liberation of iodine. This compound was analysed by Dr. Levy (Found: C, 47·3; H, 4·1. $C_{13}H_{13}O_2I$ requires C, 47·6; H, 4·0%). The methiodide cannot be prepared by the direct action of methyl iodide on the pyrone; when heated under diminished pressure it decomposed with liberation of methyl iodide and regeneration of the pyrone. The pyrone was also formed when the methiodide was shaken in aqueous solution with either silver oxide or lead oxide. On treatment of an alcoholic solution of the methiodide with perchloric acid, the perchlorate of the pyrone was formed.

2-Phenyl-6-methyl-4-pyrone d-α-*Bromocamphor-π-sulphonate*.—We have prepared this salt by two methods, the second method being preferred for the preparation in quantity, since the pyrone hydrochloride can be more effectively purified than the pyrone itself. (i) The pyrone, dissolved in the minimum quantity of alcohol, was mixed with the requisite amount of a standard aqueous solution of *d*-α-bromocamphor-π-sulphonic acid. When the solution was evaporated to dryness under diminished pressure at room temperature, the salt remained as a crystalline solid. It was recrystallised from acetone and obtained in colourless prisms, m. p. 153—154°.

(ii) The pyrone hydrochloride (10 g.) in alcohol (125 c.c.) was mixed with a solution of silver *d*-α-bromocamphor-π-sulphonate * (18·5 g.) in alcohol (100 c.c.), both solutions being slightly warmed. Silver chloride separated immediately, and after standing for some hours the solution was filtered, and the solvent removed at 30° under diminished pressure, a colourless salt remaining. This was systematically recrystallised from acetone, and after seventeen crystallisations six fractions were obtained. The optical rotatory powers, determined in all cases in absolute ethyl alcohol at 20° ($c = 0{\cdot}400$, $l = 4$), were: $[\alpha]_{5461}$ +83·05°, 82·7°, 82·6°, 82·5°, 82·35°, 82·2°. The salt crystallised from acetone in colourless prisms, softening at 153°, m. p. 157—158° (Found: C, 52·9; H, 5·2. Calc.: C, 53·1; H, 5·0%).

2-Phenyl-6-piperonylidenemethyl-4-pyrone.—To a mixture of 2-phenyl-6-methyl-4-pyrone (1·6 g.) and piperonal (1·5 g.) in alcohol (5 c.c.), a drop of concentrated potassium hydroxide solution was added. A deep red colour developed, and on standing a crystalline solid (1·4 g.) separated. The *piperonylidene* derivative crystallised from acetone, in which it was somewhat sparingly soluble, in colour-

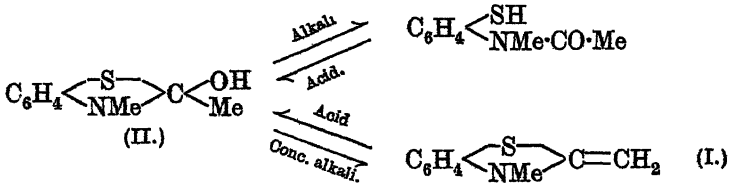
* This salt does not appear to have been analysed previously. It crystallised from alcohol with one molecule of water of crystallisation (Found: C, 27·3; H, 3·6; Ag, 24·6. $C_{10}H_{14}O_4SBrAg,H_2O$ requires C, 27·5; H, 3·7; Ag, 24·8%).

less, soft needles, m. p. 194° (Found: C, 75·4; H, 4·5. $C_{20}H_{14}O_4$ requires C, 75·4; H, 4·4%). It dissolved in concentrated hydrochloric acid, yielding a deep red solution, the salt being decomposed by addition of water. The *perchlorate*, prepared by the addition of perchloric acid to an acetone solution of the pyrone, crystallised in terra-cotta needles, decomp. 143°. Owing to its exploding just above the m. p., the compound could not be analysed. The salt dissociated somewhat readily and could only be recrystallised in the presence of perchloric acid.

For the preparation of the d-*α-bromocamphor-π-sulphonate*, the piperonylidene derivative (0·4852 g.) was dissolved in hot acetone (90 c.c.), and an aqueous solution of the acid (0·475 g.) added. The orange-coloured solution was evaporated to dryness under diminished pressure at room temperature, and an orange, crystalline solid remained. This was recrystallised from much dry acetone, from which it separated in soft orange prisms, m. p. 205—206° with slight previous softening (Found: C, 57·2; H, 4·7. $C_{30}H_{29}O_8BrS$ requires C, 57·2; H, 4·6%).

When a chloroform solution of the piperonylidene derivative of the pyrone was treated with an equivalent quantity (1 mol.) of bromine, a bright red solid separated. This rapidly redissolved, and on stirring a yellow crystalline solid was deposited. This had m. p. 155—157°, but unfortunately it was not analysed. On recrystallisation from acetone, in which it was sparingly soluble, it apparently underwent decomposition with loss of hydrogen bromide, and the *monobromo*-derivative separated in ochreous plates, decomp. 222°. The quantity available was insufficient for the determination of the position of the bromine atom (Found: Br, 19·9. $C_{20}H_{13}O_4Br$ requires Br, 20·1%).

We wish to acknowledge the assistance of Dr. J. H. Nutland who prepared some of the pyrone used in these experiments and carried out some of the analyses. A grant from the Government Grant Committee of the Royal Society, which has covered the greater portion of the cost of this investigation, is also gratefully acknowledged.



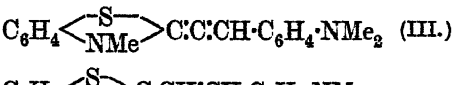
GUY'S HOSPITAL MEDICAL SCHOOL,
(UNIVERSITY OF LONDON), S.E. 1. [*Received, July 2nd*, 1928.]

CCCIII.—*The Methylene Bases from 1-Methylbenzthiazole and 1-Methylbenzselenazole Methiodides; with a Note on the Preparation of 1-Substituted Benzthiazoles.*

By LESLIE MARSHALL CLARK.

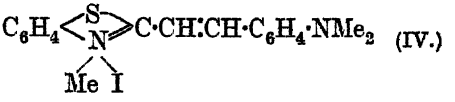
1-METHYLBENZTHIAZOLE methiodide reacts with ammonium hydroxide in dilute aqueous solution, yielding as the main product the ammonium salt of *o*-acetmethylamidothiophenol, since atmospheric oxidation of the solution gives 2 : 2′-diacetmethylamidodiphenyl disulphide (J., 1925, **127**, 973). König and Meier (*J. pr. Chem.*, 1925, **109**, 324) have shown that when 1-methylbenzthiazole methoperchlorate is suspended in acetone and shaken with concentrated sodium hydroxide solution, the acetone extracts a base which they identify as 2-methyl-1-methylenebenzthiazoline (I).

Further examination of the reaction with ammonia and with dilute sodium hydroxide proves that a certain amount of the methylene base is produced in either case, whilst in the latter case the proportion of methylene base to thiophenol is increased by increasing the alkali concentration. It is evident, therefore, that the carbinol (II) decomposes in the presence of alkali in the two directions:



When the compound (I) is heated in alcoholic hydrogen chloride solution or when alkali salts of *o*-acetmethylamidothiophenol are acidified, 1-methylbenzthiazolinium salts result. Each of the directions of reaction in which the carbinol base can decompose under the influence of alkalis is therefore reversible in the presence of acids.

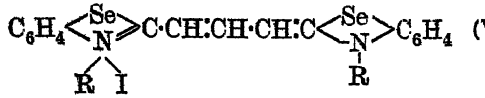
Since quaternary salts in the benzselenazole series react with alkalis to give products similar to those obtained from the analogous benzthiazolinium salts (J., 1927, 2805), the behaviour of 1-*methylbenzselenazole methiodide* has also been investigated. The base could not be obtained by the action of acetic acid on the zinc salt of *o*-aminoselenophenol, the products of this reaction being selenium and acetanilide, but was readily formed by condensation of the zinc salt with acetyl chloride. The methiodide in aqueous solution re-



immediately with dilute sodium hydroxide giving 2-*methyl*-1-*methylenebenzselenazoline* together with the sodium salt of *o*-acetylmethylaminoselenophenol.

The course of the reaction may be followed by titration with phenolphthalein as indicator, part of the methiodide yielding a precipitate of the selenazoline (and consequently neutralising one equivalent of alkali), whilst the remainder is converted into the neutral sodium salt of the selenophenol (at the same time neutralising 2 equivs. of alkali). A much higher proportion of the methylene base is formed with 1-methylbenzselenazole methiodide than with the analogous sulphur compound. 2-Methyl-1-methylenebenzselenazoline, like its sulphur analogue, is reconverted into the ammonium salt by heating with alcoholic hydrogen chloride.

Mills and Raper (J., 1925, **127**, 2466) have isolated the highly-coloured condensation product obtained by reaction of *p*-dimethylaminobenzaldehyde with the reactive methylene group in 1-methyl-2-methylene-1 : 2-dihydro-β-naphthaquinoline. The aldehyde condenses similarly with 2-methyl-1-methylenebenzthiazoline in alcohol, giving a deep red solution from which no solid material could be isolated. The solution evidently contains the compound (III), since on addition of one mol. of hydriodic acid, *p*-dimethylaminostyrylbenzthiazole methiodide (IV) is formed, addition of the acid evidently taking place in a manner analogous to that described by Mills and Raper (*loc. cit.*).



(III.)

(IV.)

The presence of the reactive methyl group in 1-methylbenzselenazole methiodide suggested that selenocarbocyanine formation might be possible. By using the general method of preparation of carbocyanines described by Hamer (J., 1927, 2796), *i.e.*, the condensation in pyridine solution of orthoformic ester with the methiodides of bases containing a reactive methyl group, good yields of both 2 : 2′-*dimethyl*- and 2 : 2′-*diethylselenocarbocyanine iodides* (V), were obtained. Like the thiocarbocyanines described by Mills (J., 1922, **121**, 455), these compounds are powerful sensitisers of the photographic plate.

(V.)

In *C*-substituted benzoxazoles, fission of the heterocyclic ring is increasingly difficult to bring about as the volume and valency demands of the substituent group increase (Skraup, *Annalen*, 1919, **419**, 1). The influence of the *C*-phenyl group, although well-marked in the benzoxazole series, is insufficient in the benzthiazolinium series to make possible the isolation of a carbinol base of the type (II), even when silver hydroxide is used instead of sodium hydroxide (J., 1925, **127**, 973) as basifying agent.

The well-known Hofmann synthesis of 1-substituted benzthiazoles (*Ber.*, 1880, **13**, 21), whereby *o*-aminothiophenol is heated with the appropriate acid, acid anhydride, or acid chloride, is not entirely satisfactory. An alternative method is therefore described. 2 : 2′-Diaminodiphenyl disulphide is acylated by treatment with the appropriate acid or acid chloride, and this compound is reduced with sodium hydrosulphite yielding the acylamino-thiophenol, which condenses with elimination of water to give the 1-substituted benzthiazole (compare Clark, *loc. cit.*, and Phillips, this vol., p. 172).

EXPERIMENTAL.

2-Methyl-1-methylenebenzthiazoline is formed in small yield by the action of ammonia, silver hydroxide, or *N*-sodium hydroxide on 1-methylbenzthiazole methiodide in aqueous solution. The maximum yield was obtained by the following modification of König and Meier's method (*loc. cit.*). The methiodide (4 g.) was suspended in acetone and shaken with 50% sodium hydroxide solution. When no quaternary salt remained undecomposed, the acetone solution was evaporated and the pinkish residue extracted with toluene (5 c.c. and 2 c.c.). A small quantity of dark red oil, which afterwards solidified, remained undissolved; this was separated by acetone into a sparingly soluble, dark red, crystalline substance and a colourless substance which separated in needles, m. p. 164°. These compounds were not further examined. The toluene solution, when cooled, deposited 0·81 g. of stout, colourless tablets of 2-methyl-1-methylenebenzthiazoline, m. p. 170° (König and Meier give 164°) (Found : C, 66·2; H, 5·6; N, 8·7. Calc. : C, 66·3; H, 5·5; N, 8·6%). A mixture of this substance with 2 : 2′-diacetmethylamidodiphenyl disulphide, m. p. 171°, melted at 128°. When these two compounds are heated together they develop a brilliant red colour.

By the action of benzoyl chloride on a solution of the sodium salt of *o*-acetmethylamidothiophenol, the *benzoyl* derivative was obtained; from light petroleum it separated in colourless needles, m. p. 87° (Found : C, 67·0; H, 5·2. $C_{16}H_{15}O_2NS$ requires C, 67·4; H, 5·3%).

1-*Methylbenzthiazole methopicrate*, prepared from the methiodide

and picric acid, separated from aqueous solution in yellow needles which, when kept in a vacuum over sulphuric acid, became liquid and then resolidified. It then had m. p. 94° (Found: N, 14·7. $C_{15}H_{12}O_7N_4S$ requires N, 14·3%). The *hydrogen sulphate* separated from alcohol–ether in colourless needles, m. p. 177—178° (Found: SO_4, 38·5. C_8H_7NS,H_2SO_4 requires SO_4, 38·75%); the *methochloroplatinate*, prepared from the methochloride and chloroplatinic acid in alcoholic solution, separated in deep yellow crystals, m. p. 224° (decomp.) [Found: Pt, 26·2. $(C_9H_{10}NS)_2PtCl_6$ requires Pt, 26·5%]; the *perchlorate* separated from alcohol–ether in colourless needles, m. p. 149°, and exploded during combustion.

Action of Silver Hydroxide on 1-Phenylbenzthiazole Methiodide.—The methiodide (2 g.), dissolved in water (35 c.c.) and acetone (50 c.c.), was shaken for an hour with excess of silver hydroxide; the filtrate from the insoluble material contained none of the expected 1-hydroxy-1-phenyl-2-methylbenzthiazoline, the major portion of the thiazole compound being mixed with the silver oxide and iodide residue, probably as the silver salt of *o*-benzoylmethylaminothiophenol (compare Mills, Clark, and Aeschlimann, J., 1923, **123**, 2353). The sodium salt of *o*-benzoylmethylaminothiophenol was benzoylated by shaking with benzoyl chloride, and the *benzoyl* derivative, when crystallised from light petroleum, had m. p. 130—131° (Found: C, 72·6; H, 4·8. $C_{21}H_{17}O_2NS$ requires C, 72·6; H, 4·85%).

For the characterisation of 1-phenylbenzthiazole quaternary salts, the following compounds were prepared by the usual methods: *1-Phenylbenzthiazole methochloroplatinate*, m. p. 243° (decomp.) [Found: Pt, 22·7. $(C_{14}H_{12}NS)_2PtCl_6$ requires Pt, 22·7%]; *methopicrate*, orange-yellow plates, m. p. 125—126° (Found: N, 12·4. $C_{20}H_{14}O_7N_4S$ requires N, 12·3%); *methoperchlorate*, colourless needles, m. p. 220° (Found: S, 10·0. $C_{14}H_{12}O_4NSCl$ requires S, 9·8%).

Preparation of 1-Methylbenzselenazole.—A preliminary experiment on the action of glacial acetic acid (150 c.c.) on the zinc salt of *o*-aminoselenophenol (17 g.) in an atmosphere of carbon dioxide showed that selenium was deposited; the only product which could be isolated from the filtrate was acetanilide, m. p. 114° (Found: C, 71·35; H, 6·1; N, 10·4. Calc.: C, 71·1; H, 6·7; N, 10·4%). When the acetic acid was replaced by acetyl chloride, the condensation took place smoothly: The zinc salt (7 g.) was suspended in benzene (50 c.c.), and acetyl chloride in excess (10 c.c.) was added slowly with constant shaking; the brown oil which separated solidified after 16 hours. The reaction mixture was heated on the water-bath for 1 hour and cooled. Water and excess of ammonia

were then added. The solid slowly dissolved, and the benzene layer was separated. The aqueous solution was extracted with ether, the combined organic extracts were dried over sodium carbonate, and most of the solvent was distilled off. Addition of light petroleum then precipitated a yellowish gum, which was probably 2 : 2′-diacetamidodiphenyl diselenide, but which was not investigated. The solution was removed and concentrated, and the residual oil distilled under reduced pressure. *1-Methylbenzselenazole* (4·6 g.) was thus obtained as an almost colourless liquid, b. p. 140°/51 mm. It was analysed as the *chloroplatinate*, which separates from alcoholic solutions in yellow needles [Found: C, 24·4; H, 1·95; Pt, 24·6. $(C_8H_7NSe)_2,H_2PtCl_6$ requires C, 23·9; H, 2·0; Pt, 24·4%). The *methiodide*, obtained by heating the base (3·8 g.) with methyl iodide (6 g.) at 100° for 8 hours, crystallised from alcohol in fine, colourless needles, m. p. 221° (decomp.); yield, 5·5 g. (Found: I, 37·4; Se, 23·6. $C_9H_{10}NISe$ requires I, 37·6; Se, 23·4%); and the *ethiodide*, similarly obtained by 16 hours' heating, crystallised from alcohol in colourless, flattened needles, m. p. 212° (decomp.) (Found: I, 35·9. $C_{10}H_{12}NISe$ requires I, 36·1%). The *methochloroplatinate*, prepared from the methochloride in the usual way, had m. p. 214° (decomp.) [Found: Pt, 23·1. $(C_9H_{10}NSe)_2PtCl_6$ requires Pt, 22·9%].

Action of Sodium Hydroxide on 1-Methylbenzselenazole Methiodide.—Addition of *N*/20- or *N*-sodium hydroxide solution to aqueous solutions of the methiodide causes the formation of a voluminous, curdy, pale yellow precipitate of *2-methyl-1-methylenebenzselenazoline*, which crystallises from its orange-red alcoholic solution in pale yellow plates, m. p. 157—158° (Found: C, 51·4; H, 4·4; N, 7·1. C_9H_9NSe requires C, 51·4; H, 4·3; N, 6·7%). The compound is sparingly soluble in alcohol and shows a tendency to form a brown mass when warmed with that solvent. From 1 g. of the methiodide, 0·346 g. of methylene base (dried over sulphuric acid) was obtained, and the change of titre was 4·0 c.c. of *N*-alkali; if the reaction proceeded as suggested on p. 2314, the change of titre should have been 4·3 c.c. The alkaline solution, after removal of the methylene base, was oxidised with potassium ferricyanide and gave an oily suspension which rapidly crystallised. The solid product, *2 : 2′-diacetmethylamidodiphenyl diselenide*, crystallised from petroleum ether in colourless flat needles, m. p. 141° (Found: C, 47·3; H, 4·4; N, 6·3. $C_{18}H_{20}O_2N_2Se_2$ requires C, 47·6; H, 4·4; N, 6·2%).

Reversibility of Methylene-base Formation in the Benzthiazole and Benzselenazole Series.—(1) *Action of hydrochloric acid on 2-methyl-1-methylenebenzthiazoline.* The methylene base (0·2 g.) in alcohol

(5 c.c.) was heated under reflux with hydrochloric acid (2 c.c.) for 2 hours. Addition of chloroplatinic acid then caused the separation of yellow needles which slowly disappeared as a heavy, brown, crystalline deposit was formed. This compound had m. p. 224° (decomp.), not depressed when mixed with authentic 1-methylbenzthiazole methochloroplatinate (Found: Pt, 26·2. Calc.: Pt, 26·5%).

(2) *Action of hydrochloric acid on 2-methyl-1-methylenebenzselenazoline.* The reaction was carried out as for the sulphur compound, the chloroplatinate separating from the alcoholic solution in stout, yellowish-brown needles, m. p. 214° (decomp.) (Found: Pt, 23·1. Calc.: Pt, 22·9%), not depressed by admixture with 1-methylbenzselenazole methochloroplatinate.

Condensation of 2-Methyl-1-methylenebenzthiazoline with p-*Dimethylaminobenzaldehyde.*—Dimethylaminobenzaldehyde and the methylene base (0·71 g. of each) were heated in alcoholic solution (15 c.c.) for 1 hour. An intense red colour developed, but no solid material separated when the mixture was cooled and kept for 12 hours. To the hot solution, therefore, hydriodic acid (*d* 1·7; 1·1 c.c., 1 mol.) was added. The purple, crystalline precipitate with bronze reflex, which separated on cooling, was easily soluble in alcohol, and was crystallised from that solvent containing a little sulphurous acid; *p*-dimethylaminostyrylbenzthiazole methiodide (Found: S, 7·6. Calc.: S, 7·6%) melted at 244—245°, unchanged by admixture with an authentic specimen, m. p. 245°, prepared by Dr. F. M. Hamer from 1-methylbenzthiazole methiodide and the aldehyde. The absorption spectra in alcohol of the two samples are identical, showing maxima at λ 4350 and λ 6400.

Condensation of Orthoformic Ester with 1-Methylbenzselenazole Methiodide.—The methiodide (1·45 g.) and orthoformic ester (1·5 c.c.) were boiled in dry pyridine solution (15 c.c.) for 1 hour. A deep purple colour rapidly developed, and a crystalline deposit was formed. The mixture was poured into water and kept for 12 hours. 2 : 2′-*Dimethylselenocarbocyanine iodide*, thus obtained, was crystallised from ethyl alcohol (1·3 l.), and separated from the hot deep red solution in flocculent masses of fine, bronze needles, m. p. 267—268° (decomp.); yield 0·8 g. (Found*: C, 40·5; H, 3·5; N, 4·8. $C_{19}H_{17}N_2ISe_2$ requires C, 40·8; H, 3·0; N, 5·0%). In alcoholic solution the dye has absorption maxima at λ 4500 and λ 6400, whilst it confers sensitivity on a bathed plate up to λ 7020.

Condensation of Orthoformic Ester with 1-Methylbenzselenazole Ethiodide.—The condensation was carried out in the manner described for the methyl compound. The yield of 2 : 2′-*diethyl-*

* Microanalysis by H. Weil, Munich.

selenocarbocyanine iodide from 0·5 g. of 1-methylbenzselenazole ethiodide was 0·27 g. The solubility of the higher homologue is considerably greater than that of the lower, since this amount of dye could be crystallised from 50 c.c. of alcohol. It separates in glistening, dark green needles, m. p. 270—271° (decomp.) (Found*: N, 4·8. $C_{21}H_{21}N_2ISe_2$ requires N, 4·8%). The absorption spectrum in alcoholic solution shows maxima at λ 4500 and λ 6420. The sensitivity band of a bathed plate has a slight maximum at λ 6200, falling off steeply to the red at λ 6940.

The Preparation of 1-Substituted Benzthiazoles.

2 : 2′-*Diacetamidodiphenyl disulphide* was prepared by boiling 2 : 2′-diaminodiphenyl disulphide (8·0 g.) with glacial acetic acid (50 c.c.) and acetic anhydride (10 c.c.) for 5 hours. Dilution of the solution and neutralisation with ammonia precipitated a colourless oil, which rapidly crystallised (9·3 g.); when recrystallised from ethyl acetate, it separated in masses of colourless, flocculent needles, m. p. 165—166° (Found: N, 8·4. $C_{16}H_{16}O_2N_2S_2$ requires N, 8·4%), readily soluble in alcohol.

1-*Methylbenzthiazole.*—2 : 2′-Diacetamidodiphenyl disulphide (12·2 g.) was dissolved in hot aqueous alcohol, and excess of solid sodium hydrosulphite (15 g.) was added in three portions. Heating was continued during 15 minutes. After the addition of hydrochloric acid (35 c.c.) the solution was concentrated on the water-bath. Basification with sodium hydroxide solution precipitated an oily paste which was extracted with ether. The ethereal solution was dried over sodium carbonate and evaporated, leaving 3·5 g. of a yellow oil, which, on distillation under reduced pressure, yielded 2·0 g. of pure 1-methylbenzthiazole, identified by means of its picrate, m. p. 155—156°, identical with that obtained from an authentic specimen.

2 : 2′-*Dipropionamidodiphenyl disulphide* was obtained by boiling 2 : 2′-diaminodiphenyl disulphide (6 g.) for 12 hours with propionic acid (50 g.); the disulphide was precipitated as a dark brownish oil on dilution and neutralisation of the acid solution, but solidified on standing over-night. A portion, washed with ether and crystallised from light petroleum (b. p. 60—80°), separated in colourless, flocculent masses, m. p. 138° (Found: N, 7·95. $C_{18}H_{20}O_2N_2S_2$ requires N, 7·8%).

1-*Ethylbenzthiazole.*—Reduction of the foregoing unpurified solid with sodium hydrosulphite as described above for the acetyl compound eventually gave a small quantity of dark-coloured oil. This was not distilled, but 1·6 g. of a picrate were obtained from it by addition of a saturated solution of picric acid in alcohol; after

* Microanalysis by H. Weil, Munich.

recrystallisation from alcohol (charcoal), 1-*ethylbenzthiazole picrate* had m. p. 138° (Found: C, 45·8; H, 3·0; N, 14·1. $C_{15}H_{12}O_7N_4S$ requires C, 45·9; H, 3·05; N, 14·3%).

2 : 2′-*Dibenzamidodiphenyl Disulphide*.—This was obtained in good yield by the Schotten–Baumann method from the base; it crystallised from alcohol, in which it is sparingly soluble, in pale yellow plates, m. p. 143—144·5° (Found: N, 6·3. $C_{26}H_{20}O_2N_2S_2$ requires N, 6·1%).

Reduction. The disulphide (1·2 g.) was dissolved in aqueous acetone, and an excess of sodium hydrosulphite added. The mixture was kept hot for 5 minutes. Hydrochloric acid (10 c.c.) was added and the acetone evaporated. Basification with ammonia precipitated a colourless oil which immediately crystallised. The solid, which when heated had the geranium-like odour characteristic of 1-phenylbenzthiazole, was crystallised from aqueous alcohol, and separated in long needles, m. p. 113°, showing no depression on admixture with an authentic specimen of 1-phenylbenzthiazole; yield 0·9 g.

Preparation of 2 : 2′-*Diaminodiphenyl Disulphide*.—The method described by Hofmann (*Ber.*, 1894, **27**, 2808) for the preparation of this compound is not satisfactory. Most of the material used in carrying out the above work was prepared by the method of Möhlau (*Ber.*, 1912, **45**, 131). Dr. F. M. Hamer, of Ilford Ltd., kindly prepared 10 g. of the disulphide by Hofmann's method and to her I am indebted for the following note: "After heating aniline (120 g.) and sulphur (35 g.) according to Hofmann's directions, 67% of the aniline was recovered unchanged by steam distillation. From the residue, 400 c.c. of hydrochloric acid (8%) extracted a mixture of bases. The hydrochlorides left on evaporation of this solution were separated by extraction with 400 c.c. of hot water. The sparingly soluble residue was the hydrochloride of a base which had m. p. 81° and was probably 4 : 4′-diaminodiphenyl disulphide. The hot aqueous solution deposited a hydrochloride which on basification gave 5 g. of 2 : 2′-diaminodiphenyl disulphide, m. p. 93°."

I wish to thank Messrs. Ilford Ltd. for the gift of 2 : 2′-diaminodiphenyl disulphide, and for examining the optical and photographic properties of the sensitisers described in this paper. My thanks are due to Dr. F. M. Hamer for the loan of a specimen of *p*-dimethylaminostyrylbenzthiazole methiodide.

CCCIV.—*The Effects of the Spatial Position of Substituent Groups on Acidic Strength.*

By DONALD HOLROYDE HEY.

IN an investigation on the rotatory powers of a number of the homologous menthyl alkyloxyacetic and hydrogen dicarboxylic esters (Rule, Hay, and Paul, this vol., p. 1347), it was observed that the maxima in the rotation curves of the one series corresponded to the minima in the other. From these results it was concluded that the terminal alkyloxy- and carboxy-groups of the growing chains give rise to opposite changes in rotatory power when they return to the neighbourhood of the asymmetric atom, and, further, that the characteristic influence of *o*-substituents in the optically active benzoic esters is propagated through space rather than through the chain of intervening atoms. In support of these conclusions the authors observed that parallel phenomena may be found in the influence of substituents on the acidity of geometrically isomeric acids.

There appears, however, to be little justification for this generalisation, and available data on the dissociation constants of acids of the type of crotonic acid (as well as of other acids) show that it is not possible to correlate the two phenomena. Recent work on the configuration of the crotonic acids, both from the chemical and physical standpoint, shows that crotonic acid (m. p. 72°) has the *trans*-configuration (Errera and Henri, *Compt. rend.*, 1925, **181**, 548; Langseth, *Z. physikal. Chem.*, 1925, **118**, 49; Auwers and Wissebach, *Ber.*, 1923, **56**, 715). The dissociation constants of the two crotonic acids, and of other acids of the same type on which there is now little doubt with regard to their configuration, are given below:

$CH_3\cdot C\cdot H$ $H\cdot C\cdot CO_2H$ Crotonic acid, $0{\cdot}22 \times 10^{-4}$.	$H\cdot C\cdot CH_3$ $H\cdot C\cdot CO_2H$ *iso*Crotonic acid, $0{\cdot}36 \times 10^{-4}$.	$Cl\cdot C\cdot CH_3$ $H\cdot C\cdot CO_2H$ β-Chloro*iso*crotonic acid, $0{\cdot}95 \times 10^{-4}$.	$CH_3\cdot C\cdot Cl$ $H\cdot C\cdot CO_2H$ β-Chlorocrotonic acid, $1{\cdot}44 \times 10^{-4}$.
$CH_3\cdot C\cdot H$ $CH_3\cdot C\cdot CO_2H$ Tiglic acid, $0{\cdot}09 \times 10^{-4}$.	$H\cdot C\cdot CH_3$ $CH_3\cdot C\cdot CO_2H$ Angelic acid, $0{\cdot}50 \times 10^{-4}$.	$CH_3\cdot C\cdot H$ $Cl\cdot C\cdot CO_2H$ α-Chlorocrotonic acid, $7{\cdot}2 \times 10^{-4}$.	$H\cdot C\cdot CH_3$ $Cl\cdot C\cdot CO_2H$ α-Chloro*iso*crotonic acid, $15{\cdot}8 \times 10^{-4}$.

The dissociation constants of the above acids indicate that the spatial proximity of a CH_3 or Cl group to the carboxyl group in every case increases the acidic strength, and that the change thus pro-

duced is in the same direction as (though smaller in magnitude than) that produced by the carboxyl group in fumaric and maleic acids ($K = 10 \times 10^{-4}$ and 150×10^{-4} respectively). From these observations it will be seen that it is not possible to adduce corroborative evidence from this source as claimed by Rule, Hay, and Paul, who infer that the spatial proximity of a CH_3 or Cl group to the carboxyl group produces a lowering of the dissociation constant, *i.e.*, an effect in the opposite direction to that produced by the carboxyl group. The analogy between the two phenomena cited by them is therefore invalid.

The increase in the acidic strength of these acids by the spatial proximity of substituents is in close conformity with the behaviour of substituted benzoic acids, and it is possible to observe a close analogy between the effect of *o*-substitution, which is known always to increase the strength of a benzoic acid independently of the polar character of the substituent, and *cis*-substitution, which is seen to have an effect of the same type on acids of the acrylic acid series. In both cases the increase may be attributed to steric inhibition to the return of the hydrogen ion.

In the case of ortho-substituted benzoic acids (*i.e.*, β-substitution), the increase in the dissociation constant is considerably greater than the increase in the corresponding β-substituted aliphatic acids, due to the superimposed secondary effect of the spatial proximity of the groups. On the other hand, with the meta- and para-acids, the increase is in nearly every case of the same order of magnitude as is met with in corresponding γ- and δ-substituted acids of the aliphatic series. This is clearly illustrated in the following table of dissociation constants (taken from Landolt–Börnstein, " Tabellen ").

Benzoic acid, $K \times 10^4 = 0{\cdot}66$.

Acid.	$K \times 10^4$.	Acid.	$K \times 10^4$.	Acid.	$K \times 10^4$.
o-Chlorobenzoic	13·0	*m*-Chlorobenzoic ...	1·5	*p*-Chlorobenzoic	0·93
o-Bromobenzoic	14·5	*m*-Bromobenzoic ...	1·37	*p*-Bromobenzoic	0·59
o-Hydroxybenzoic ...	10·0	*m*-Hydroxybenzoic	0·83	*p*-Hydroxybenzoic ...	0·29
Phthalic	12·0	Homophthalic	2·9	Terephthalic	—
o-Toluic	1·2	*m*-Toluic	0·56	*p*-Toluic	0·43

Propionic acid, $K \times 10^4 = 0{\cdot}14$.

β-Chloropropionic ...	0·85	γ-Chlorobutyric ...	0·3	δ-Chlorovaleric	0·204
β-Bromopropionic ...	0·98	γ-Bromobutyric ...	0·26	δ-Bromovaleric	0·191
β-Hydroxypropionic...	0·31	γ-Hydroxybutyric	0·19	δ-Hydroxyvaleric ...	0·2
Succinic	0·66	Glutaric	0·47	Adipic	0·37
Butyric	0·148	Valeric	0·16	Caproic	0·145

With the ortho-substituted acids, the configuration of the molecule is such that the substituent group is permanently maintained at an effective distance from the carboxyl group, and the resulting spatial proximity of the groups is shown in the abnormal increase in the dissociation constant. From these considerations, it would be

expected that *cis*-substitution in like manner would result in an increase in dissociation constant (when compared with *trans*-substitution), and if the new configurations for the crotonic acids are accepted, this analogy is borne out in fact.

UNIVERSITY COLLEGE, SWANSEA. [*Received, June 21st,* 1928.]

CCCV.—*The Intermolecular Condensation of Styryl Ketones. Part II. Styryl Nonyl Ketone and the Formation of Dimerides.*

By ISIDOR MORRIS HEILBRON and FRANCIS IRVING.

IN a previous communication (Dickinson, Heilbron, and Irving, J., 1927, 1888), it was shown that certain styryl methyl ketones on treatment with alkali underwent intermolecular condensation with formation of *cyclo*hexenones, whilst treatment with piperidine resulted in the formation of saturated dimerides, probably of *cyclo*butane structure. We have now extended the investigation to a series of styryl nonyl ketones, and in no case has the formation of *cyclo*hexenones been observed, but a number of saturated dimerides have been obtained by the action of alkali.

Methyl nonyl ketone has previously been condensed with benzaldehyde by means of 0·25% alcoholic potassium hydroxide (Carette, *Compt. rend.*, 1900, **131**, 1225), the product being the simple styryl nonyl ketone, m. p. 41—42°. Carette also discovered that by employing hot 1% alcoholic potassium hydroxide, a dimeride melting at 116° was obtained. Styryl nonyl ketone itself on similar treatment was found to yield the same dimeride.

Scholtz and Meyer (*Ber.*, 1910, **43**, 1861) by means of alkali condensed anisaldehyde, piperonal, *p*-tolualdehyde, and cuminal with methyl nonyl ketone, claiming to have obtained the monomeric styryl nonyl ketones in each case. A re-examination of their products has proved, as could be inferred from their high melting points, that the condensation products from *p*-tolualdehyde and cuminal are actually dimerides.

We have further found that whereas *p*-methoxy-, 3 : 4-dimethoxy-, 3 : 4-methylenedioxy-, and *p*-chloro-styryl nonyl ketones are formed when cold, dilute, aqueous alkali or piperidine is used as condensing agent, dimerides are produced by increasing the alkali concentration and preferably carrying out the reaction on the steam-bath instead of at room temperature. *o*- and *m*-Chloro- and *m*-methoxy-benzaldehydes, *o*-tolu- and salicyl-aldehydes did not yield dimerides when treated under such conditions, and it would

appear that dimeric forms are more readily produced when the aldehyde is substituted in the para-position.

The dimerides are all colourless substances which react as saturated compounds and are extremely inert towards ketone reagents. Carette (*J. Pharm.*, 1901, **13**, 412) found that bis-(styryl nonyl ketone) failed to react with semicarbazide. We have confirmed this observation, but have succeeded in obtaining a *monoxime* from this compound by prolonged treatment with hydroxylamine. This same inactivity has been noted by Stobbe and Hensel (*Ber.*, 1926, **59**, 2254), who only succeeded in obtaining a monoxime from the dimeride of phenyl 4-methoxystyryl ketone. These dimerides doubtless possess a *cyclo*butane structure similar to the products obtained by the action of short wave-length light or piperidine on unsaturated ketones (Stobbe and Hensel, *loc. cit.*).

EXPERIMENTAL.

Styryl Nonyl Ketone.—Benzaldehyde (2·5 g.) and methyl nonyl ketone (4 g.) were mixed with alcohol (2 c.c.), and piperidine (3 drops) was added. The solution was allowed to stand for several days, small amounts of piperidine being added daily; finally, it was diluted and cooled in a freezing mixture, crystals of styryl nonyl ketone then separating. These were recrystallised from methyl alcohol, appearing in colourless leaflets, m. p. 44° (Carette gives 41—42°; Thoms, *Ber. Deut. pharm. Ges.*, 1901, **11**, 3, gives 44—45°).

Monoxime of Bis-(Styryl Nonyl Ketone).—Bis-(styryl nonyl ketone) (1 mol.), prepared according to the method of Carette (*Compt. rend., loc. cit.*), was refluxed with hydroxylamine (2 mols.) for 2 hours in alcoholic solution, and the product recrystallised from alcohol, fine, colourless needles of the *monoxime* being obtained, m. p. 125—126° (Found: N, 2·7. $C_{36}H_{53}O_2N$ requires N, 2·6%).

Bis-(4-methoxystyryl Nonyl Ketone).—Anisaldehyde (3·2 g.) and methyl nonyl ketone (4 g.) were refluxed for 6 hours with 1% alcoholic potassium hydroxide solution (30 g.). The product was repeatedly crystallised from alcohol, being finally obtained in the form of colourless needles, m. p. 120° [Found: C, 79·3; H, 9·4; *M* (Pregl), 474. $C_{38}H_{56}O_4$ requires C, 79·2; H, 9·7%; *M*, 576]. 4-Methoxystyryl nonyl ketone (Scholtz and Meyer, *loc. cit.*) crystallises in colourless leaflets, m. p. 63°.

3 : 4-*Dimethoxystyryl Nonyl Ketone.*—Veratraldehyde (4 g.) and methyl nonyl ketone (4 g.) were dissolved in alcohol (10 c.c.) together with 2 c.c. of 8% sodium hydroxide solution. Crystals separated after 12 hours, and were purified by recrystallisation from methyl alcohol, a small amount of less soluble dimeride being removed during the process. The *ketone* forms faintly yellow, rhombic plates,

m. p. 61° (yield, 5·5 g.) [Found: C, 75·4; H, 9·5; *M* (Menzies), 314, (Pregl), 323. $C_{20}H_{30}O_3$ requires C, 75·4; H, 9·4%; *M*, 318].

Bis-(3 : 4-*dimethoxystyryl Nonyl Ketone*).—Veratraldehyde (4 g.) and methyl nonyl ketone (4 g.) were refluxed with 1% alcoholic potassium hydroxide (25 g.) for 4 hours. The crude product was repeatedly recrystallised from alcohol, separating in colourless needles, m. p. 135° [Found: C, 75·5; H, 9·2; *M* (Menzies), 646. $C_{40}H_{60}O_6$ requires C, 75·4; H, 9·4%; *M*, 636].

Bis-(3 : 4-*methylenedioxystyryl Nonyl Ketone*).—Piperonal (4 g.) and methyl nonyl ketone (4 g.) were refluxed with 2% alcoholic potassium hydroxide (40 c.c.) for 6 hours. The product which separated on cooling was repeatedly crystallised from alcohol, and obtained finally in fine, colourless needles, m. p. 128° [Found: C, 75·6; H, 8·5; *M* (Menzies), 608. $C_{38}H_{52}O_6$ requires C, 75·5; H, 8·6%; *M*, 604]. Scholtz and Meyer (*loc. cit.*) describe 3 : 4-methylenedioxystyryl nonyl ketone as forming pale yellow needles, m. p. 56°.

Bis-(4-*methylstyryl Nonyl Ketone*).—This was first prepared by Scholtz and Meyer (*loc. cit.*) by the addition of 15% sodium hydroxide solution to an alcoholic solution of *p*-tolualdehyde and methyl nonyl ketone, and allowing the solution to stand at room temperature. These authors, however, described the compound as 4-methylstyryl nonyl ketone, m. p. 129°. We have prepared the compound by a similar method, but find it to melt at 134—135° [Found: *M* (Pregl), 425. $C_{38}H_{56}O_2$ requires *M*, 544].

4-iso*Propylstyryl Nonyl Ketone*.—Cuminaldehyde (2 g.) and methyl nonyl ketone (2·5 g.) were dissolved in alcohol (5 c.c.), and 6 drops of 8% sodium hydroxide added. After 2 days, the solution was cooled in ice and salt, and the separated product recrystallised from methyl alcohol, appearing as colourless plates, m. p. 40° [Found: C, 83·9; H, 10·9; *M* (Pregl), 297. $C_{21}H_{32}O$ requires C, 84·0; H, 10·7%; *M*, 300].

Bis-(4-iso*propylstyryl Nonyl Ketone*).—This compound was obtained by Scholtz and Meyer (*loc. cit.*) by the action of 15% sodium hydroxide on cuminaldehyde and methyl nonyl ketone in cold alcoholic solution, and was described as 4-*iso*propylstyryl nonyl ketone, m. p. 144°. We have prepared the compound by a similar method, but find it to be a dimeride, m. p. 150° [Found: C, 84·1; H, 10·7; *M* (Menzies), 605. $C_{42}H_{64}O_2$ requires C, 84·0; H, 10·7%; *M*, 600].

4-*Chlorostyryl Nonyl Ketone*.—*p*-Chlorobenzaldehyde (2 g.) and methyl nonyl ketone (2·5 g.) were dissolved in alcohol (45 c.c.), and 1 c.c. of 8% sodium hydroxide was added. The product separated after standing for 24 hours at room temperature, and

recrystallised from alcohol, forming colourless plates, m. p. 62—63° (yield, 2·5 g.) [Found: C, 73·5; H, 8·7; *M* (Menzies), 294. $C_{18}H_{25}OCl$ requires C, 73·8; H, 8·5%; *M*, 293].

Bis-(4-chlorostyryl Nonyl Ketone).—*p*-Chlorobenzaldehyde (2 g.) and methyl nonyl ketone (2·5 g.) were refluxed for 4 hours with 1% alcoholic potassium hydroxide (40 c.c.). The separated product was recrystallised from alcohol, colourless, fine needles being obtained, m. p. 126—127° [Found: C, 73·7; H, 8·3; *M* (Menzies), 614. $C_{36}H_{50}O_2Cl_2$ requires C, 73·8; H, 8·5%; *M*, 585].

3-Chlorostyryl Nonyl Ketone.—This compound was prepared by a method similar to that employed for the 4-chloro-derivative. The product obtained by cooling in ice gave colourless plates on recrystallisation from methyl alcohol, m. p. 57° (Found: C, 74·0; H, 8·6%).

2-Chlorostyryl Nonyl Ketone Semicarbazone.—*o*-Chlorobenzaldehyde (2 g.) and methyl nonyl ketone (2·5 g.) were treated with 0·25% alcoholic potassium hydroxide (20 c.c.) for 7 days. The crude condensation product could not be induced to solidify, and for identification was converted into its *semicarbazone*, which separated from alcohol in colourless needles, m. p. 123—124° (Found: N, 12·1. $C_{19}H_{28}ON_3Cl$ requires N, 12·0%).

2-Hydroxystyryl Nonyl Ketone.—Salicylaldehyde (5 g.) and methyl nonyl ketone (7 g.) were dissolved in absolute alcohol, and sodium hydroxide (30 c.c. of 30%) was added. After standing at room temperature for 5 days, the dark solution was diluted with water and rendered neutral with carbon dioxide. The crude product separated from methyl alcohol (charcoal) in colourless leaflets, m. p. 79° (yield, 5·5 g.) (Found: C, 78·7; H, 9·4. $C_{18}H_{26}O_2$ requires C, 78·7; H, 9·5%).

THE UNIVERSITY, LIVERPOOL. [*Received, June 6th*, 1928.]

CCCVI.—*Ammonium Polysulphides, Hydrogen Pentasulphide, and the Thiocarbonic Acids.*

By HERBERT MILLS and PERCY LUCOCK ROBINSON.

POLYSULPHIDES of ammonium may be prepared by passing hydrogen sulphide into a suspension of sulphur in aqueous ammonia, and Bloxam (J., 1895, **67**, 2707) claimed to have obtained the tetra-, penta-, hepta-, and nona-sulphides in this way, but Thomas and Riding (J., 1923, **123**, 1726), using alcoholic in place of aqueous solutions, only obtained the di-, penta-, and hepta-sulphides. We have prepared the pentasulphide, and bring forward evidence that the alleged heptasulphide is a solid solution of sulphur in the penta-

sulphide, but we have been unable to confirm the existence of the disulphide.

Previous workers (for references see Walton and Parsons, *J. Amer. Chem. Soc.*, 1921, **43**, 2539) obtained yellow oils, which on fractional distillation yielded hydrogen disulphide and trisulphide, by treating cold concentrated hydrochloric acid with a cold solution of sodium polysulphides. Examination of the solubility of sulphur in hydrogen trisulphide led to the inference that the hexasulphide existed below −1·45° (Walton and Whitford, *ibid.*, 1923, **45**, 601). In the present investigation pure anhydrous ammonium pentasulphide has been decomposed by anhydrous formic acid with the formation of *hydrogen pentasulphide*, the properties of which have been investigated.

Red crystals obtained by refluxing ammonium pentasulphide with carbon disulphide in the manner of Thomas and Riding (*loc. cit.*), and believed by them to have been $(NH_4)_2S_2$ although analysing to $(NH_4)_2S_{2\cdot2}$, have been shown to be pure ammonium thiocarbonate, $(NH_4)_2CS_3$, whilst a yellow residue, not mentioned by these authors, consists of ammonium perthiocarbonate, $(NH_4)_2CS_4$. From these salts the corresponding *thiocarbonic acids* have been prepared and their properties investigated.

EXPERIMENTAL.

Ammonium Polysulphides.

Ammonium Pentasulphide.—Sulphur (40 g.) suspended in 100 c.c. of aqueous ammonia (*d* 0·88) and saturated with hydrogen sulphide in the absence of air, gave a deep red solution from which yellow crystals separated slowly on cooling [Found, mean of five closely-agreeing analyses of separate preparations: NH_3, 17·2; H_2S, 17·1; S, 65·3. Calc. for $(NH_4)_2S_5$: NH_3, 17·4; H_2S, 17·4; S, 65·2%]; these had all the properties previously ascribed to ammonium pentasulphide.

Ammonium Heptasulphide (alleged).—When greater proportions of sulphur were used, the hard cake formed on crystallising was obviously non-homogeneous, consisting mainly of yellow pentasulphide together with darker crystals. Hand-picked (*a*) dark red and (*b*) orange-red crystals were repeatedly analysed (Table I) and showed both considerable variation amongst themselves and an increase in the sulphur content with darkening colour. Any of these crystals when extracted with cold carbon disulphide gave a yellow substance having all the properties of the pentasulphide. Such crystals are decomposed by water with liberation of sulphur, and when treated with anhydrous formic acid give a considerable deposit

TABLE I.

* Number of analyses, four.

of sulphur together with a yellow oil, similar in most respects to that obtained from the pentasulphide. The conclusion reached is that materials of greater sulphur content than the pentasulphide consist of solid solutions of these two substances, and this is borne out by the preparative methods employed by other investigators, *viz.*, (i) allowing saturated alcoholic solutions of pentasulphide to stand in contact with sulphur for 4 months in stoppered bottles, and (ii) slow decomposition of the pentasulphide.

Ammonium Disulphide (alleged).—The preparation of this substance would be of considerable importance, because its decomposition by anhydrous formic acid would probably yield hydrogen disulphide directly. Weighed quantities of ammonium pentasulphide were decomposed in evacuated Faraday tubes, one limb being heated to 100° and the other cooled to −7°, for a considerable period. A yellow liquid, which subsequently solidified to a white solid, collected in the cooled limb and proved on analysis to be ammonium monosulphide [Found: NH_3, 50·1; H_2S, 49·9. Calc. for $(NH_4)_2S$: NH_3, 50·0; H_2S, 50·0%]. The residue of sulphur left in the heated limb amounted to 66·0% of the pentasulphide taken, thus indicating the decomposition $(NH_4)_2S_5 \longrightarrow (NH_4)_2S + 4S$: we have been unable to confirm the observations of Thomas and Riding (*loc. cit.*), who claim that the reaction is represented by $(NH_4)_2S_5 \longrightarrow (NH_4)_2S_2 + 3S$. The fact that the pale yellow liquid or the white solid plunged into either dilute or concentrated hydrochloric acid gives neither free sulphur nor any oil confirms the conclusion indicated by the quantitative synthesis from pentasulphide and the analysis of the material. Thus the decomposition here follows the usual course observed on dry distillation in open vessels or on refluxing with organic solvents, in both of which monosulphide is produced.

Hydrogen Pentasulphide.

The production of hydrogen polysulphides by the wet methods previously employed is invariably accompanied by the precipitation of much sulphur. It has been found that dry ammonium poly-

sulphide crystals give hydrogen polysulphides on treatment with concentrated mineral acids (except nitric) at either laboratory or higher temperatures, but sulphur, varying in extent with the excess of sulphur in the crystals over that required for pentasulphide, is always liberated. Even selected pure pentasulphide yields sulphur under these conditions. Formic acid as concentrated as 90% offers no advantage over mineral acids, but commercial anhydrous formic acid, further dried by phosphorus pentoxide, gives excellent results, the formation of the polysulphide being unaccompanied by free sulphur. Probably the presence of water accounts for the formation of the free sulphur in these reactions.

From ammonium pentasulphide crystals, pale yellow oils were repeatedly prepared in this way and analysed; from Table II it will be seen that the persulphide sulphur (S_{n-1} in H_2S_n) falls only twice below the 82·5% required for H_2S_6, but rises as high as 92·6% (Calc. for H_2S_7 85·0; for H_2S_8 86·8; for H_2S_9 88·3%). Observation proved that the more free sulphur liberated in a reaction the higher was the indicated persulphide sulphur of the accompanying oil. It was believed that the differences found in the oils prepared with

TABLE II.

Acid used.	Persulphide sulphur in separately prepared samples, %.
Hot HCl	92·6, 92·0, 90·3, 90·0, 89·3.
Cold HCl	88·0, 85·0.
Cold anhydrous $H{\cdot}CO_2H$	86·4, 86·1, 85·9, 85·4, 84·9, 84·6, 83·3, 82·3, 81·9.

formic acid were due to differences in the sulphur content of the crystals, and in order to test this, they were ground to a powder and extracted with boiling carbon disulphide. The centrifuged residue gave a reddish-brown oil which had 77% of persulphide sulphur, the low sulphur content and the colour being due to the formation of a certain amount of ammonium perthiocarbonate (see below). If the crystals were extracted with cold carbon disulphide for a short period and centrifuged, the trouble was avoided, and they gave a pale orange-yellow oil, separate specimens of which had persulphide sulphur 79·0, 79·0, 79·3, 79·9, 79·6% respectively, mean 79·3% (H_2S_5 requires 79·0%). The faint orange tint is doubtless due to traces of thiocarbonic acids, and attempts were made to avoid this by extracting the crystals with benzene at various temperatures, but this did not furnish material suitable for the preparation.

Pure *hydrogen pentasulphide* is a thin, clear, yellow oil, which on cooling becomes suddenly viscous at −25°, almost solid at −35°, and glassy at −50°, melting to a clear liquid again on warming; d 1·67 at 16° (Found: M, cryoscopic in benzene, 152·5. H_2S_5 requires

M, 162). It froths badly at 40°/15 mm., but cannot be distilled. The solubility of sulphur in the liquid, expressed for convenience as the percentage of sulphur not evolved as hydrogen sulphide, has been found to be 93 at 15°, 90 at 0°, and 88 at −18°. From Walton and Whitford's figures (*loc. cit.*) for the solubility of sulphur in hydrogen trisulphide, similarly expressed, *viz.*, 86·8 at 17·9°, 83·0 at 0·0°, and 71·2 at 15·4°, it is seen to be improbable that the material here considered is a solution of sulphur in a lower sulphide.

Ammonium Thiocarbonates and the Thiocarbonic Acids.

Ammonium thiocarbonates have been described by Yeoman (J., 1921, **119**, 38) and by O'Donoghue and Kahn (J., 1906, **89**, 1812), but they have not been prepared by the methods here used (compare Thomas and Riding, *loc. cit.*).

Ammonium Thiocarbonate.—This is most conveniently obtained by digesting ammonium pentasulphide with carbon disulphide in a wide-necked flask fitted with a cork carrying a wide tube, in which cold water is rapidly circulated, and a reflux condenser. A deposit of white, crystalline ammonium monosulphide first forms on the cold surface, and this is later converted into the pale orange-yellow thiocarbonate by the carbon disulphide vapour. On exposure to moisture or air these orange-yellow crystals turn red. The material obtained from this sublimation process is remarkably pure if washed with carbon disulphide and ether, and centrifuged [Found: NH_3, 23·68; H_2S, 23·40; total S, 65·70. Calc. for $(NH_4)_2CS_3$: NH_3, 23·61; H_2S, 23·61; total S, 66·66%].

Ammonium Perthiocarbonate, $(NH_4)_2CS_4$.—The yellow, crystalline residue from the incomplete refluxing of ammonium pentasulphide in carbon disulphide was shown to be ammonium perthiocarbonate. A better product was obtained by extracting the pentasulphide with carbon disulphide in a Soxhlet apparatus, washing with hot fresh carbon disulphide followed by ether, and then centrifuging [Found: NH_3, 19·10; H_2S, 19·10; total S, 73·88; persulphide S, 19·8. $(NH_4)_2CS_4$ requires NH_3, 19·32; H_2S, 19·32; total S, 72·73; persulphide S, 18·18%].

Earlier workers have been unable to decide satisfactorily whether the acid obtained from thiocarbonates is tri- or tetra-thiocarbonic. Yeoman (*loc. cit.*) considers it to be tetra-, whilst O'Donoghue and Kahn (*loc. cit.*), although believing it to be tri-thiocarbonic, were unable to demonstrate this with certainty.

Trithiocarbonic Acid.—This was prepared by dropping pure solid ammonium thiocarbonate into a large excess of concentrated hydrochloric acid, and the bright red liquid which separated was dried with phosphorus pentoxide [Found: Total S (by Carius), 87·28 (mean

of 8 concordant determinations on independent specimens); *M*, cryoscopic in bromoform, 107·2. H_2CS_3 requires total S, 87·28%; *M*, 110]. The liquid has $d_4^{17·0°}$ 1·47 and freezes sharply to an orange-yellow solid at −30·5°. The surface tension by capillary rise = 48·3 dynes/cm. at 12·5°, giving a parachor of 197·3 (H_2CS_3 requires 201·1, if the parachor of sulphur is taken as 46·2, the mean from the data for carbon disulphide).

The acid decomposes on standing, rapidly at first but more slowly later, evidently forming a red solution of itself in the carbon disulphide produced; distillation of the fresh material leads to its dissociation to carbon disulphide and hydrogen sulphide without residue of sulphur. It is slightly soluble in water, organic solvents, or acids, giving yellow solutions which rapidly decompose with loss of colour. Its behaviour with acetone, in which it dissolves without liberation of sulphur even on long standing, deserves special note because of the marked difference shown by the tetrathiocarbonic acid with this reagent.

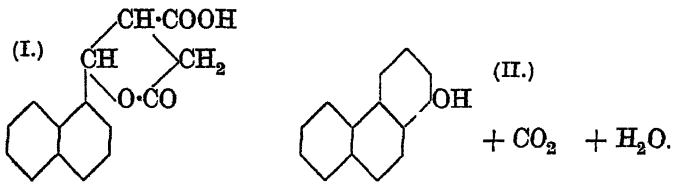
Yeoman (*loc. cit.*) has stated that aqueous solutions of pure thiocarbonates do not give the red liquid when acted upon by concentrated hydrochloric acid in the complete absence of oxygen. This statement has been examined by conducting the reaction with the ammonium salt at −5° both in a vacuum and in an atmosphere of hydrogen sulphide, and, provided the concentration of the thiocarbonate is more than sufficient to saturate the hydrochloric acid with thiocarbonic acid, the red liquid separates.

Tetrathiocarbonic (*Perthiocarbonic*) *Acid*, H_2CS_4.—This is a dark brown liquid obtained by the action of 98% formic acid upon ammonium perthiocarbonate, but the total and persulphide sulphur and the estimated molecular weight show considerable variation from sample to sample. The following properties, however, indicate that the liquid is largely composed of this acid. It is decomposed vigorously, with *crackling*, by acetone, giving a colourless solution with deposition of sulphur ($H_2CS_4 \longrightarrow CS_2 + H_2S_2 \longrightarrow H_2S + S$); on distillation under reduced pressure with a small bead-column two fractions are obtained—first carbon disulphide, and subsequently a small quantity of a pale yellow oil distilling at 70° and having all the properties of hydrogen disulphide. A large residue of sulphur is left.

It is interesting that concentrated hydrochloric acid used in place of formic acid gives a red liquid which proves to be a solution of sulphur in trithiocarbonic acid. This liquid is soluble in acetone to a yellow solution, without the violence or crackling associated with the hydrogen polysulphides; from this solution the sulphur previously dissolved in the trithiocarbonic acid is slowly precipitated.

On distillation this liquid gives no evidence of a polysulphide, the distillate being colourless carbon disulphide, and the residue sulphur.

It has been observed that ammonium polysulphides and thiocarbonates are only very slowly decomposed by anhydrous formic acid below −7°.



The authors wish to thank Mr. Herbert Smith for assistance in the preparative work, and Electrolux Ltd. for the loan of a refrigerating unit which, after having been fitted with a suitable brine tank, has been in almost constant use during the course of this investigation.

CCCVII.—*The Synthesis of* 1-*Phenanthrol.*

By JOHN BALDWIN SHOESMITH and ALEXANDER GUTHRIE.

1-PHENANTHROL (II) is the only one of the five theoretically possible monohydroxy-derivatives of phenanthrene not described in the literature. It has been obtained by heating *α-naphthylparaconic acid* (I), loss of carbon dioxide and ring closure with elimination of water taking place as follows:

α-Naphthaldehyde was prepared (*a*) in a yield of 33% by the catalytic reduction of α-naphthoyl chloride, m. p. 22°, b. p. 158°/12 mm., by Rosenmund's method (*Ber.*, 1918, **51**, 591)—it is noteworthy that in absence of solvent during this reduction the side chain was completely removed and naphthalene produced in quantity—and (*b*) in a yield of 25% by the action of ethyl orthoformate in ethereal solution on magnesium naphthyl bromide in the usual manner. The second is the more convenient method although the yield is somewhat smaller. By both methods the aldehyde was obtained as an oil, b. p. 173—174°/35 mm.; p-*nitrophenylhydrazone*, scarlet needles from acetic acid, m. p. 233—235°.

α-Naphthylparaconic Acid.—α-Naphthaldehyde (7·5 g.), succinic anhydride (5 g.), and anhydrous sodium acetate (6 g.) were heated together under reflux for 6 hours at 122° (a higher temperature causes formation of tarry by-products which render the subsequent purification of the acid difficult); excess of α-naphthaldehyde was

removed from the reaction product in a current of steam, and the residue filtered hot, cooled, extracted with ether, and acidified. The precipitated *α-naphthylparaconic acid* (2 g.) was recrystallised from aqueous alcohol (water 2 parts, alcohol 1 part), from which it separated in well-defined, white, rectangular prisms, m. p. 169° (evolution of carbon dioxide) (Found: C, 70·2; H, 4·7. $C_{15}H_{12}O_4$ requires C, 70·3; H, 4·7%).

1-*Phenanthrol.*—α-Naphthylparaconic acid was heated in a distillation flask immersed in a metal-bath at 180—200° until evolution of carbon dioxide had ceased (30 minutes). The temperature of the bath was then rapidly raised to about 340° and distillation of the vapour prevented by impinging a blast of cold air on the neck of the flask. After 15—20 minutes the temperature was raised again and distillation allowed to proceed. The red oil which distilled over solidified and was dissolved in ether; the ethereal solution was extracted with sodium carbonate to remove carboxylic acids and then with aqueous sodium hydroxide. The latter extract was saturated with carbon dioxide, the precipitate extracted with ether, and the ether evaporated; the 1-*phenanthrol* so obtained was crystallised from light petroleum, separating as colourless, prismatic needles, m. p. 156° (Found: C, 85·9; H, 5·2. $C_{14}H_{10}O$ requires C, 86·6; H, 5·2%); yield, 5%. In another experiment crude α-naphthylparaconic acid was used, and the yield of 1-phenanthrol increased to about 15%; this observation is similar to that of Fittig and Erdmann (*Annalen*, 1885, **227**, 242), who found that crude phenylparaconic acid gives a better yield of α-naphthol than does the pure acid.

1-Phenanthrol is stable in air and in solution (contrast the 9-isomeride, which is very unstable, Japp and Findlay, J., 1897, **71**, 1115). It resembles α-naphthol in giving a deep blue coloration on warming with chloroform in alkaline solution, but differs in giving no coloration with glucose solution and concentrated sulphuric acid (compare Molisch's test for carbohydrates). It dissolves in concentrated sulphuric acid with a yellow colour, the solution slowly becoming red and finally colourless when heated. Its alkaline solution gives dyes with diazotised aniline, etc. The picrate crystallises in orange-red, feathery needles, m. p. 182°, from methyl alcohol.

In order to characterise the compound further it was methylated as follows. To 1-phenanthrol (0·8 g.) dissolved in 8 c.c. of methyl alcohol, 4 c.c. of 10% methyl-alcoholic potassium hydroxide and 8 c.c. of a 13% solution of methyl sulphate in methyl alcohol were added, and the solution was heated on the steam-bath for 1 hour, after which it was diluted with water, extracted with ether, and

ethereal solution extracted with alkali to remove unchanged phenanthrol, and the 1-methoxyphenanthrene left on evaporation was recrystallised from methyl alcohol; yield, 50%. The colourless prismatic needles had m. p. 105°, and were found to be identical in all respects with a sample of 1-methoxyphenanthrene prepared by the method described by Pschorr, Wolfes, and Buckow (*Ber.*, 1900, **33**, 170).

The authors wish to acknowledge the grant of a Carnegie Teaching Fellowship to one of them (J. B. S.) during the tenure of which the investigation was carried out.

EDINBURGH UNIVERSITY. [*Received, June 28th*, 1928.]

CCCVIII.—*Alternating Reactive Positions in the Nucleus of* tert.-*Butylbenzene.*

By JOHN BALDWIN SHOESMITH and ALEXANDER MACKIE.

IT is well known that when a substituent enters the nucleus of *tert.*-butylbenzene it does so almost exclusively in the para-position, *i.e.*, as far as possible from the *tert.*-butyl group. The isolation of ortho-compounds has been reported in only two cases: Seńkowski (*Ber.*, 1890, **23**, 2414), claimed to have prepared both ortho- and para-nitro-*tert.*-butylbenzenes by direct nitration, and Kozak (*Bull. Akad. Sci. Cracow*, 1906, 407) brominated the hydrocarbon and submitted the reaction product to the action of methyl iodide and sodium, whereby he isolated two isomeric *tert.*-butyltoluenes, one of which he described as the ortho-compound. Since Malherbe (*Ber.*, 1919, **52**, 319) was unable to repeat Seńkowski's results, the evidence that reaction can take place at both ortho- and para-positions is confined to the observations of Kozak.

It has now been proved that Seńkowski isolated *o*-nitro-*tert.*-butylbenzene, and a further example has been obtained of the alternating influence of the *tert.*-butyl group in that, when treated with hydrogen iodide, the isomeric iodo-*tert.*-butylbenzenes only react if the iodine is in the *o*- or *p*-position.

o-Nitro-tert.-*butylbenzene.*—It was not found possible to prepare this compound by direct nitration (compare Malherbe, *loc. cit.*), but it was obtained in the following manner. *p*-Nitro-*tert.*-butylbenzene (the constitution of which was proved definitely by Malherbe) on further nitration gives a dinitro-compound, m. p. 62°, which might be 2 : 4- or 3 : 4-dinitro-*tert.*-butylbenzene, the latter possibility requiring consideration because of the inhibiting effect of the *tert.*-butyl group on substitution in the ortho-position. The

dinitro-compound on reduction with ammonium hydrogen sulphide gives a nitroamino-compound, m. p. 55°, and elimination of the amino-group gives an oil, b. p. 250·5°/765 mm.; this can be converted into an amine of which the acetyl derivative has m. p. 161° and strongly depresses the m. p. of *p*-acetamido-*tert.*-butylbenzene (169°). Since the m. p. of the corresponding meta-compound, which would result in the same way from the 3 : 4-isomeride, is 99° (see p. 2338), this leaves no doubt as to the constitution of the *o*-nitro-compound and also classifies the nitroamino-compound as 2-*nitro*-4-*amino*-tert.-*butylbenzene*, and the dinitro-compound as 2 : 4-dinitro-*tert.*-butylbenzene. The above proof is necessitated by the fact that it was not found possible to obtain *o*-nitrobenzoic acid from *o*-nitro-*tert.*-butylbenzene, a point stressed by Seńkowski (*loc. cit.*), who gave the b. p. of the compound as 247—248°/738 mm. and the m. p. of the *o*-acetamido-compound as 159°.

The Reduction of the Isomeric Iodo-tert.-*butylbenzenes.*—The ease of removal of iodine from these compounds by hydrogen iodide is $o>p>m$, and the comparative ease with which the ortho-isomeride was reduced shows that iodine may be removed from a position which is almost immune from attack by the ordinary substituting reagents. This can readily be understood if the preliminary stage in the replacement of iodine by hydrogen is the attraction of a proton to a negatively polarised position such as would be expected to occur in both the ortho- and para-positions in the nucleus of *tert.*-butylbenzene. It would not be expected that the attachment of a proton in the ortho-position would be inhibited to the same extent as that of the more bulky molecules of nitrating, halogenating, and sulphonating agents; moreover, when these experiments are compared with the corresponding experiments in the toluene series (Shoesmith and Slater, J., 1924, **125**, 2278), it is found that whilst the rates of removal of iodine from *o*-iodotoluene and *o*-iodo-*tert.*-butylbenzene are similar, the quantities of ortho-compounds formed by direct substitution of the corresponding hydrocarbons are markedly different.

The Behaviour of o-*Bromo*-tert.-*butylbenzene with Magnesium.*—In a recent communication, Tschitschibabin, Elgasine, and Lengold (*Bull. Soc. chim.*, 1928, **43**, 238) have stated that when the mixture produced by the bromination of *tert.*-butylbenzene is allowed to react with magnesium, followed by ethyl orthoformate, *p-tert.*-butylbenzaldehyde is formed exclusively, since on oxidation only *p-tert.*-butylbenzoic acid could be isolated. They conclude that any *o*-bromo-*tert.*-butylbenzene present does not form a magnesium derivative. As the present authors had already found that *o*-iodo-

tert.-*butylbenzene* readily gives a Grignard reagent, this appeared remarkable, and o-*bromo*-tert.-*butylbenzene* was therefore prepared as follows: *p*-Nitro-*tert.*-butylbenzene is brominated with difficulty at 90° in presence of finely divided iron, giving a compound which must be 2-*bromo*-4-*nitro*-tert.-*butylbenzene*, since on reduction it gives an amine the *acetyl* derivative of which is different from 3-bromo-4-acetamido-*tert.*-butylbenzene (the only other possible reaction product). 2-*Bromo*-4-*amino*-tert.-*butylbenzene* on elimination of the amino-group gives *o*-bromo-*tert.*-butylbenzene which in ethereal solution reacts *vigorously* with magnesium, and from the product o-tert.-*butylbenzoic acid* may be produced in the usual manner. This acid may also be prepared from the *o*-iodo-derivative. The authors do not suggest that this is additional evidence in favour of the polarisation of the ortho-position, but merely wish to point out that the steric effect of the *tert.*-butyl group is not sufficient to inhibit a reaction involving the attack by magnesium of a halogenated ortho-position.

EXPERIMENTAL.

There is much confusion in the literature with respect to *iso*- and *tert.*-butylbenzene derivatives, and we therefore used as our starting product the authentic *tert.*-butylbenzene prepared by the method of Schramm (*Monatsh.*, 1888, **9**, 615), who proved that *iso*- or *tert.*-butyl chloride condensed with benzene in presence of aluminium chloride to give *tert.*- and not *iso*-butylbenzene. References which describe compounds as *iso*butyl when in reality they are *tert.*-butyl are marked with an asterisk.

*iso*Butyl alcohol was converted to a mixture of *iso*- and *tert.*-butyl chlorides by means of zinc chloride and phosphorus trichloride (Dehn and Davis, *J. Amer. Chem. Soc.*, 1907, **29**, 1332), but only a 32% yield could be obtained, the chief product being apparently a mixture of polymerised butylenes. The mixed chlorides were condensed with benzene as described by Schramm (*loc. cit.*); continuous stirring and efficient condensing apparatus improved the yield (27%), and *white* aluminium chloride of very good quality was found to be advantageous. The *tert.*-butylbenzene had b. p. 165—170°.

p-*Nitro*-tert.-*butylbenzene*.—Nitric acid (*d* 1·52) was gradually added to an equal weight of vigorously stirred *tert.*-butylbenzene at the ordinary temperature; when reaction was complete (2 hours), the mixture was poured into water, and the yellow oil washed with water, dried, and distilled: b. p. 125—130°/10 mm. It could not be solidified.

2 : 4-*Dinitro*-tert.-*butylbenzene*.—A mixture of nitric acid (*d* 1·51; 2 parts by weight) and concentrated sulphuric acid (3 parts) was

added during 5 hours to vigorously stirred *tert.*-butylbenzene (1 part) maintained at 60°. The nitration product was poured on ice, and the precipitated yellow oil slowly solidified. The solid was filtered off and washed with water. It crystallised from aqueous alcohol in white prisms, m. p. 61—62° (compare Malherbe, *loc. cit.*, and Baur, *Ber.*, 1894, **27**, 1610), which slowly turned yellow on exposure to light. The same compound was obtained by heating vigorously stirred *p*-nitro-*tert.*-butylbenzene with an equal weight of nitric acid (*d* 1·51) at 60° for 2—4 hours.

2-*Nitro*-4-*amino*-tert.-*butylbenzene*.—Finely divided 2 : 4-dinitro-*tert.*-butylbenzene (20 g.) was added to a mixture of ethyl alcohol (76 c.c.) and ammonia (*d* 0·880; 10 c.c.), and hydrogen sulphide passed into the mixture for one hour, the reaction flask being occasionally agitated. The mixture was then heated for a few minutes on the steam-bath, cooled, and the process repeated. To the reaction mixture an excess of water was added, and the nitro-amino-compound, precipitated as a yellow solid mixed with sulphur, was filtered, washed with water, and heated under reflux with an excess of hydrochloric acid (*d* 1·05) for 5 minutes. The solution was filtered from sulphur, the filtrate cooled until the hydrochloride commenced to crystallise out, and an excess of ammonia (*d* 0·880) was immediately added. The nitroamine separated as an oil which rapidly solidified; yield 71%. 2-*Nitro*-4-*amino*-tert.-*butylbenzene* crystallises from aqueous alcohol as yellow plates, and from light petroleum as yellow needles, m. p. 55° (Found: N 14·7. $C_{10}H_{14}O_2N_2$ requires N, 14·4%). When boiled with acetic anhydride, it gives the acetyl derivative, colourless needles, m. p. 112° from aqueous alcohol.

o-*Nitro*-tert.-*butylbenzene*.—To the amino-compound (1 part), dissolved in absolute alcohol (3 parts), concentrated sulphuric acid (3 parts) was added, and the whole cooled to 0°; the sulphate crystallised out and the amine was diazotised, the reaction mixture then being allowed slowly to attain the laboratory temperature and finally heated on the steam-bath. *o*-Nitro-*tert.*-butylbenzene was removed in a current of steam, extracted from the distillate with ether, and ultimately obtained as a yellow oil (yield 54%) with a characteristic odour, b. p. 114—115°/10 mm. or 250·5°/765 mm.

o-*Amino*-tert.-*butylbenzene*.—Fine iron filings (12 g.) were mixed with water (15 c.c.) and the mixture slowly stirred and heated whilst 1 c.c. of glacial acetic acid and 0·3 c.c. of *o*-nitro-*tert.*-butylbenzene were added; the temperature was raised to 90° and 10 g. of the *o*-nitro-compound were slowly introduced during 3 hours. After a further 2 hours' heating, the amine was distilled in steam, extracted from the distillate with ether, dissolved in dilute hydrochloric acid,

separated from unchanged nitro-compound by ether extraction, and precipitated from its hydrochloric acid solution by addition of ammonia; when re-extracted with ether and purified by distillation it had b. p. 102°/10 mm.; yield 75%. The amine was found to be a colourless liquid, very volatile in steam, becoming red on exposure to air which caused separation of a small quantity of crystals, probably carbonate (compare Seńkowski, *loc. cit.*). *o*-Acetamido-*tert.*-butylbenzene was obtained from the amine in the usual way, and crystallised from benzene in prismatic needles, m. p. 161° (Seńkowski gives 159°).

o-*Iodo*-tert.-*butylbenzene*.—Dilute sulphuric acid (60 c.c.; *d* 1·12) was added to the above amino-compound (5·5 g.), the whole well stirred to ensure formation of a finely divided precipitate of amine sulphate, and the latter diazotised by a solution of sodium nitrite (5 g. in 10 c.c. of water) at −10°. The diazonium sulphate is very unstable and appeared to decompose at about −8°. Potassium iodide (15 g.) in water (25 c.c.) was then rapidly added to the *very vigorously stirred* diazo-solution, the temperature was allowed slowly to rise to 18°, and decomposition completed on the steam-bath. Excess of aqueous alkali was added to the reaction mixture to remove free iodine, and the iodo-compound distilled in a current of steam. The ethereal extract of the distillate finally yielded an oil, and that from several experiments was fractionated under reduced pressure. o-*Iodo*-tert.-*butylbenzene* is a colourless oil, b. p. 116—118°/10 mm. (Found: I, 48·3. $C_{10}H_{13}I$ requires I, 48·8%); yield 13%.

m-*Iodo*-tert.-*butylbenzene*.—This was obtained as follows: *p*-nitro-*tert.*-butylbenzene was reduced by iron and hydrochloric acid (as for the ortho-compound), the amino-derivative acetylated (m. p. of acetamido-compound, 169°; Malherbe, *loc. cit.* gives 169°), the acetyl derivative nitrated at 35—40° by acid of *d* 1·46, and the product hydrolysed by alkali to *m*-nitro-*p*-amino-*tert.*-butylbenzene; the amino-group was removed and the resulting nitro-compound reduced (as before) to *m*-amino-*tert.*-butylbenzene (an oil of b. p. 107—108°/9 mm.); acetylation then gave a product of m. p. 99° (Gelzer,* *Ber.*, 1888, **21**, 2949 gives 101°) from which the amino-compound was regenerated, and this was finally converted into the iodo-compound. m-*Iodo*-tert.-*butylbenzene* is a liquid, b. p. 106—108°/9 mm. (Found: I, 48·4. $C_{10}H_{13}I$ requires I, 48·8%).

p-Iodo-*tert.*-butylbenzene, obtained by the usual methods from the *p*-nitro-compound, distilled at 116—118°/9 mm. (compare Willgerodt and Rampacker, *Ber.*, 1901, **34**, 3669; Pahl,* *Ber.*, 1884, **17**, 1233; Boedtker, *Bull. Soc. chim.*, 1906, **35**, 832). It is noteworthy that whilst *o-tert.*-butylbenzenediazonium sulphate is very

* See p. 2336.

unstable even at 0°, the *m*- and *p*-isomerides are comparatively stable, a phenomenon which is paralleled in the corresponding toluene derivatives.

o-*Bromo*-tert.-*butylbenzene*. — 2-*Bromo*-4-*nitro*-tert.-*butylbenzene* was prepared by heating *p*-nitro-*tert.*-butylbenzene (6 g.) with bromine (7 g.) in presence of finely divided iron (1·2 g.) in a flask fitted with a reflux condenser and calcium chloride tube, to about 90°. Evolution of hydrogen bromide was moderately brisk, and after about ½ hour, a further 7 g. of bromine were slowly added and the whole was heated for 7 hours. When cold, the product formed a semi-solid mass, and on distillation in a current of superheated steam, a yellow, oily solid slowly collected in the receiver. This was filtered off, pressed on a porous plate, and crystallised from alcohol, forming long, colourless needles, m. p. 94·5° (Found: Br, 30·6. $C_{10}H_{12}O_2NBr$ requires Br, 31·0%). This bromination is much slower than that of *p*-nitrotoluene, but if all unbrominated oil is recovered, a yield of about 88% may be obtained.

2-*Bromo*-4-*amino*-tert.-*butylbenzene*. Concentrated hydrochloric acid (1 c.c.) was added to a solution of the foregoing bromo-compound (7·5 g.) in 30 c.c. of alcohol, and the mixture heated under reflux to the boiling point, finely divided iron (5 g.) then being added in 4 equal portions. After 2 hours, reduction was complete and the alcoholic solution was filtered from iron, water added to the filtrate, and the filtrate extracted with ether. The amine hydrochloride, precipitated on the addition of hydrochloric acid to the ethereal extract, was filtered, washed with ether, and dissolved in hot dilute hydrochloric acid, the amine then being precipitated by addition of concentrated ammonia and extracted with ether. After distillation of the ether, 2-*bromo*-4-*amino*-tert.-*butylbenzene* was obtained as a pale yellow liquid, b. p. 153—155°/11 mm. (Found: Br, 35·1. $C_{10}H_{14}NBr$ requires Br, 35·1%); yield 70%. Its *hydrochloride* has m. p. 235° (decomp.), and its *acetyl* derivative crystallised from aqueous alcohol in colourless rectangular plates, m. p. 142—143°.

o-*Bromo*-tert.-*butylbenzene*. The amino-group was eliminated from 2-bromo-4-amino-*tert.*-butylbenzene as for the corresponding *o*-nitro-compound. The diazonium compound was unstable and decomposed above −2°. o-*Bromo*-tert.-*butylbenzene* is a colourless liquid, b. p. 96—98°/12 mm. (Found: Br, 38·0. $C_{10}H_{13}Br$ requires Br, 37·6%); yield 54%.

o-tert.-*Butylbenzoic Acid*.—*o*-Bromo (or *o*-iodo)-*tert.*-butylbenzene was dissolved in ether and the equivalent quantity of magnesium added. On the addition of a crystal of iodine, reaction commenced immediately and continued at the ordinary temperature until

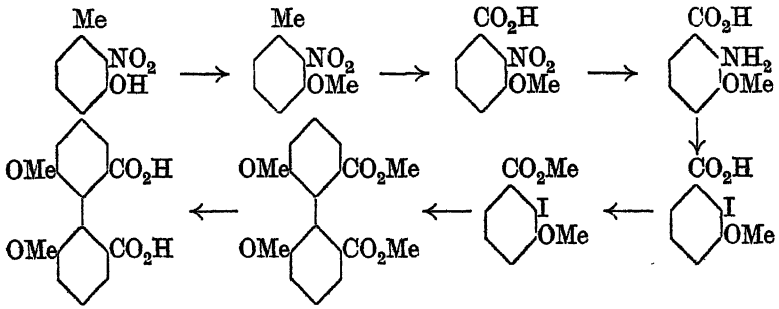
all the magnesium had disappeared. The flask was finally heated on the water-bath for 1 hour, after which a current of carbon dioxide was passed into the solution for approximately 15 hours. The viscous mass was disintegrated by the addition of ice, followed by dilute hydrochloric acid, the whole extracted with ether, the ethereal layer in turn extracted with sodium carbonate solution, which was acidified with dilute acid, and again extracted with ether. *o*-tert.-*Butylbenzoic acid* was thus obtained after crystallisation from aqueous alcohol (20%) as well-defined, hexagonal plates, m. p. 68·5° (Found: C, 73·8; H, 7·8. $C_{11}H_{14}O_2$ requires C, 74·2; H, 7·9%); yield 60%.

Reduction of the Isomeric Iodo-tert.-*butylbenzenes.*—A weighed quantity (*w*) of each of these was allowed to stand at 25° in a solution of glacial acetic acid containing 0·40 g. of hydrogen iodide per c.c., and the rate of reduction measured as previously (Shoesmith and Slater, *loc. cit.*). The results are recorded below, *t* being the time in days, and *x* the proportion changed.

	o-Isomeride (w = 0·3955 g.).	*p*-Isomeride (w = 0·4045 g.).
t.	*x.*	*x.*
2	61%	11%
4	76	19
14	86	35

The meta-isomeride was unaffected under these conditions. The order of reduction was unchanged even at 100° and 110°.

The authors wish to acknowledge a grant from the Earl of Moray Research Fund, and a teaching fellowship (to J. B. S.) from the Carnegie Trustees during the tenure of which the investigation was completed.



EDINBURGH UNIVERSITY. [*Received, July 19th,* 1928.]

CCCIX.—*The Molecular Configurations of Polynuclear Aromatic Compounds. Part VIII. 6:6′-Dimethoxydiphenic Acid.*

By JAMES KENNER and HAROLD AUGUSTUS TURNER.

THE relatively simple method of preparing 2-nitro-*m*-cresol devised by Gibson (J., 1923, **123**, 1273; compare Hodgson and Beard, J., 1925, **127**, 498) has rendered it easily accessible and thus provided a convenient starting point for the synthesis of 6:6′-*dimethoxy*-

diphenic acid. This has been achieved by the following series of reactions:

The acid was found to be asymmetric, and was conveniently resolved into optically active forms by means of its *quinine* salts, a partial resolution being also achieved by means of quinidine.

Experimental.

2-*Nitro*-m-*cresol*.—The conditions of sulphonation and nitration of *m*-cresol prescribed by Gibson (*loc. cit.*) were followed, but it was found advisable to employ only 50 c.c. of water in place of 100 c.c. for dilution prior to steam distillation, and to conduct this operation at first so that the temperature of the vapour issuing from the distillation flask was 110°. After about 200 c.c. of distillate had been collected, the temperature of distillation was rapidly raised to 130—160°. The buttery mass of 2-nitro-*m*-cresol then obtained was suitable for immediate treatment with methyl sulphate and alkali, but could, if desired, be further purified by freezing. It was unnecessary to distil the crude methyl ether, since it crystallised when stirred or inoculated with the pure material, and could then be purified by crystallisation from dilute alcohol. For its oxidation, the ether (5 g.) was boiled with a solution of potassium permanganate (13 g.) in water (550 c.c.).

2-Amino-3-methoxybenzoic acid (Pschorr, *Annalen*, 1912, **391**, 27) was converted by the ordinary procedure into 2-*iodo*-3-*methoxybenzoic acid*, which crystallised from dilute alcohol in yellowish needles, m. p. 150—151° (Found: *M*, 281. $C_8H_7O_3I$ requires *M*, 279). Its *methyl* ester crystallised from benzene–light petroleum in prisms, m. p. 57°, and was converted by treatment with an equal weight of copper powder at 205—210° into *methyl* 6 : 6′-*dimethoxydiphenate*, which crystallised from benzene in small prisms, m. p. 137—138° (Found: C, 65·01; H, 5·78. $C_{18}H_{18}O_6$ requires C, 65·45; H, 5·45%). 6 : 6′-*Dimethoxydiphenic acid* was precipitated as a gummy mass from a cold solution of its sodium salt, but in the

crystalline condition from hot solutions; by crystallisation from alcohol, it was obtained in stout prisms, m. p. 288—290° (decomp.) (Found: C, 63·25; H, 4·7; *M*, 153. $C_{16}H_{14}O_6$ requires C, 63·57; H, 4·6%; *M*, 151).

Brucine hydrogen dimethoxydiphenate was obtained as a uniform salt, m. p. 268° (Found: N, 4·4. $C_{39}H_{40}O_{10}N_2$ requires N, 4·0%), and acid to phenolphthalein, when the acid was treated with two molecular proportions of brucine hydrate. Its sparing solubility in acetone rendered it easily separable from the unneutralised brucine, and the salt separated in prisms from a mixture of chloroform and acetone.

Resolution of the Acid into Optically Active Components.—A solution of the acid (3 g.) in methyl alcohol (70 c.c.) was neutralised by a solution of quinine hydrate (7·54 g.) in methyl alcohol (30 c.c.), and the solvent then evaporated. When the residue was triturated with successive amounts of cold acetone (200 c.c. in all), 4·5 g. remained undissolved, whilst a resinous mass (5·3 g.) was recovered from the acetone. In other experiments a similar separation was achieved by means of ethyl acetate.

Quinine l-*dimethoxydiphenate* (Found: N, 5·91. $C_{56}H_{60}O_{10}N_4$ requires N, 5·89%), the less soluble of the two salts thus obtained, melted at 172—173° after crystallisation from acetone, and this m. p. was unaffected by two further crystallisations from the same solvent. It had $[\alpha]_D$ + 126° (c = 0·95 in chloroform; l = 1), and the corresponding ammonium salt, prepared by shaking the quinine salt with chloroform and a slight excess of dilute ammonia, and repeatedly extracting the aqueous solution with chloroform, had $[\alpha]_D$ −291° (c = 0·59 in water; l = 1): the strength of the solution was determined by evaporating an aliquot portion. The free l-*acid* was precipitated from a solution of the sodium salt similarly prepared, and, after being dried in a vacuum at the ordinary temperature to constant weight, had $[\alpha]_D$ −115° (c = 0·56 in acetone; l = 2); it was only sparingly soluble in chloroform or ether, and melted at 294—295°.

When the resin mentioned above was rubbed with successive small quantities of cold ether, it was obtained in the form of a powder which gradually shrank and decomposed about 60°. It was easily soluble in benzene, but was precipitated as an oil by ligroin, and could not be crystallised; when dried to constant weight it had $[\alpha]_D$ −68° (c = 1·27 in chloroform; l = 1) and an aqueous solution of the ammonium salt prepared from it had $[\alpha]_D$ +254°. Clearly, therefore, the resin was a fairly pure sample of *quinine* d-*dimethoxydiphenate*.

A mixture of salts was also obtained when the acid (4·5 g.) was

neutralised by anhydrous quinidine (9·75 g.) in methyl-alcoholic solution. The product was easily soluble in methyl alcohol, acetone, and ethyl acetate, but an incomplete separation was achieved by allowing the solution of the mixed salts in benzene (50 c.c.) and ligroin (300 c.c.; b. p. 90—110°) spontaneously to evaporate. The weights, melting points, and specific rotatory powers in 2% alcoholic solution of the five successive fractions of prismatic crystals obtained were 1·8 g., m. p. 171—174°, $[\alpha]_D$ +88° (Found: N, 5·5%); 3·3 g., 170—176°, −23°; 1·0 g., 169—175°, −20°; 1·5 g., 170—175°, +50°; 1·7 g., 173—179°, +76° (Found: N, 5·8. $C_{56}H_{60}O_8N_4$ requires N, 5·9%). For a 0·4% solution of the sodium salt prepared from the first fraction, $[\alpha]_D$ −216°, whilst the second fraction yielded a totally inactive solution.

CCCX.—*The Chemistry of the Three-carbon System. Part XVIII. Quantitative Investigations on the Influence of Alkyl Substituents on the αβ–βγ Change in Unsaturated Acids: Observations on the Reduction of Sorbic Acid, and a New Synthesis of Pyroterebic Acid.*

By ALAN AUGUST GOLDBERG and REGINALD PATRICK LINSTEAD.

THE position of equilibrium in the reversible change between αβ- and βγ-olefinic acids in the presence of alkali appears to be independent of the physical conditions under which the interconversion proceeds (Linstead, J., 1927, 362, 2579). It has, therefore, become possible to ascertain the effect of internal conditions, *i.e.*, molecular substitution, upon the position of equilibrium and upon the ease with which it is attained. The present communication describes an examination of the simplest mono-olefinic acids from this point of view.

In the two butenoic acids, *viz.*, vinylacetic (βγ-) and crotonic (αβ-), the change appears to be irreversible in the direction $\beta\gamma \longrightarrow \alpha\beta$, and the same preponderance of the αβ-form is met with in α- and β-alkylcrotonic acids, although, since in many instances only the αβ-forms have as yet been isolated, the evidence is not final. With

(I.) $CH_3 \cdot CR_\gamma{:}CR_\beta \cdot CHR_\alpha \cdot CO_2H \overset{KOH}{\rightleftharpoons} CH_3 \cdot CHR_\gamma \cdot CR_\beta{:}CR_\alpha \cdot CO_2H$ (II.)

the pentenoic acids, a balanced reaction is possible, and we have therefore examined the unsubstituted pentenoic acids themselves

($R_{\alpha,\beta,\gamma} = H$), and two of the three monomethyl derivatives (R_α or $R_\gamma = Me$), the third possible series ($R_\beta = Me$) having already been studied (Kon and Linstead, J., 1925, **127**, 618; Linstead, J., 1927, 355). In addition, the effect of lengthening the chain ("δ-substitution," resulting in the *n*-hexenoic acids) was investigated, and the *cyclo*pentenylacetic acids (III and IV) were studied for comparison with the *cyclo*hexenyl analogues. The unsubstituted

(III.) $\begin{matrix}CH_2\cdot CH_2\\ CH_2\cdot CH_2\end{matrix}\!\!>\!C\cdot CH_2\cdot CO_2H \overset{KOH}{\rightleftharpoons} \begin{matrix}CH_2\cdot CH_2\\ CH_2\cdot CH_2\end{matrix}\!\!>\!C{:}CH\cdot CO_2H$ (IV.)

pentenoic and hexenoic acids were of especial interest as they were among the original substances studied by Fittig (*Annalen*, 1894, **283**, 47).

The preparation of the ten unsaturated acids used in this work is described in the experimental portion. The methods available for the preparation of α-methyl-Δ^α-pentenoic acid (II; $R_\alpha = Me$, $R_{\beta,\gamma} = H$) did not appear to be very satisfactory, but we find that it can readily be prepared in a state of purity from propaldehyde through the aldol $CH_3\cdot CH_2\cdot CH(OH)\cdot CHMe\cdot CHO$, by dehydration and oxidation by the method of Delépine and Bonnet (*Compt. rend.*, 1909, **149**, 39). A detailed investigation was made into the preparation of terebic acid which was required in the synthesis of pyroterebic acid (I; $R_\gamma = Me$, $R_{\alpha,\beta} = H$): the methods involving the oxidation of pinene and camphor appeared to afford uncertain yields and were not examined, but the remaining methods were investigated and much the best was found to be that due to Stobbe, in which teraconic acid is prepared from acetone and succinic ester and subsequently isomerised to terebic acid. We were able to improve upon Fittig's final method for the preparation of pyroterebic acid, but subsequently developed a new method (see pp. 2349, 2354).

Equilibration of the Acids.—In examining the interconversion between the pairs of acids, both the temperature and the concentration and excess of catalyst were maintained at the standard figures used in previous work, and analyses of the mixed acids were again carried out by iodometric methods. In all cases, when the pure isomeric acids were treated with 25% potassium hydroxide at 100°, the same equilibrium was reached in a few hours from either side. In the two pairs of acids already examined by Fittig we were able to confirm and amplify his statement that the equilibrium is on the αβ side, but our results differ in that, using 25% alkali (Fittig used 10 or 20%), we could detect only very slight formation of β-hydroxy-acid—generally about 2%. This absence of pronounced side reaction serves to support the evidence already obtained (J., 1927, 362) as to the tautomeric nature of the change.

The movement towards equilibrium is shown for three of the aliphatic series in Fig. 1 and for the alicyclic acids in Fig. 2, where the results previously obtained for the *cyclo*hexenylacetic acids are added for comparison. The more important data are summarised in Table I, the approximate time (in hours) required for equilibration being given in the last column.

FIG. 1.

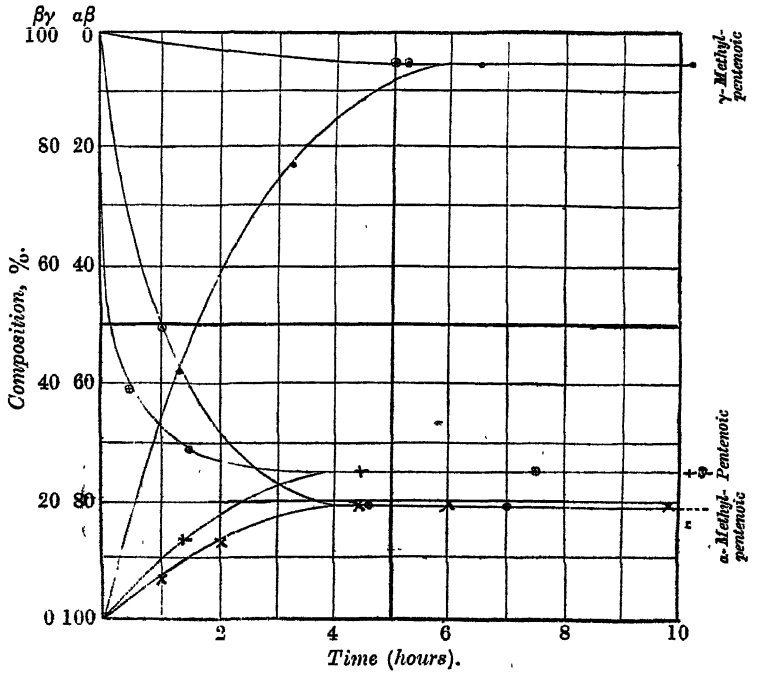

TABLE I.

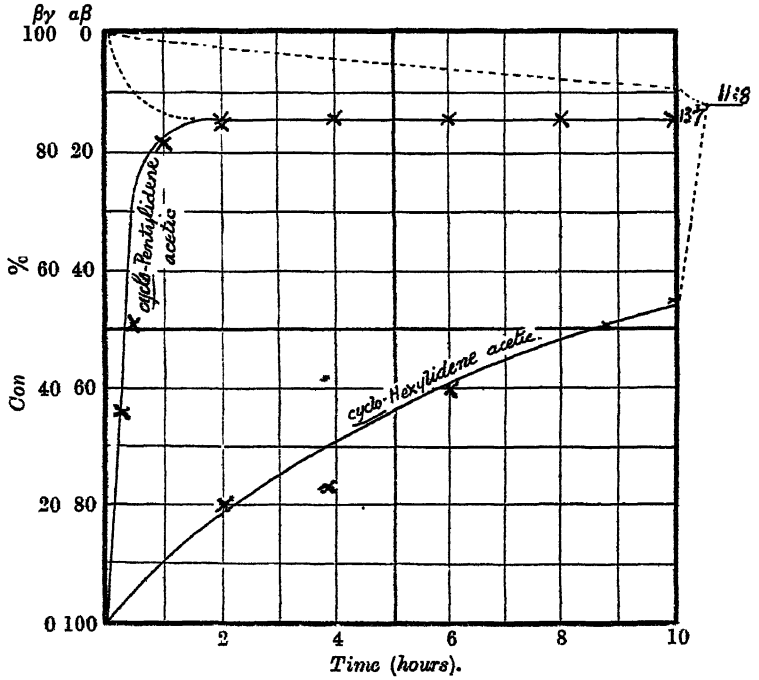


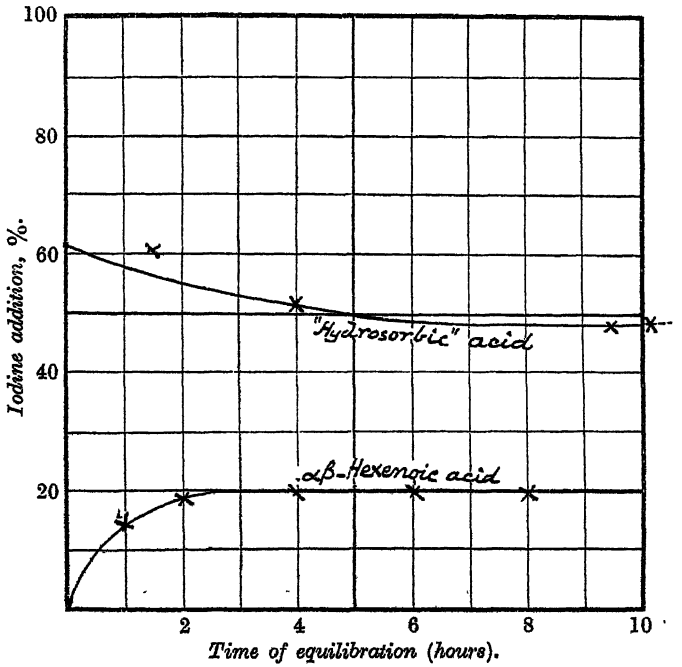
Interconversion under Standard Conditions.

Acid (as αβ form).	% of αβ-acid at equilibrium. From αβ-acid.	From βγ-acid.	Mean.	Time.
Δ$^{\alpha}$-Pentenoic	75·6, 75·4, 75·2	75·6, 75·4	75·4	3
α-Methyl-Δ$^{\alpha}$-pentenoic ...	80·9, 80·2, 80·5	81·2, 80·7	80·7	4½
γ-Methyl-Δ$^{\alpha}$-pentenoic ...	6·0, 5·1, 5·4	5·4, 6·3	5·6	6
*cyclo*Pentylideneacetic ...	13·7 13·7 13·7 13·5	13·7	13·7	2

The Hexenoic Acids.—The results obtained from the hexenoic acids were abnormal and presented several features of interest. The αβ-acid behaved normally: treatment with alkali resulted in a fall in boiling point and an increase in affinity for iodine, indicating

the production of the βγ-isomeride. After some 4 hours the iodine value of the product became constant (% addition of iodine, 19·9), and was unchanged by further treatment; when, however, the βγ-acid (hydrosorbic acid) was treated similarly, a very slow fall in the iodine value of the product was observed, becoming constant after about 20 hours' treatment at an addition value of 47·4%. Even on prolonged treatment with stronger alkali at the boiling point no further change could be effected. Hence, equilibrium

FIG. 2.



was not attained, as shown in Fig. 3, where the time of reaction is plotted against the iodine addition of the product.

The three possible explanations of these anomalous results were: (1) the use of unsuitable experimental methods, (2) the presence of impurity in the acid used, or (3) definite abnormality of the βγ-acid in its behaviour with caustic alkali. The first explanation was not considered probable on account of the excellent results already obtained with other acids, whilst the third seemed unlikely, since the βγ-acid formed from the αβ-isomeride in equilibration behaved normally. On the other hand, the βγ-acid had been prepared from sorbic acid by the method due to Fittig and Baker (*Annalen*, 1894, **283**, 117) and subsequently used by a number of investigators.

The authenticity of our acid was carefully checked. It had a sharp boiling point, the correct physical properties, and gave the anilide, m. p. 55°, described by von Auwers and Henya (*Annalen*, 1923, **434**, 140). It was noticed, however, that the anilide had an indefinite m. p. even after repeated crystallisation, and that the difference

FIG. 3.

between this and the m. p. of the anilide of the αβ-acid was unusually large, thus :

Series.	Pentenoic.	Hexenoic.	α-Methyl-pentenoic.	γ-Methyl-pentenoic.
M. p. of αβ-anilide.....	100°	109—110°	84°	119°
M. p. of βγ-anilide.....	75	54—56	75	106
Difference	25	55	9	13

This abnormality suggested the presence of impurity in the βγ-acid, which might be either the αβ- or the γδ-isomeride, formed by 3 : 4- and 1 : 2-addition of hydrogen to sorbic acid, respectively. The iodine addition was high, and therefore the presence of αβ-acid (or of fully reduced acid) was unlikely, and, moreover, acid containing αβ-acid as impurity would give normal results on equilibration. The γδ-acid, on the other hand, appeared to be a probable impurity : its physical properties closely resemble those of the βγ-isomeride (Fichter, *Ber.*, 1896, **29**, 2367), and its presence would account for

the observed abnormalities, for it would be expected to resemble allylacetic acid in its inertness towards alkali. A study of the literature showed that Fittig's work, which established the presence of the $\beta\gamma$-isomeride in his hydrosorbic acid without, we think, proving its homogeneity, had always been accepted without verification. Indeed, in the course of one oxidation (*Annalen*, 1892, **268**, 38) he obtained a small quantity of succinic acid which could only have been derived from the $\gamma\delta$-acid. The bulk of the chemical evidence is ambiguous. We have oxidised samples of hydrosorbic acid prepared from sorbic acid by Fittig's method: with ozone, succinic acid and a mixture of acetaldehyde and propaldehyde were obtained, whilst with alkaline permanganate, succinic, propionic, and acetic acids were all identified. From the proportions of these oxidation products and from the equilibration experiments on the original acid, it is estimated that the " hydrosorbic acid " prepared in this way contained rather more than 50% of the $\gamma\delta$-isomeride. The reduction of sorbic acid was then repeated both with aluminium amalgam (which had little action) and with sodium amalgam under a variety of conditions; we were unable to isolate the pure $\beta\gamma$-acid from any of the products, and indeed in one experiment a mixture containing about 90% of the $\gamma\delta$-acid was obtained, which was hardly affected by prolonged treatment with alkali. No separation of the acids could be effected by fractional crystallisation of the cadmium salts, as suggested by Fichter's work. The *p*-toluidide of our acid formed mixed crystals (well-defined needles, m. p. 74—77°), whereas the m. p. of the pure $\gamma\delta$-derivative is 103° and that of pure hydrosorbic acid (prepared from the corresponding paraconic acid) is 95·5° (Fichter and Pfister, *Ber.*, 1904, **37**, 1997). The preparation and equilibration of hydrosorbic acid will shortly be described, but it may be said that equilibrium is attained in about 4 hours at about 77% of $\alpha\beta$-acid.

Two points of interest arise. (1) It is believed that this represents the first proof of 1 : 2 addition to a conjugated system of this type, although it was predicted by Burton and Ingold (this vol., p. 913); more recently, in the course of their study of the hydrogenation of conjugated systems, Farmer and his collaborators have obtained other examples of the same kind of addition. (2) The results show that the production of a definite equilibrium furnishes an admirable test of the purity of an $\alpha\beta$- or $\beta\gamma$-unsaturated acid: the presence of any impurity (other than the isomeride) in such an acid will be shown by the inability of the sample to yield the correct equilibrium, which can be determined if only one of the two isomerides is available in a state of purity. An application is furnished by the pentenoic acids, for the $\beta\gamma$-acid yields the correct equilibrium value

and therefore contains no $\gamma\delta$-acid ; hence 1 : 2-addition of hydrogen to vinylacrylic acid does not occur.

Synthesis of Pyroterebic Acid.—As shown in Table I, the equilibrium between the γ-methylpentenoic acids is 94·4% $\beta\gamma$- $\rightleftharpoons$ 5·6% $\alpha\beta$- ; this is so one-sided that the pure $\beta\gamma$-acid can readily be prepared from the equilibrium mixture by fractionation under reduced pressure, and pyroterebic acid can thus be obtained from its $\alpha\beta$-isomeride in 75% yield. As the latter acid can very easily be prepared from *iso*butaldehyde, the advantages of this method over those previously reported are obvious. The authenticity of the pyroterebic acid was checked by the preparation of derivatives, by oxidation, and by the determination of its iodine addition value, which agrees with the figure obtained for the acid prepared from terebic acid.

The Mobility of the Acids.—The mobility of the acids studied in this work was in every case greater than that of the *cyclo*hexenylacetic acids, in which series equilibrium was only reached after 21 hours' treatment under the standard conditions. As calculated from the equation previously used (J., 1927, 2579), but multiplying the results by 10 for convenience (instead of by 100, as formerly), the values for $10(k_1 + k_2)$ are : *cyclo*pentenylacetic acids 22, α-methylpentenoic acids 7, γ-methylpentenoic acids 4·5. The mobilities of the hexenoic and of the pentenoic acids (Figs. 1 and 2) are of the same order, about 7. These figures, calculated from the results given on p. 2358, serve to illustrate the important point, also made clear in the graphs, that alkyl substituents have little effect on the mobility of the change, if reversible, although a gradual decrease in mobility is to be expected with increase in molecular weight. The only exception lies in the large difference between the *cyclo*pentenylacetic acids (mobility = 22) and the *cyclo*hexenyl homologues (mobility = 1); this had been foreshadowed by earlier results, for it had been shown (Kon and Linstead, *loc. cit.*) that *cyclo*pentylideneacetic acid was completely equilibrated in less than 10 minutes with boiling 60% caustic potash, whereas the corresponding *cyclo*hexane acid required an hour's treatment under these conditions.

The Effect of Alkyl Substituents on Equilibrium.

The results so far obtained from the study of simple mono-olefinic acids containing no second unsaturated group * are summarised in Table II. (All values are reduced to whole numbers.)

From the figures in Table II, the following generalisations may be drawn regarding the comparative stability of the isomeric acids

* The presence of such groups (*e.g.*, CO_2H,Ph) introduces complicating factors still under study.

TABLE II.

[1] Kon and Linstead, *loc. cit.* [2] Linstead, J., 1927, 361. [3] Kon and May, J., 1927, 1549. [4] Linstead and May, J., 1927, 2565.

[5] Fittig (*loc. cit.*) obtained a mixture of unsaturated acids of this composition by the action of alkali on Δ^{α}-*iso*heptenoic acid, and this probably represents an equilibrium value.

towards equilibrating agents (alkyl substituents only are referred to throughout): (1) Butenoic acids without γ-substituents show no stability of the $\beta\gamma$-form even when substituted on the β-carbon atom. (2) Butenoic acids with one γ-substituent show a small but definite stability of the $\beta\gamma$-form, which is not appreciably affected by the nature of the substituent or by the presence of α-substituents. (3) γ-Substituted butenoic acids having a second alkyl group on the γ-carbon show great stability of the $\beta\gamma$-form, and a similar but weaker effect is produced if the second substituent is on the β-carbon atom. The maximum effect in the β-position is given by an ethyl group. (4) These principles are still valid if the substituting groups form part of a polymethylene ring.

No exceptions to these rules are known at present, and it may therefore be predicted that the equilibrium in the methyl*cyclo*hexenylacetic acids derived from *o*-methyl*cyclo*hexanone will be more on the $\beta\gamma$-side than that in the *m*- and *p*-homologues; that di*iso*propylacrylic acid will give a much higher proportion of the $\beta\gamma$-isomeride on equilibration than di-*n*-propylacrylic acid; and that the acrylic acid derived from methyl *iso*propyl ketone will be converted almost completely into its $\beta\gamma$-isomeride on suitable treatment with alkali. It is hoped to test these predictions in the near future.

The theoretical significance of these results is obvious, particularly in the light of the electronic hypothesis of three-carbon tautomerism (Ingold, Shoppee, and Thorpe, J., 1926, 1477; Ingold, *Ann. Reports*, 1927, **24**, 109), but consideration of this point is reserved for a future communication.

EXPERIMENTAL.

A. *Preparation, Purification, and Characterisation of the Acids.*

Δ^{α}-*Pentenoic Acid* (II; $R_{\alpha,\beta,\gamma} = H$).—This was prepared from propaldehyde by the Döbner reaction, pyridine containing ½% of

piperidine being used as condensing agent; it had b. p. 105°/19 mm., m. p. 8° (compare von Auwers, *Annalen*, 1923, **432**, 46). Its identity was confirmed by the preparation of the acid chloride, b. p. 51°/24 mm., dibromide, m. p. 56°, and anilide, m. p. 100° (Wohlgemuth, *Ann. Chim.*, 1914, **2**, 332, gives 99°).

Δ^{β}-*Pentenoic acid* (I; $R_{\alpha,\beta,\gamma} = H$).—Vinylacrylic acid, prepared by the method of Kohler and Butler (*J. Amer. Chem. Soc.*, 1926, **48**, 1036), was purified by washing with light petroleum until it melted at 80° and was then immediately reduced with sodium amalgam by the method of Thiele and Jehn (*Ber.*, 1902, **35**, 2320), a 60% yield being obtained of the pure acid, b. p. 98°/19 mm. The acid chloride, b. p. 46°/23 mm., dibromide, m. p. 64° (Thiele gives 65°), and anilide, m. p. 75° (Wohlgemuth gives 73°) were prepared.

Δ^{α}-*Hexenoic Acid.*—This was prepared from *n*-butaldehyde by the method used for the lower homologue. The pure acid, flattened needles from alcohol, m. p. 32°, was obtained in 60% yield. The dibromide, m. p. 70°, and acid chloride, b. p. 70°/23 mm., were prepared. The latter was converted into the *anilide*, needles, m. p. 109—110° (Found: N, 7·5. $C_{12}H_{15}ON$ requires N, 7·4%).

Δ^{β}-*Hexenoic Acid* (Hydrosorbic Acid).—Sorbic acid was prepared from crotonaldehyde by the method of Döbner (*Ber.*, 1900, **33**, 2140), and the product (yield 35%) had m. p. above 132°. The reduction was carried out in the first place under the conditions used for vinylacrylic acid: Sorbic acid (25 g.), suspended in cold water (2 l.), was treated with 1300 g. of 3% sodium amalgam, the solution being kept neutral by passage of carbon dioxide. At the end of the reaction, the solution was decanted from the mercury, acidified with dilute sulphuric acid and extracted with ether. The product, after drying and removal of the solvent, gave a colourless, rancid-smelling oil, b. p. 98°/9 mm.; n_D^{19} 1·4398, $d_4^{19°}$ 0·9632, $[R_L]_D = 31·21$; yield, 18 g., 72%. This substance gave an acid chloride, b. p. 52°/18 mm., and an anilide, needles, which in spite of recrystallisation from a variety of solvents melted at about 55° (Auwers and Henya, *loc. cit.*, give 54—56°) (Found: N, 7·3. Calc.: N, 7·4%). A solid dibromide could not be obtained. The acid added on 61·6% of iodine under the standard conditions, and, after equilibration, 47·6% (see p. 2358).

5 G. of the acid were dissolved in chloroform (30 c.c.) and treated with ozonised oxygen for 12 hours; the ozonide was freed from solvent and decomposed by water. The evolved gases were led through a solution of *p*-nitrophenylhydrazine in excess of dilute hydrochloric acid, and the thick, orange precipitate, after recrystallisation, melted at 117°: mixed with an authentic sample of acet-aldehyde-*p*-nitrophenylhydrazone (m. p. 126°) it melted at 124°.

whereas the mixed m. p. with propionaldehyde-*p*-nitrophenylhydrazone (m. p. 118°) was 114°. When all the aldehyde had been evolved the residue was treated with perhydrol (20 c.c.) and allowed to stand over-night. On evaporation the solution gave succinic acid, m. p. 183° (Found : *M*, by titration, 119. Calc. : *M*, 118), which was further identified by a mixed m. p. determination.

Another sample (5 g.), prepared by the same method, was dissolved in 500 c.c. of water, excess of sodium bicarbonate was added, and the solution was treated slowly with 22 g. of potassium permanganate and 12 g. of magnesium sulphate in 750 c.c. of water. A further quantity of 7·1 g. of permanganate and 15 g. of magnesium sulphate was subsequently added (6 g.-atoms + 5%, in all). The product was worked up in the usual way, and the acid fraction yielded 2·55 g. of a semi-solid residue. The liquid portion of this (0·68 g.) was separated by filtration and converted into the acid chloride with phosphorus trichloride. Some two-thirds of this boiled between 50° and 60° and yielded aceto-*p*-toluidide on reaction with *p*-toluidine. The last few drops of the remaining liquid (b. p. about 75°) were also converted into a *p*-toluidide and gave bold needles of propion-*p*-toluidide, m. p. 123°, from light petroleum. The residual solid acid was succinic acid, m. p. 182°. The identities of these products were confirmed by mixed m. p. determinations.

Modified Reductions of Sorbic Acid.—(1) The reaction was carried out as before, except that dilute sulphuric acid was added at half-hour intervals until the solution was slightly acid (compare Fittig and Baker, *loc. cit.*). The product obtained as before boiled at 98—99°/9 mm., and had an "iodine value" of 57·3%, which after equilibration for 48 hours fell to 49·0%. Another sample had b. p. 204—206°/760 mm. and gave a *p*-toluidide forming well-defined tufts of needles, m. p. 74° (indefinite). The cadmium salt (compare Fichter, *Ber.*, 1896, **29**, 2367) was extracted with cold water until one-third remained as residue, and the solution, which should have contained the more soluble salt of the $\beta\gamma$-acid, was evaporated to dryness. The acid was extracted from the residue by treatment with dilute sulphuric acid and ether; it boiled constantly at 101·5°/12 mm. and had $n_D^{18°}$ 1·4405, $d_4^{18°}$ 0·9640, whence $[R_L]_D$ 31·23 (v. Auwers, *loc. cit.*, finds b. p. 112°/10 mm., $n_D^{20°}$ 1·4394, $d_4^{20°}$ 0·9655, $[R_L]_D = 31·11$); it did not solidify in a freezing mixture, and gave an acid chloride, b. p. 50—51°/14 mm., and an anilide, m. p. 52—56°.

(2) Acetic acid was added during the reduction at such a rate as to keep the solution slightly *acid* throughout. In this way it was hoped to obtain addition of hydrogen to the molecule of sorbic acid as distinct from the ion. The product boiled at 101°/11 mm. and

had an "iodine value" of 52·6%, which fell to 48·9% after equilibration for 48 hours.

(3) Sorbic acid (10 g.), dissolved in moist ether (2000 c.c.), was reduced with aluminium amalgam (20 g.) in the usual way. The product yielded 2 g. of the pure reduced acid, b. p. 102°/12 mm., iodine value 59·8%, falling on equilibration for 48 hours to 50·6%. A considerable quantity of unchanged sorbic acid was recovered from the higher-boiling fractions.

γ-Methyl-Δ$^{\alpha}$-pentenoic Acid (Δ$^{\alpha}$-*iso*Hexenoic acid) (II; $R_{\alpha,\beta}$ =H, R_{γ} = Me).—This was prepared from *iso*butaldehyde by the method used for Δ$^{\alpha}$-pentenoic acid. After refractionation of the product, the pure acid was obtained in 66% yield; b. p. 113°/20 mm., 104°/10 mm. The *acid chloride* boiled at 67°/20 mm.; the *anilide* crystallised in fine needles from aqueous alcohol, m. p. 119° (Found: N, 7·4. $C_{12}H_{15}ON$ requires N, 7·4%); the dibromide crystallised in heavy white cubes, m. p. 124°.

Terebic Acid.—(1) Ethyl diaterebate was hydrolysed with concentrated hydrochloric acid (Simonsen, J., 1907, **91**, 184) but gave a poor yield, never exceeding 20% of terebic acid. Hydrolysis with 50% sodium hydroxide was very violent, but the use of potassium hydroxide gave better results: Ethyl diaterebate (30 g.) was poured into 50% aqueous potassium hydroxide solution (100 c.c.); hydrolysis, which was accompanied by the evolution of much heat, was completed by an hour's heating on the steam-bath, the solution was cooled, the unchanged ester extracted with ether, and the alkaline liquid acidified with concentrated hydrochloric acid and evaporated to dryness. The solid residue was exhaustively extracted with ether in a Soxhlet apparatus, and the solid obtained was repeatedly recrystallised from water. It melted between 162° and 166° and probably contained much teraconic acid. After being heated with concentrated hydrochloric acid and recrystallised, pure terebic acid was obtained, m. p. 175°; yield, nearly 50%.

(2) Ethyl carbethoxysuccinate was prepared in 60% yield by the action of ethyl chloroacetate on ethyl sodiomalonate; its sodio-compound readily reacted with *iso*propyl iodide and gave a 65% yield of ethyl α-carbethoxy-α-*iso*propylsuccinate, b. p. 153—155°/10 mm. This was boiled over-night under reflux with seven times its volume of concentrated hydrochloric acid, and the resulting solution gave *iso*propylsuccinic acid on evaporation to small volume, m. p. 110°; yield, 86%. This acid, when oxidised by the method of Lawrence (J., 1899, **75**, 527), yielded 51% of terebic acid, which melted sharply at 175° after one crystallisation from hot water, together with 20% of the unchanged starting material.

(3) Teraconic acid (Stobbe, *Ber.*, 1893, **26**, 2314) was converted

into terebic acid by boiling over-night with concentrated hydrochloric acid under reflux (compare Fittig and Frost, *Annalen*, 1884, **226**, 365), a 90% yield being obtained.

γ-Methyl-Δ$^{\beta}$-pentenoic Acid (Pyroterebic Acid) (I; $R_{\alpha,\beta} = H$, $R_{\gamma} = Me$).—(1) *By dry distillation of terebic acid.* The method of Fittig and Geisler (*Annalen*, 1881, **208**, 37) was improved as follows: Terebic acid, in 20 g. portions, was placed in a 100 c.c. distilling flask fitted with a thermometer, the bulb of which almost touched the bottom of the flask. To the side arm was attached a 50 c.c. distilling flask and to the side arm of this a small water condenser in a vertical position. The acid was heated *as quickly as possible* to 240°. At 175—180° it melted to a clear golden oil, and at about 240° water began to separate. The oil then distilled without charring. The distillate partly solidified on cooling, owing to the presence of unchanged terebic acid. It was distilled in steam, terebic acid and teraconic acid (2·8 g.) being left in the residue. The aqueous distillate was saturated with sodium bicarbonate and extracted with ether to remove *iso*caprolactone (0·5 g.). The alkaline solution was then acidified and extracted thoroughly with ether. The product, isolated after removal of the solvent and refractionation, distilled at 99°/10 mm.; yield, 6·5 g. (33%). The *acid chloride* boiled at 60°/15 mm. The *anilide* crystallised from alcohol and water in needles, m. p. 106° (Found: N, 7·5. $C_{12}H_{15}ON$ requires N, 7·4%). The dibromide was obtained as hard white crystals, m. p. 99°.

(2) *From* Δ$^{\alpha}$-iso*hexenoic acid.* The αβ-acid (20 g.) was heated for 15 hours with a solution of potassium hydroxide (120 g.) in 250 c.c. of water. The solution was cooled, acidified, and extracted thoroughly with ether. After removal of the ether, the residual oil was distilled in steam and extracted as in the previous method. Almost the whole product distilled at 99—100°/10 mm., the last fractions, about 2 c.c., being rejected. On refractionation, 15 g. of a clear colourless oil were obtained, b. p. 99°/10 mm. (75% yield). This preparation gave the following derivatives: acid chloride, b. p. 62°/16 mm.; anilide, in needles from benzene–light petroleum, m. p. 104° [mixed m. p. with the αβ-anilide (of m. p. 119°) 85—87°; mixed m. p. with anilide prepared by method (1) 106°]; dibromide, m. p. 99°, not depressed in admixture with dibromide from preparation (1).

The new acid (5 g.), dissolved in dry chloroform (30 c.c.), was treated with dry ozonised oxygen for 20 hours; the precipitated white, solid *ozonide*, sparingly soluble in chloroform, had m. p. 110° (decomp.) after drying in a vacuum. A portion of the ozonide was treated with an excess of water, and the aldehyde evolved was

converted into the *p*-nitrophenylhydrazone; this formed yellow needles from alcohol, m. p. 126°, and was identified as the acetaldehyde derivative by comparison with an authentic sample: a mixture with a specimen of the *p*-nitrophenylhydrazone of *iso*-butaldehyde (m. p. 128°) melted at 103°. When all the acetaldehyde had been removed, the residual solution was heated under reflux for an hour, and a white, crystalline deposit was formed in the condenser. An excess of sodium bicarbonate was added and the liquor slowly distilled under a column, the first 10 c.c. being collected. The presence of acetone in this was shown by the immediate formation of iodoform and by the preparation from it of dibenzylidene-acetone (m. p. 111°, identified by mixed m. p.). The white solid, volatile in steam, was undoubtedly acetone superoxide.

The remainder of the ozonide was left over-night with an excess of perhydrol, and the solution subsequently evaporated to small bulk; malonic acid crystallised on cooling, and was identified by its m. p. (129°), by its decomposition to acetic acid, and by a mixed m. p. determination.

α-Methyl-Δ$^{\alpha}$-pentenoic Acid (II; R_{α} = Me, $R_{\beta,\gamma}$ = H).—α-Methyl-β-ethylacrolein (Döbner and Weissenborn, *Ber.*, 1902, **35**, 1144) was distilled, and the fraction of b. p. 55—60°/18 mm. was immediately oxidised. The aldehyde (40 g.), mixed with silver nitrate (230 g.), water (500 g.), and rectified spirit (200 c.c.), was stirred vigorously, and to it were added during 3 hours 75 g. of sodium hydroxide in 1 litre of water (compare Delépine and Bonnet, *loc. cit.*); reaction was completed by standing over-night. The filtered solution was acidified and thoroughly extracted with ether. The product, after drying and removal of the solvent, was fractionated, α-methyl-Δ$^{\alpha}$-pentenoic acid being obtained as a colourless oil, b. p. 112°/12 mm. (yield, 25 g., 60%). On cooling in ice, the product solidified completely and melted at 22—23° (Lieben and Zeisel, *Monatsh.*, 1883, **4**, 46, give 24·4°).

The *acid chloride* boiled at 63°/16 mm. The *amide*, prepared from this by the action of dry ammonia in benzene solution, crystallised from benzene or carbon disulphide in plates, m. p. 80° (Found: N, 12·3. $C_6H_{11}ON$ requires N, 12·4%). All the crops obtained by fractional crystallisation of this substance melted sharply at 80°, and the m. p. could not be raised by further purification; we were unable therefore to obtain either of the amides, m. p. 65·5° and 96°, described by Macq (*Bull. Acad. roy. Belg.*, 1926, **12**, 753) as those of the *cis*- and *trans*-forms of this acid. The preparative method used by Macq (hydrolysis of the corresponding unsaturated nitrile) would, however, certainly lead to the production of a mixture, and it is probable that this was insufficiently separated (cf.

pare Newbery, J., 1925, **127**, 295; von Auwers, *Annalen*, 1923, **432**, 46).

The *anilide* of α-methyl-Δ^{α}-pentenoic acid, prepared from the acid chloride, crystallised from benzene–light petroleum in needles, m. p. 84° (Found: N, 7·2. $C_{12}H_{15}ON$ requires N, 7·4%). The dibromide crystallised from carbon disulphide in hard, white prisms, m. p. 96—97° (Lieben and Zeisel, *loc. cit.*, p. 77, give 97·6°).

α-Methyl-Δβ-pentenoic Acid (I; $R_{\alpha} = Me$, $R_{\beta,\gamma} = H$).—This was prepared by the method of Fichter and Rudin (*Ber.*, 1904, **37**, 1615), who, however, gave scanty details. Ethyl α-methyl-β-acetosuccinate (100 g.), obtained in 62% yield from ethyl sodioacetoacetate and ethyl α-bromopropionate, was dissolved in 200 c.c. of rectified spirit and 150 c.c. of water, and cooled to 0°. To the mechanically stirred solution were added 1400 g. of 3% sodium amalgam in seven equal lots at one-hour intervals, 100 c.c. of water being added with each addition. The solution was kept over-night and the supernatant liquor separated from the mercury, carefully acidified with dilute sulphuric acid (evolution of carbon dioxide) and extracted with ether. The extract was dried and the residue after removal of the solvent was fractionated in a vacuum. The low-boiling fraction, 140—160°/12 mm. (15 g.), was presumably α-methyl-lævulic acid. At 195°/12 mm., αγ-dimethylparaconic acid, $CH_3{\cdot}CH{\cdot}CH(CO_2H){\cdot}CHMe{\cdot}CO$ (O bridge), came over and solidified to a mass of long, white crystals (30 g., 40%), m. p. 130° after crystallisation (Fichter and Rudin report a 70% yield, but we were unable to obtain this in spite of many variations of conditions).

The paraconic acid (20 g.) was distilled from the same apparatus as that used for terebic acid, the temperature being raised *very gradually* to 240°; distillation commenced at 280° and continued up to 285°, there being no charring of the paraconic acid. The product was worked up as described for pyroterebic acid, and on fractionation gave 7·5 g. of a liquid, b. p. 101—103°/16 mm., and 102°/16 mm. after refractionation; yield, 33%. From the residue of the steam-distillation, 3 g. of the paraconic acid were recovered. Fichter and Rudin (*loc. cit.*), using a different method of separation, obtained only 16% of the unsaturated acid.

The *acid chloride* boiled at 47°/17 mm. The *amide*, prepared in the same way as the αβ-isomeride, crystallised from carbon disulphide or benzene in glistening plates, m. p. 74° (Found: N, 12·2. $C_6H_{11}ON$ requires N, 12·4%). The *anilide* crystallised from aqueous alcohol or benzene–light petroleum in needles, m. p. 76° (Found: N, 7·4. $C_{12}H_{15}ON$ requires N, 7·4%).

cyclo*Pentylideneacetic acid* (IV) (Kon and Linstead, *loc. cit.*)

boiled at 133°/15 mm. and solidified to a white mass which on crystallisation from alcohol melted sharply at 64°.

Δ^1-cyclo*Pentenylacetic acid* (III) was prepared by the action of a large excess of 40% potassium hydroxide on the αβ-isomeride for 1 hour. The acid, isolated in the usual way, was freed from adhering oil by washing with light petroleum, and recrystallised from aqueous alcohol, m. p. 52°; yield, 50%.

B. *Equilibration of the Acids.*

The same potassium hydroxide solution was used throughout: it contained 300 g. KOH per litre of solution, and was standardised from time to time against *N*-acid. Equilibrations were carried out by the standard procedure (J., 1927, 2579), 2 g. of the acid being sealed up with exactly ten times the theoretical amount of the alkali. The reaction mixture was then heated in a bath of boiling water. Owing to the formation of hydroxy-acids, the method of working up the product differed from that used previously. At the end of the required time the tube was opened and the contents were acidified and extracted with ether. The undried extract was freed from solvent under a good column and slowly distilled in steam for 1 hour. The mixed unsaturated acids in the distillate (about 1 litre) were isolated in the usual way after removal of lactone. The residual oil was washed into a tared beaker with pure ether and weighed after removal of the ether in a vacuum over paraffin wax. In every case about 1·7 g. of mixed acids (*ca.* 85%) were recovered in this way.

The residue from the distillation in steam was extracted with ether and the hydroxy-acids were isolated, after drying and removal of the solvent, as sweet-smelling viscous oils. The following amounts were obtained during the equilibrations: Pentenoic acids, traces; hexenoic acid, 22%; *iso*hexenoic acid, 5%; α-methylpentenoic acids, traces; *cyclo*pentenyl acids, nil.

The molecular weight of the β-hydroxy-*n*-caproic acid derived from Δ^α-hexenoic acid was found by titration with standard baryta to be 131 ($C_6H_{12}O_3$ requires 132). The other hydroxy-acids were not obtained in quantities sufficient for examination. In this respect the results are contrasted with those of Fittig, who obtained quantities of β-hydroxy-acids varying from 15 to 35%.

C. *Analysis of the Equilibrated Acids.*

The method of Linstead and May (*loc. cit.*) was used throughout. Data for reference were first obtained by determining the % addition of iodine under the standard conditions to mixtures of the isomerides of known composition, at least three determinations being made

on every mixture. These data were then incorporated into reference curves, this "iodine value" being plotted against the % composition of the mixed acids. Quantities of the equilibrated acids equivalent to $M/300$ were then examined in the same way, three determinations of the iodine value being made in each case. The composition of the acid mixture was then found from the reference curve. The time of equilibration was increased until there was no further change in the iodine value of the product. The curves obtained from each pair of isomerides by plotting time of equilibration against composition of the product were of the exponential type, becoming asymptotic to each other at the equilibrium point (Figs. 1 and 2).

The following tables summarise this section of the experimental work.

Pentenoic acids : Reference data.

% αβ-Acid	100	80	66·6	50	33·3	20	0

* Hydrosorbic acid prepared by first method : iodine value 61·6%. The variation in the iodine values of other samples of hydrosorbic acid on equilibration has already been given (p. 2352).

Since the pure hydrosorbic (βγ-)acid was not obtained in the course of this work the position of equilibrium could only be determined approximately. It will be noticed from the figures given on p. 2352 that the samples of mixed βγ- and γδ-hexenoic acids which gave the lowest iodine values were also those whose iodine values *changed least on equilibration*, *i.e.*, were those containing the most γδ-acid. From a study of these results, we deduce that the iodine values of the βγ- and γδ-acids are approximately 70 and 50%, respectively, and assuming this figure for the pure βγ-acid, the equilibrium is of the order 22% βγ : 78% αβ. This equilibrium was also deter-

mined by Bougault's method (*Ann. Chim. Phys.*, 1908, **14**, 145), the unchanged αβ-acid being actually isolated (Linstead and May, *loc. cit.*). In three experiments, from 2 g. of the equilibrium mixture there were isolated 1·44 g., 1·60 g., and 1·57 g. of the solid αβ-acid, which give a mean value for the equilibrium of 77% αβ : 23% βγ. The variation in the above figures shows, however, that the method is by no means accurate.

γ-Methylpentenoic acids : Reference data.

Mean iodine value at equilibrium : 83·4. αβ-Acid = 13·7%.

In this series, the residual iodine was titrated with thiosulphate without previous acidification, and there is a slight absolute

which does not extend to the interconversion curves and the position of equilibrium.

Much of the heavy cost of this investigation has been defrayed by grants from the Government Grant Committee of the Royal Society and from the Chemical Society, to whom we wish to acknowledge our indebtedness. Our thanks are also due to Professor J. F. Thorpe, F.R.S., and Dr. G. A. R. Kon for their interest in the progress of the work.

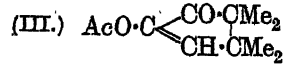
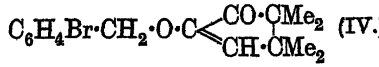
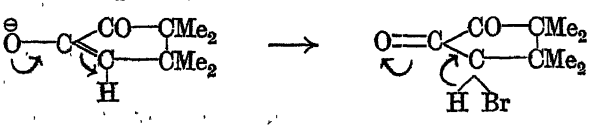
CCCXI.—*On the Possibility of Ring-chain Valency Tautomerism and of a Type of Mobile-hydrogen Tautomerism analogous to the Wagner–Meerwein Rearrangement. Part IV. Substitution Reactions of some Cyclic Derivatives of Phorone.*





By CHARLES WILLIAM SHOPPEE.

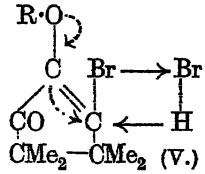
IN the course of previous investigations (Francis and Willson, J., 1913, **103**, 2238; Ingold and Shoppee, this vol., p. 365) on the cyclic phorone derivatives represented by the formulæ (I) and (II), numerous observations have been made which indicate that the 5-carbon nucleus possesses remarkable stability such as is sometimes found to be associated with tautomeric complexes. Reference may be made to the smooth formation of bromohydroxyphorone (X = O, Y = Br) by the action of concentrated sulphuric acid on dibromophorone and by the action of bromine and water on 3 : 3 : 4 : 4-tetramethyl*cyclo*pentanone; to the conversion of hydroxyphorone (Y = H) into the bromohydroxy-compound by direct bromination without detectable intermediate addition; to the direct reduction of derivatives of bromohydroxyphorone to corresponding derivatives of hydroxyphorone without loss of the unsaturation on which tautomeric character depends; and finally to the stability towards brominating, reducing, and certain oxidising agents of some of the derivatives of hydroxy- and bromohydroxy-phorone. These observations call to mind the properties of the *gem*-dialkyl*cyclo*pentadiene nucleus investigated by Farmer, Ingold, and Thorpe (J., 1922, **121**, 128), and the analogy between compounds containing this nucleus and aromatic substances (Ingold, Seeley, and Thorpe, J., 1923, **123**, 852); it was therefore decided to study the action of substituting agents on hydroxyphorone and its derivatives in order



to determine the conditions under which the nuclear type is preserved.

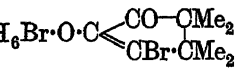
(I.)  (II.)

By the action of bromine in chloroform upon the acetoxy-compound (III) and the methoxy- and *p*-bromobenzyloxy-compounds represented by (IV), bromohydroxyphorone was produced. Hydrogen bromide was evolved from the commencement of the reaction and no evidence was obtained of intervening bromine

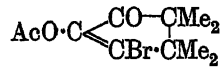


(III.)   (IV.)

addition. The fact that the alkyl and acyl groups are eliminated in the course of these reactions places difficulties in the way of their interpretation, since it is not known whether the eliminations are antecedent or subsequent to the nuclear substitution; if they are antecedent, substitution might occur through the ion of hydroxyphorone with the formation of a tautomeride of the product isolated (compare Part I, p. 383):

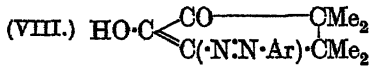


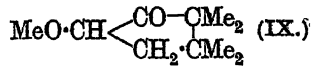
The facility with which this reaction would be expected to occur is such that, assuming the elimination of the *O*-substituent to be brought about by hydrogen bromide, a very small amount of fission at the commencement of the reaction would suffice to cause the whole of the subsequent process to pursue the course indicated. This mechanism is not analogous to the general case of substitution in the aromatic series, and the behaviour of other halogenating agents was therefore investigated. Quinolinium perbromide also causes the elimination of the acetyl group from the acetoxy-compound (III) and yields the same bromination product as that obtained by means of bromine. In the case of the *p*-bromobenzyloxy-compound (IV), however, fission did not take place and simple nuclear substitution was observed, the product being (VI). A similar result was achieved in the formation of (VII) from the acetoxy-compound (III) by brominating with quinolinium perbromide in the presence of a quantity of quinoline sufficient to prevent the formation of free hydrogen bromide during the process. These substitutions cannot involve prior ionisation of the organic



molecule and are regarded as taking the course indicated in formula (V).

(V.)





(VI.)

(VII.)

The acyl and alkyl derivatives mentioned above appear to show but little tendency to couple with diazonium salts, but hydroxyphorone readily does so, and it is therefore assumed that in this case the reaction occurs through the anion. Deep red dyes of the type (VIII) have been prepared from hydroxyphorone and several aromatic diazonium salts. The position of coupling was indicated in the first place by the fact that the reaction fails with bromohydroxyphorone, and was definitely proved by complete reduction of the dye given by *p*-carbethoxybenzenediazonium sulphate. Hydrolysis of the carbethoxy-group present in one of the pair of bases formed by reduction enabled the aliphatic constituent to be separated and this was then identified as 2 : 2 : 3 : 3-tetramethyl*cyclo*pentylamine.

(VIII.) 

(IX.)

In the above examples, the nuclear form originally present is preserved throughout the substitution, and it became of interest to ascertain whether, if the type were destroyed by previous reduction, it would be regenerated during halogenation. For this purpose, the saturated methoxy-compound (IX) was prepared, and when it was subjected to the action of bromine and chloroform, the tautomeric bromohydroxy-compound was produced.

EXPERIMENTAL.

Bromination with Free Bromine in Chloroform Solution.—*5-Acetoxy-2 : 2 : 3 : 3-tetramethyl-*Δ^4*-cyclopentenone.* The substance, b. p. 120—121°/10 mm., reacted readily at 35° with one molecular proportion of bromine, evolution of hydrogen bromide taking place. The residual oil, obtained after removal of the solvent on the steam-bath, readily solidified; it was pressed on porous tile and crystallised from ligroin (b. p. 80—100°), from which it separated in colourless needles, m. p. 116°, identified as bromohydroxyphorone by direct comparison and mixed melting point.

5-Methoxy-2 : 2 : 3 : 3-tetramethyl-Δ^4*-cyclopentenone.* The pure methoxy-derivative, prepared by methylating the hydroxy-ketone, b. p. 110°/18 mm., was treated with 1 mol. of bromine; substitution

with evolution of hydrogen bromide occurred readily on gentle warming. The product, bromohydroxyphorone, m. p. 116°, was isolated and identified as above.

5-p-*Bromobenzyloxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenone*. The crystalline solid, m. p. 86°, was treated with 1·2 mols. of bromine in boiling chloroform, and substitution slowly took place. When evolution of hydrogen bromide had ceased, the solvent and the excess of bromine were removed on the steam-bath. The residual oil, which was lachrymatory and had the characteristic odour of *p*-bromobenzyl bromide, solidified on stirring, and was washed with a little hot ligroin (b. p. 40—60°) to remove this product. The solid was crystallised from ligroin (b. p. 80—100°) and then it had m. p. 116°; it was identified as before.

5-*Methoxy*-2 : 2 : 3 : 3-*tetramethyl*cyclo*pentanone*. The methoxy-compound was treated with excess of bromine in hot chloroform, substitution taking place with evolution of hydrogen bromide. The solvent, excess of bromine, and hydrogen bromide were removed on the steam-bath and the residual oil soon became solid. It was identified as bromohydroxyphorone. In another experiment, bromine (1 mol.) was added to the warm chloroform solution of the methoxy-compound. Substitution took place after a short induction period, and bromine was added until a permanent red colour was obtained. The residue remaining after evaporation partially crystallised, and the solid separated from ligroin (b. p. 60—80°) in colourless prisms, m. p. 99—100° The *dibromo*-compound gave no colour with aqueous-alcoholic ferric chloride, and was stable to bromine in acetic acid, and to alkaline permanganate; on keeping it decomposed with evolution of free bromine (Found: C, 37·1, 37·3; H, 5·6, 5·8. $C_{10}H_{16}O_2Br_2$ requires C, 36·6; H, 4·9%).

3 : 3 : 4 : 4-*Tetramethyl*cyclo*pentanone*. The ketone was treated with bromine (2 mols.), substitution taking place on gentle warming. The product obtained on evaporation crystallised from ligroin (b. p. 60—80°) in long needles, m. p. 93°, and depressed the m. p. (99—100°) of the substance described above (Found: C, 36·7, 37·2; H, 4·6, 4·4; Br, 53·8, 53·9. $C_9H_{14}OBr_2$ requires C, 36·2; H, 4·7; Br, 53·7%).

5-*Benzoyloxy*-3 : 3 : 4 : 4-*tetramethyl*cyclo*pentanone*. The bromination of this substance (Part II, this vol., p. 1662) has been reinvestigated, but with little success. In addition to free benzoic acid, a bromine-free *substance* is formed, m. p. 100—101°, to which no formula has been assigned (Found: C, 71·3, 71·6; H, 7·4, 7·2%).

Bromination with Quinolinium Perbromide.—The reagent was prepared by the method of Rosenmund and Kühnhenn (*Ber.*, 1923,

56, 1264); alcohol, which these authors recommend for crystallisation, may be advantageously replaced by chloroform.

Acetoxy-derivative (III). (1) The compound was dissolved in glacial acetic acid, and the calculated quantity of quinolinium perbromide added. The whole was warmed on the steam-bath for ½ hour, during which the red colour of the solution disappeared. On dilution with ice-water, a crystalline precipitate separated; this was filtered off, dried in a vacuum, crystallised from ligroin (b. p. 80—100°), and identified as bromohydroxyphorone (yield, /o).

(2) The above experiment was repeated, but with the addition of quinoline (1 mol.). The product was isolated as described above, and when crystallised from dilute acetic acid had m. p. 73°. It was identified as 4-bromo-5-acetoxy-2 : 2 : 3 : 3-tetramethyl-Δ^4-*cyclo*pentenone by direct comparison and by mixed m. p. (yield, 70%).

p-*Bromobenzyloxy-derivative* (IV). The same product was obtained with or without the presence of free quinoline. After crystallisation from ligroin (b. p. 60—80°), it had m. p. 64°, and did not depress the m. p. (64°) of 4-bromo-5-*p*-bromobenzyloxy-2 : 2 : 3 : 3-tetramethyl-Δ^4-*cyclo*pentenone on admixture (yield, 80%).

Coupling of the Hydroxy-ketone with Diazonium Salts.—With benzenediazonium sulphate the dye produced by coupling was amorphous, but with 2 : 4 : 6-tribromobenzenediazonium sulphate and with *p*-carbethoxybenzenediazonium sulphate, crystalline products were obtained. The diazonium sulphates were prepared according to the method of Knoevenagel (*Ber.*, 1895, **28**, 2049).

4-2′ : 4′ : 6′-*Tribromobenzeneazo*-5-*hydroxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenone* separates in crimson needles when the theoretical quantity of dry 2 : 4 : 6-tribromobenzenediazonium sulphate, dissolved in aqueous methyl alcohol, is added to the aqueous methyl-alcoholic solution of the hydroxy-ketone. It is soluble in cold 2*N*-sodium hydroxide (Found : C, 36·2; H, 3·1. $C_{15}H_{15}O_2N_2Br_3$ requires C, 36·3; H, 3·0%).

4-p-*Carbethoxybenzeneazo*-5-*hydroxy*-2 : 2 : 3 : 3-*tetramethyl*-Δ^4-cyclo*pentenone*, obtained similarly, forms crimson needles, m. p. 160° (decomp.), and is soluble in cold 2*N*-sodium hydroxide (Found : C, 65·4; H, 6·7. $C_{18}H_{22}O_4N_2$ requires C, 65·4; H, 6·7%).

Reduction of the p-*Carbethoxy-dye.*—The substance (2·0 g.) was reduced in hot aqueous-alcoholic solution with successive small quantities of sodium hydrosulphite (5·0 g.). The product, which contained some substance readily oxidised by atmospheric oxygen, was extracted with ether, and the ethereal extract evaporated under a column. The residual oil was boiled with phosphorus and

hydriodic acid (*d* 1·7) for 2 hours to effect reduction of the phorone nucleus and hydrolysis of the *p*-carbethoxy-group. The liquid was then made strongly alkaline and steam-distilled, and the distillate extracted with ether. The ethereal extract was dried with anhydrous potassium carbonate and evaporated under a column. The product was identified as 2 : 2 : 3 : 3-tetramethyl*cyclo*pentylamine; it was accompanied by a trace of some other base yielding a picrate, m. p. 185° (decomp.).

The author wishes to record his thanks to the Royal Commission of 1851 for a Senior Studentship.

THE UNIVERSITY, LEEDS. [*Received, July 21st*, 1928.]

CCCXII.—*An Attempt to prepare Optically Active Derivatives of Quadrivalent Tin.*

By FREDERIC BARRY KIPPING.

THE only optically active compound of tin hitherto described is that of Pope and Peachey (P., 1900, **16**, 42, 116), who obtained externally compensated methylethyl-*n*-propylstannic, iodide, and hence prepared both the *d*-camphorsulphonate and the *d*-α-bromo-π-camphorsulphonate. Evaporation of aqueous solutions of these salts produced in each case salts of the dextrorotatory base only, the whole of the lævorotatory base being converted into its dextrorotatory isomeride. From these salts was isolated *d*-methylethyl-*n*-propylstannic iodide, having $[\alpha]_D = +23°$ in ethereal solution. Furthermore, *d*-methylethyl-*n*-propylstannic *d*-α-bromo-π-camphorsulphonate was found to be completely racemised by heating in aqueous solution on the water-bath for 2 hours, such a solution again giving the dextrorotatory salt on evaporation to dryness.

In view of these results it appeared to be of interest to attempt the preparation of further optically active derivatives of tin in order to ascertain if the remarkable mobility of the groups attached to this atom persisted in all its compounds. The aromatic derivatives were chosen for this investigation, as being more readily crystallised and possibly less easily racemised than the aliphatic compounds. The proposed method of preparation was that of Pope and Peachey, *i.e.*, to start with a triarylstannic halide, introduce a different aryl group by means of the Grignard reagent and remove one of the three original radicals by treatment with iodine:

$$SnPh_3Cl \xrightarrow{BzMgCl} SnPh_3Bz \xrightarrow{I_2} SnPh_2BzI$$

A third aryl group was then to be introduced and one of the two like radicals again removed,

$$SnPh_2BzI \xrightarrow{p\text{-}CH_3\cdot C_6H_4\cdot MgBr} SnPh_2Bz(CH_3\cdot C_6H_4) \xrightarrow{I_2} SnPhBz(CH_3\cdot C_6H_4)I$$

As a preliminary, it was therefore decided to prepare some mixed tin-aryls and study the action of iodine on these compounds in order to determine in which order the various groups must be introduced into the molecule for the above purpose.

The only available data on this subject are that treatment of a benzyl-alkyl compound with iodine results in the elimination of a benzyl group (Smith and Kipping, J., 1912, **101**, 2553), and that one of the phenyl groups is similarly removed from *cyclo*hexyltriphenyl stannane (Krause and Pohland, *Ber.*, 1924, **57**, 544).

In the present instance, it was found that the ease with which various groups were removed by iodine from a molecule containing two or three different radicals decreased in the following order: *o*-tolyl, *p*-tolyl, phenyl, benzyl. Thus triphenyl-*p*-tolylstannane with iodine gave triphenylstannic iodide and *p*-iodotoluene, but *triphenylbenzylstannane* yielded diphenylbenzylstannic iodide and iodobenzene. The tin aryls are also decomposed by boiling with concentrated hydrochloric acid, and it was found that this reagent often removed two aryl groups.

For example, triphenylbenzylstannane yields *phenylbenzylstannic chloride* and benzene, whilst tetraphenylstannane gives diphenylstannic chloride. The order in which the groups were removed by hydrochloric acid was the same as that with iodine, except that, whereas iodine removes one of the benzyl radicals from tribenzylethylstannane, hydrochloric acid removes the ethyl group.

Phenylbenzyl-p-*tolylstannic hydroxide* was then prepared by the following series of reactions:

$$SnPh_4 \xrightarrow{I_2} SnPh_3I \xrightarrow{BzMgCl} SnPh_3Bz \xrightarrow{HCl} SnPhBzCl_2 \xrightarrow{MgBr(p\text{-}CH_3\cdot C_6H_4)}$$
$$SnPhBz(p\text{-}C_7H_7)_2 \xrightarrow{I_2} SnPhBz(p\text{-}C_7H_7)I \xrightarrow{NH_4OH} SnPhBz(p\text{-}C_7H_7)OH$$

and *salts* of this base were prepared with *d*-camphorsulphonic, *d*-α-bromo-π-camphorsulphonic and tartaric acids, but they could not be obtained crystalline.

Phenylbenzyl-n-*butylstannic iodide* was then prepared:

$$SnPh_3Bz \xrightarrow{I_2} SnPh_2BzI \xrightarrow{MgBuBr} SnPh_2BzBu \xrightarrow{I_2} SnPhBzBuI$$
$$\uparrow MgBzCl$$
$$SnPh_3I \xrightarrow{MgBuBr} SnPh_3Bu \xrightarrow{I_2} SnPh_2BuI$$

but again the salts, with the exception of the *fluoride*, proved to be oils. It was then thought that the aromatic nucleus directly

attached to the tin atom might be the cause of the failure of the salts to crystallise, and a third compound, *benzylethyl-n-butylstannic iodide*, was prepared in which no nucleus is thus attached :

$$SnBz_3Cl \xrightarrow{MgEtBr} SnBz_3Et \xrightarrow{I_2} SnBz_2EtI \xrightarrow{MgBuBr} SnBz_2EtBu \xrightarrow{I_2} SnBzEtBuI$$

Here again the salts resisted all attempts at crystallisation.

EXPERIMENTAL.

Phenyltribenzylstannane.—To a solution of phenyl magnesium bromide (2 mols.) in ether was added tribenzylstannic chloride (1 mol.) (J., 1912, **101**, 2556), and the mixture heated on the water bath for ½ hour. The ether was then removed by distillation and the heating continued for a further 1½ hours. The product was treated with water, distilled in steam, and the residual oil extracted with ether, dried, and distilled in a vacuum, b. p. 290°/5 mm.* (Found : C, 69·4; H, 5·5. $C_{27}H_{26}Sn$ requires C, 69·1; H, 5·5 %). *Phenyltribenzylstannane* does not solidify at 0° and is miscible with all the ordinary solvents, with the exception of alcohol; it is converted by boiling concentrated hydrochloric acid into tribenzylstannic chloride and benzene.

Tribenzylstannic iodide was obtained from tribenzylstannic hydroxide (*Z. anorg. Chem.*, 1910, **68**, 102) by warming with dilute hydriodic acid; it crystallises easily from glacial acetic acid in glistening, needle-like prisms, m. p. 102—103° (Found : I,† 24·3; Sn, 22·7. $C_{21}H_{21}ISn$ requires I, 24·5; Sn, 22·9%). The same compound was obtained by treatment of phenyltribenzylstannane (1 mol.) dissolved in carbon tetrachloride with iodine (1 mol.), removal by steam-distillation of the solvent and iodobenzene, and crystallisation from acetic acid.

Dibenzylstannic Chloride.—Attempts to prepare benzylstannic chloride by treatment of tribenzylstannic chloride with 2 mols. of iodine resulted in failure, as only one benzyl group could be removed in this way; the product, isolated in the usual way and converted from iodide into chloride, proved to be dibenzylstannic chloride, m. p. 158°.

Tetraphenylstannane was prepared in quantity by a modification of the method of Pfeiffer and Schnurmann (*Ber.*, 1904, **37**, 319). Stannic chloride (100 g.) was slowly added to absolute ether (440 c.c.) which was cooled in ice and stirred mechanically. Magnesium

* The pressures given in this paper are probably only accurate to 2—3 mm.

† All halogen determinations were carried out by dissolving the material in alcohol, adding excess of *N*/10-silver nitrate and titrating the excess with potassium thiocyanate.

(36·8 g.) was then added and bromobenzene (244 g.) dropped in slowly. After the addition of the first 10 c.c. or so, a crystal of iodine was added to start the reaction, the mixture being warmed if necessary. The bromobenzene was afterwards added at such a rate that the mixture, still cooled in ice and stirred well, boiled gently. Addition occupied about 1 hour, and the product was then heated on the water-bath for 2 hours, the ether distilled away, and heating continued for a further 2 hours. The solid residue was then added to cold water, acidified with hydrochloric acid, and filtered. The solid, after drying in air, was boiled with about 600 c.c. of xylene and the solution filtered hot. Tetraphenylstannane crystallised from the filtrate in slender needles and was recrystallised from the same solvent; yield about 50—55%.

Triphenylstannic Chloride.—Attempts to prepare this substance directly from stannic chloride (1 mol.) and phenyl magnesium bromide (3 mols.) by a method similar to that used for tribenzylstannic chloride (J., 1912, **101**, 2556) yielded tetraphenylstannane as the principal product, with only small amounts of the halogen compound; the method of Chambers and Scherer (*J. Amer. Chem. Soc.*, 1926, **48**, 1055) was finally found to be best for the preparation of both the chloride and iodide: Tetraphenylstannane was boiled with hydrochloric acid for about 10 mins. and the oily product extracted with petroleum; on standing, a solid mass of diphenylstannic chloride, m. p. 42°, was produced from which, by boiling with water, diphenylstannic hydroxychloride, m. p. 187°, could be prepared.

Triphenylbenzylstannane was prepared from triphenylstannic iodide and benzyl magnesium chloride in the usual manner. After removal of impurities by distillation in steam, the product solidified, and then crystallised from alcohol in beautiful colourless plates, m. p. 90°, b. p. 250°/3 mm. (Found: C, 67·9; H, 5·04; Sn, 26·5. $C_{25}H_{22}Sn$ requires C, 68·1; H, 5·0; Sn, 27·0%). The substance is readily soluble in the usual solvents with the exception of alcohol.

Phenylbenzylstannic Chloride.—Triphenylbenzylstannane (1 mol.) in chloroform was treated with iodine (1 mol.), which was added gradually as the colour was discharged. After removal of the solvent and iodobenzene by distillation either in steam or under diminished pressure, an oil remained which could not be obtained crystalline. It was therefore treated with ammonia, and the resultant hydroxide warmed with dilute hydrochloric acid. On cooling, a solid was produced which crystallised from petroleum (b. p. 80—100°) in colourless needles, m. p. 83—84° (Found: C, 43·98; H, 3·4; Cl, 19·6. $C_{13}H_{12}SnCl_2$ requires C, 43·6; H, 3·4; Cl, 19·8%). Here, apparently, the gentle warming with hydro-

chloric acid has been sufficient to remove one of the phenyl groups from the molecule. *Phenylbenzylstannic chloride* was also produced by warming triphenylbenzylstannane with concentrated hydrochloric acid for a few minutes—prolonged boiling results in the complete breakdown of the molecule, stannous chloride being formed.

Tribenzyl-p-*tolylstannane* was prepared from tribenzylstannic chloride and *p*-tolyl magnesium bromide in the usual way. It does not solidify at 0°, and treatment with iodine or hydrochloric acid results in the formation of tribenzylstannic iodide or chloride respectively.

Triphenyl-*p*-tolylstannane (*Ber.*, 1919, **52**, 2150), on treatment with iodine and conversion of the iodide into chloride, yielded triphenylstannic chloride.

Triphenyl-o-*tolylstannane*, from triphenylstannic iodide and *o*-tolyl magnesium bromide, crystallised easily from diacetone-alcohol or petroleum in stout, colourless needles, m. p. 165° (Found: C, 67·6; H, 5·4; Sn, 26·7. $C_{25}H_{22}Sn$ requires C, 68·1; H, 5·0; Sn, 27·0%). Treatment with iodine resulted in the formation of *o*-iodotoluene and triphenylstannic iodide. Boiling with hydrochloric acid for a few seconds similarly gave toluene and triphenylstannic chloride.

Tetra-*p*-tolylstannane (*Z. anorg. Chem.*, 1910, **68**, 122) on treatment with 1 mol. of iodine in choroform yielded tri-*p*-tolylstannic iodide (*Ber.*, 1920, **53**, 183). Boiling hydrochloric acid converted tetra-*p*-tolylstannane into an oil which was extracted with petroleum; after prolonged standing, crystals, m. p. 38—40°, were formed, which were doubtless di-*p*-tolylstannic chloride (J., 1913, **103**, 2049).

Tri-p-*tolyl*-o-*tolylstannane*, prepared as usual from tri-*p*-tolylstannic chloride and *o*-tolyl magnesium bromide, crystallised readily from petroleum in colourless prisms, m. p. 168° (Found: Sn, 24·5, 24·65. $C_{28}H_{28}Sn$ requires Sn, 24·65%). It is readily soluble in benzene and chloroform, fairly so in hot acetone, and not very readily in alcohol. Treatment with iodine results in the formation of *o*-iodotoluene and tri-*p*-tolylstannic iodide.

Tri-m-*tolylstannic Chloride*.—Treatment of tetra-*m*-tolylstannane (*Ber.*, 1920, **53**, 184) with 1 mol. of iodine resulted in the production of an oily iodide which was decomposed with ammonia and then treated with dilute hydrochloric acid; the *chloride* crystallised easily from alcohol or petroleum in small, colourless prisms, m. p. 108—109° (Found: Cl, 8·2. $C_{21}H_{21}SnCl$ requires Cl, 8·3%).

Tri-m-*tolyl*-*p*-*tolylstannane*, from tri-*m*-tolylstannic chloride and *p*-tolyl magnesium bromide, crystallised from alcohol in minute, colourless needles, m. p. 103° (Found: Sn, 24·8. $C_{28}H_{28}Sn$ requires Sn, 24·65%). Treatment with iodine resulted in the formation of an

iodide which could not be obtained pure and was probably a mixture of tri-*m*-tolylstannic and di-*m*-tolyl-*p*-tolylstannic iodides. The iodotoluene evolved would not solidify and was probably a mixture of the *o*- and *p*-isomerides.

Phenyldi-p-*tolylbenzylstannane* was prepared by addition of phenylbenzylstannic chloride to excess of *p*-tolyl magnesium bromide; it has b. p. 265—270°/2—3 mm. and does not solidify (Found: C, 69·2; H, 5·6. $C_{27}H_{26}Sn$ requires C, 69·1; H, 5·55%). It is readily soluble in the usual solvents with the exception of methyl and ethyl alcohols. Treatment with boiling hydrochloric acid resulted in the expulsion of the two tolyl groups and formation of phenylbenzylstannic chloride.

Phenyl-p-*tolylbenzylstannic Hydroxide*.—Attempts to prepare salts of this base by treatment of phenylbenzylstannic chloride with 1 mol. of *p*-tolyl magnesium bromide resulted in failure, phenyldi-*p*-tolylbenzylstannane being formed and some of the halide remaining unattacked; but treatment of phenyldi-*p*-tolylbenzylstannane in chloroform solution with 1 mol. of iodine resulted in elimination of *p*-iodotoluene and formation of an oily *iodide*. This salt was therefore treated with ammonia and a solid *hydroxide* produced, which after three crystallisations from ethyl acetate melted at 136—137° (Found: C, 60·98; H, 5·14; Sn, 30·1. $C_{20}H_{20}OSn$ requires C, 60·8; H, 5·07; Sn, 30·1%). The d-*camphorsulphonate* of this base was obtained by dissolving equimolecular proportions of it and the acid in acetone. Evaporation of the solvent left an oil which resisted all attempts at crystallisation. It was readily soluble in acetone, alcohol, ethyl acetate, and chloroform, but almost insoluble in water and petroleum. Solution in acetone followed by precipitation by water was carried out six times, but the product was still oily, and the base recovered from the salt optically inactive. The d-*α-bromo-π-camphorsulphonate*, prepared by dissolving the base in an equivalent quantity of the acid in alcoholic solution, was also oily; it is readily soluble in ether, sparingly so in alcohol, and almost insoluble in water. After fractional precipitation of an acetone solution by addition of water, the salt still resisted crystallisation, and the base recovered from it was optically inactive. The d-*tartrate* was an amorphous solid almost insoluble in the usual solvents, with the exception of alcohol; fractional precipitation of an alcoholic solution by addition of petroleum produced no change in the properties of the salt and the recovered base was optically inactive.

Triphenyl-n-*butylstannane*, prepared in the usual manner from triphenylstannic iodide and *n*-butyl magnesium bromide, crystallises readily from hot alcohol in colourless needles, m. p. 61—62°, b. p.

222°/3 mm. (Found: Sn, 28·9; 29·7. $C_{22}H_{24}Sn$ requires Sn, 29·3%), and is readily soluble in petroleum, ethyl acetate, and benzene. Boiling with hydrochloric acid for a few seconds converts this compound into *phenyl*-n-*butylstannic chloride*, crystallising from light petroleum (b. p. 40—60°) in colourless prisms, m. p. 50° (Found: C, 37·12; H, 4·39; Cl, 21·4. $C_{10}H_{14}SnCl_2$ requires C, 37·0; H, 4·32; Cl, 21·9%).

Diphenylbenzyl-n-*butylstannane*.—Triphenylbenzylstannane (1 mol.) in chloroform was treated with iodine (1 mol.), and after completion of the reaction, the solvent and iodobenzene were removed by distillation under reduced pressure. To the oily *iodide* produced in this manner was added an ethereal solution of *n*-butyl magnesium bromide (1½ mols.); the product was worked up as usual and a colourless oil isolated, b. p. 215°/2—3 mm. (Found: Sn, 28·5, 28·3. $C_{23}H_{26}Sn$ requires Sn, 28·3%). This compound was also prepared by treatment of triphenylbutylstannane successively with iodine and benzyl magnesium chloride.

Phenylbenzyl-n-*butylstannic Hydroxide*.—Diphenylbenzylbutylstannane was treated with 1 mol. of iodine in chloroform solution, and the solvent evaporated. Distillation of the residue under reduced pressure yielded an iodide, b. p. 185—189°, which was clearly iodobenzene, and left an oil which was converted into a solid *hydroxide* by treatment with ammonia; crystallisation twice from benzene and then twice from alcohol gave a product, m. p. 135—137° (not sharp) (Found: Sn, 33·0. $C_{17}H_{22}OSn$ requires Sn, 33·0%). Although the chloride, bromide, and iodide of this base were oils, a crystalline *fluoride* was precipitated by addition of an aqueous solution of neutral potassium fluoride to the base dissolved in alcohol and acetic acid; the product crystallised from alcohol in colourless needles, m. p. 218° (Found: C, 56·3; H, 5·9. $C_{17}H_{21}SnF$ requires C, 56·3; H, 5·8%).

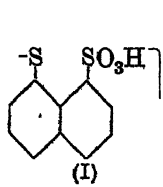
The d-*camphorsulphonate* of phenylbenzyl-*n*-butylstannic hydroxide was formed both by dissolution of the base in an acetone solution of the acid and by double decomposition of the iodide with silver *d*-camphorsulphonate. The salt could not, however, be obtained solid even after fractional precipitation of an acetone solution with water; the d-*α-bromo-π-camphorsulphonate* and the d-*camphorate* were also persistently oily. The d-*tartrate* was an amorphous solid which did not melt at 250°, but melted under hot alcohol; it was dissolved in this solvent and allowed to separate again several times, and the alcoholic solution was then precipitated with aqueous potassium fluoride, but the fluoride so formed was optically inactive in alcoholic solution.

Tribenzylethylstannane is decomposed by iodine with the elimin-

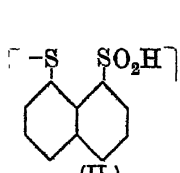
ation of one of the benzyl groups (J., 1912, **101**, 2553). On the other hand, it was found that hydrochloric acid acts on this substance only with extreme slowness, and after an hour's heating under reflux a solid product was obtained which proved to be tribenzylstannic chloride.

Dibenzylethyl-n-*butylstannane*, prepared from tribenzylethylstannane in an exactly similar manner to the preparation of diphenylbenzyl-*n*-butyl- from triphenylbenzyl-stannane, is a colourless oil, b. p. 195—200°/3—5 mm. (Found: C, 61·6; H, 7·5. $C_{20}H_{28}Sn$ requires C, 62·0; H, 7·3%).

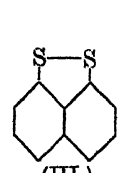
Salts of Benzylethyl-n-*butylstannic Hydroxide*.—Treatment of dibenzylethyl-*n*-butylstannane with 1 mol. of iodine gave an oily *iodide* which was dissolved in alcohol and treated with one equivalent of silver *d*-camphorsulphonate in water; the silver iodide was removed by filtration and the filtrate evaporated, but the resulting oil could not be crystallised. Similar results were obtained by using silver *d*-α-bromo-π-camphorsulphonate.



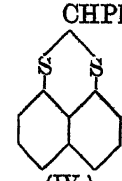
UNIVERSITY CHEMICAL LABORATORY,
CAMBRIDGE. [*Received, July 4th*, 1928.]



CCCXIII.—*Naphthylene* 1 : 8-*Disulphide*.



By WILLIAM BENNETT PRICE and SAMUEL SMILES.



THE experiments which have been made on the formation of sulphur ring systems (J., 1922, **121**, 87; 1926, 1821, 2265; 1927, 534; this vol., pp. 697, 1142) have now been extended to the inclusion of the *peri*-system of naphthalene in five- and six-membered dithio-ring systems.

1-Naphthylamine-8-sulphonic acid was found to be the most convenient source of the required 1 : 8-dithiolnaphthalene. When naphthalene-1 : 8-diazosulphonate was treated with sulphurous acid in presence of copper the 1 : 8-*sulphino-sulphonic acid* was obtained, and reduction of this acid in aqueous solution with sulphurous acid and dilute hydriodic acid gave a good yield of the corresponding *disulphide-disulphonic acid* (I).

(I)

(II.)

(III.)

(IV.)

Treatment of the chloride of this acid in the usual way gave 1 : 1′-*dithiodinaphthalene*-8 : 8′-*disulphinic acid* (II), which finally was

reduced to the required 1 : 8-*dithiolnaphthalene*. This unstable mercaptan on exposure to air or in solution with mild oxidising agents yielded the orange *disulphide* (III), whilst the simultaneous formation of complex polysulphides was not observed. The ease with which this cyclic system is formed at the *peri*-position of naphthalene accords with the existence of the corresponding sultone and sultan, and also with the stability of *o*-dithiobenzoyl and of diphenyl 2 : 2′-disulphide and -disulphoxide. A further resemblance between the behaviour of 2 : 2′-dithioldiphenyl and that of 1 : 8-dithiolnaphthalene is found in the action of the latter with aldehydes, which furnish the six-membered system in the mercaptals (IV). The results of these experiments amplify the evidence now available from numerous sources of the stability of five- and six-membered dithio-ring systems.

EXPERIMENTAL.

1-*Sulphinonaphthalene*-8-*sulphonic Acid*.—A mixture of water (250 c.c.) and the diazosulphonate prepared from 50 g. of 1-naphthylamine-8-sulphonic acid was saturated with sulphur dioxide. After treatment with copper powder in the usual manner, the liquid was warmed and passed through a filter (2 g. of charcoal). When the clear liquid was saturated with salt, the *sodium* salt of the required sulphonic acid separated. A sample was purified from hot water (Found: S, 22·3. $C_{10}H_7O_5S_2Na$ requires S, 21·77%).

1 : 1′-*Dithiodinaphthalene*-8 : 8′-*disulphonic Acid* (I).—An aqueous solution (400 c.c.) of the mono-sodium salt obtained from the foregoing process, containing hydrogen iodide (3 or 4 drops, *d* 1·7), was kept at 95—100° for 3 hours and treated with a slow current of sulphur dioxide. After the clear liquid had been concentrated and cooled, the *sodium* salt of the required acid separated in flocculent aggregates, and was purified from hot water (Found: Na, 9·0. $C_{20}H_{12}O_6S_4Na_2$ requires Na, 8·8%).

1 : 1′-*Dithiodinaphthalene*-8 : 8′-*disulphinic Acid* (II).—The dried sodium sulphonate thus obtained was triturated (10 g.) with phosphorus pentachloride (20 g.). The mixture was kept for 6 hours, the crude sulphonic chloride being then isolated in the usual manner. The use of larger quantities of material and higher temperatures gave less favourable results. The crude acid chloride was treated for 10 minutes with a boiling aqueous solution of an equal weight of sodium sulphite. When the cooled and clear solution (charcoal) was mixed with sulphuric acid, the required *sulphinic acid* separated in needles, which when purified from alcohol had m. p. 144° (Found: C, 53·7; H, 3·0. $C_{20}H_{14}O_4S_4$ requires C, 53·8; H, 3·1%).

1 : 8-*Dithiolnaphthalene*.—Zinc dust (4·5 g.) was gradually added

to the warm mixture of the sulphinic acid (1 g.) with alcohol (15 c.c.) and concentrated hydrochloric acid (15 c.c.). After the reaction had been maintained for 2 hours, the required mercaptan separated from the cooled liquid in colourless plates; these had m. p. 113—114° and were readily soluble in common organic solvents, but attempts further to purify the substance were abandoned owing to the ease with which it is converted into the disulphide. The substance was characterised as the dimethylthiol which was obtained by treatment with methyl sulphate in presence of aqueous alkali. 1 : 8-*Dimethyldithiolnaphthalene* formed colourless plates, m. p. 84°, from acetic acid (Found: C, 65·3; H, 5·5. $C_{12}H_{12}S_2$ requires C, 65·4; H, 5·4%).

When alcoholic solutions of the dithiol and nickel acetate are mixed, a characteristic *nickel* derivative is precipitated in the crystalline state. This brownish-purple substance (Found: Ni, 23·5. $C_{10}H_6S_2Ni$ requires Ni, 23·7%) is slightly soluble in chloroform; it appears to contain the co-ordinated metal but its constitution has not been examined.

2-*Phenyl*-peri-*naphtha*-1 : 3-*dithiane* (IV).—1 : 1′-Dithiodinaphthalene-8 : 8′-disulphinic acid was reduced with zinc dust and alcohol into which dry hydrogen chloride was passed. When reduction was complete, the requisite amount of benzaldehyde was added to the solution, which was then saturated with hydrogen chloride. After being kept for 12 hours, the solution was mixed with water and the required material then separated in the crystalline state. It was purified from aqueous alcohol and formed needles, m. p. 116° (Found: C, 73·1; H, 4·7. $C_{17}H_{12}S_2$ requires C, 72·85; H, 4·3%).

Naphthylene 1 : 8-*Disulphide* (III).—This is readily obtained by spontaneous oxidation of the dithiol in presence of atmospheric oxygen. It was prepared by passing air through a solution of the dithiol in ammonia. The precipitated material was purified from alcohol and formed orange plates, m. p. 116° (Found: C, 62·8; H, 4·3; *M*, 191. $C_{10}H_6S_2$ requires C, 63·1; H, 3·1%; *M*, 190). In the preparation of this disulphide, the use of ferric chloride should be avoided owing to the formation of complex iron derivatives of the mercaptan which contaminate the product. Oxidation of the disulphide readily ensues in presence of hydrogen peroxide in acetic acid; a study of the process has shown that it proceeds beyond the thiolsulphonate and that successive oxidation products are generally formed simultaneously. The separation of these was not satisfactorily accomplished with the amount of material available.

KING'S COLLEGE, LONDON. [*Received, July 11th*, 1928.]

CCCXIV.—*Certain Aryl Arsenoxides and the Corresponding Dichloro- and Di-iodo-arsines.*

By GEORGE NEWBERY and MONTAGUE ALEXANDRA PHILLIPS.

IN the course of chemo-therapeutic studies proceeding in these laboratories, a number of dichloro- and di-iodo-arsines and the corresponding arsenoxides were prepared, and some of their chemical properties are now recorded. Some phenyl-arsine derivatives, prepared for comparison, are also described.

In general, the dihalogeno-arsines are hydrolysed by water to give the corresponding arsenoxides, and can be regenerated by the action of the halogen acid. The hydrolysis is obvious in cases such as those of 3 : 5-*diacetamido*-2- and -4-*hydroxyphenyldichloroarsines*, where the product of hydrolysis is insoluble in the concentration of mineral acid simultaneously formed (compare the dicyano-arsines, Grischkievitsch-Trochimovski, Mateyak, and Zablotski, *Bull. Soc. chim.*, 1927, **41**, 1323). The amino-di-iodoarsine hydriodides are much less soluble in water than the corresponding chloro-derivatives, from which they can readily be made by addition of hydriodic acid or potassium iodide in aqueous solution. In general, the attachment of the iodine atom to the arsenic atom appears to be firmer than that of the chlorine atom in the corresponding chloro-compound; this stability extends to concentrated nitric acid, and in one case, *viz.*, 3 : 5-*diamino*-4-*hydroxyphenyldi-iodoarsine dihydriodide*, even to 5*N*-sodium hydroxide solution. The di-iodo-arsines are deep yellow, crystalline compounds, whereas the pure chloro-compounds are white.

It is noteworthy that 3 : 5-*diacetamido*-4-*hydroxyphenylarsenoxide*, made either by hydrolysis of the dichloro-arsine or by acetylation of 3-*amino*-5-*acetamido*-4-*hydroxyphenylarsenoxide*, appears to exist only as the arsinous acid, which does not lose water at 100°. In this way it differs from the " arsenoxide hydrates " of Lewis and Cheetham (*J. Amer. Chem. Soc.*, 1921, **43**, 2119) and from 3 : 5-*diacetamido*-2-*hydroxyphenylarsenoxide*, although it resembles the latter in its ready solubility in ammonium hydroxide and sodium carbonate solutions (compare also benzarsenious acid, La Coste, *Annalen*, 1881, **208**, 14).

Attention must also be directed to a curious property of 3-*amino*-5-*acetamido*-2- and -4-*hydroxyphenylarsenoxide hydrochlorides* and *hydriodides*. These four compounds will only dissolve in water after standing for a few seconds, and it is possible that they may actually be the free bases corresponding to chloro-hydroxy-arsines of the type $C_6H_2(NH_2)(OH)(NHAc)\cdot As(OH)Cl$, hydrolysed by water

to give $C_6H_2(NH_2,HCl)(OH)(NHAc)\cdot AsO$. Addition of hydrochloric acid to the alkaline solutions until they are acid to Congo-red precipitates the original compounds with their characteristic delayed solubility in water.

In attempts to prepare compounds of the type As(OH)ClR by the action of methyl-alcoholic hydrogen chloride on the corresponding arsenoxide, *methoxy*-3-*acetamido*-4-*hydroxy*- and -5-*acetamido*-2-*hydroxy*-*phenylchloroarsines* were obtained. These compounds gave the corresponding *arsenoxides* on treatment with water.

EXPERIMENTAL.

3-*Nitro*-5-*acetamido*-2-*hydroxyphenylarsinic Acid*.—This compound was obtained by dissolving 100 g. of 5-acetamido-2-hydroxyphenylarsinic acid (Newbery and Phillips, this vol., p. 116) in sulphuric acid (300 c.c.) at 20°, nitrating it at 10—20° with a mixture of nitric acid (*d* 1·420; 35 c.c.) and sulphuric acid (35 c.c.), and pouring into ice water; the pure nitro-compound separated in 80% yield as yellow prisms, giving red solutions in caustic alkalis and alkali carbonates (Found: As, 23·5. $C_8H_9O_7N_2As$ requires As, 23·4%).

3-*Amino*-5-*acetamido*-4- and -2-*hydroxyphenylarsinic acids* were obtained by reduction of the corresponding nitro-acids (compare Jacobs, Heidelberger, and Rolf, *J. Amer. Chem. Soc.*, 1918, **40**, 1580; 60% yield in each case), and purified by the method described by Christiansen (*ibid.*, 1920, **42**, 2403) for 3-amino-4-hydroxyphenylarsinic acid. The former consists of stout white prisms, readily soluble in dilute mineral acids, and in alkali hydroxides and carbonates (Found: As, 25·6; N, 9·3. $C_8H_{11}O_5N_2As$ requires As, 25·8; N, 9·7%), whilst the isomeric acid (Found: As, 25·8; N, 9·6%) is only soluble in excess of dilute mineral acids.

3 : 5-*Diacetamido*-2-*hydroxyphenylarsinic acid* and 3 : 5-diacetamido-4-hydroxyphenylarsinic acid, the latter of which has been described by Raiziss and Gavron (*ibid.*, 1921, **43**, 584), were best made by the following method: 3-Nitro-5-acetamido-2- or -4-hydroxyphenylarsinic acid (30 g.) was dissolved in 2*N*-sodium hydroxide, and sodium hyposulphite (54 g.) was slowly added at 10° with stirring. After 30 minutes, 10*N*-sodium hydroxide was added, the solution filtered, and acetic anhydride (30 c.c.) run in. After 1 hour the reaction mixture was acidified (Congo-red), and the precipitated arsinic acid purified through its alkaline solution. The yield varied from 10 to 15 g. in each case. The 2-hydroxy-acid forms white needles, readily soluble in alkalis (Found: As, 22·6; N, 8·3. $C_{10}H_{13}O_6N_2As$ requires As, 22·6; N, 8·4%), and its orientation is shown by its conversion into 2 : 4-diaminophenol (isolated as diacetyl derivative) by boiling with 5 parts of 15% hydrochloric acid.

The aminophenyldichloroarsines were prepared by sulphurous acid reduction of the arsinic acid in hydrochloric acid at room temperature, a trace of potassium iodide being present; some acetamido-derivatives were made by addition of a warm solution of the corresponding arsinic acid in hydrochloric acid to a solution of sulphurous acid containing potassium iodide, and passage of sulphur dioxide at 10° until reduction was complete. The dichloro-arsine was precipitated where necessary by addition of a sufficient amount of concentrated hydrochloric acid. The aminodi-iodoarsine hydriodides were similarly prepared by use of either an acidified solution of potassium iodide or hydriodic acid.

3-*Amino*-5-*acetamido*-4-*hydroxyphenylarsine Derivatives*.—The *dichloro-arsine hydrochloride*, obtained in 60% yield by the general method, formed white prisms, soluble in dilute alkali hydroxide (Found: As, 21·5; N, 8·0; Cl, 30·5. $C_8H_9O_2N_2Cl_2As,HCl$ requires As, 21·6; N, 8·05; Cl, 30·6%). This hydrochloride (5 g.) was suspended in water (30 c.c.) and stirred for 30 minutes; the resulting amorphous solid was collected, washed with water, and crystallised by addition of concentrated hydrochloric acid to the solution in sodium hydroxide until faintly acid to Congo-red (yield, 2·3 g.). 3-*Amino*-5-*acetamido*-4-*hydroxyphenylarsenoxide hydrochloride* thus obtained formed white prisms, soluble in water after a few seconds' shaking, and readily soluble in dilute caustic alkalis (Found: As, 25·6; N, 9·7; Cl, 12·2. $C_8H_9O_3N_2As,HCl$ requires As, 25·6; N, 9·6; Cl, 12·1%).

The amorphous arsenoxide, obtained as described above from 2 g. of dichloro-arsine hydrochloride, was collected, washed with water, and stirred into a mixture of hydriodic acid (*d* 1·7; 40 c.c.) and water (20 c.c.); the gum formed soon crystallised as prisms and was found to be pure 3-*amino*-5-*acetamido*-4-*hydroxyphenyldi-iodoarsine hydriodide* (Found: As, 11·9; N, 4·4; I, 61·9. $C_8H_9O_2N_2I_2As,HI$ requires As, 12·0; N, 4·5; I, 61·2%). This compound was also obtained by the general method; its acetyl group is remarkably stable to hot mineral acids, and it readily dissolves in water to give a yellow solution which deposits crystals of the arsenoxide. 3-*Amino*-5-*acetamido*-4-*hydroxyphenylarsenoxide hydriodide* forms white prisms, soluble in water only after a few seconds' shaking (Found: As, 19·7; I, 32·6. $C_8H_9O_3N_2As,HI$ requires As, 19·5; I, 33·0%).

3 : 5-*Diamino*-4-*hydroxyphenyldichloroarsine dihydrochloride*. The above dichloro-arsine hydrochloride (30 g.) was boiled for 15 minutes with 120 c.c. of 5*N*-hydrochloric acid, and sufficient hot water to dissolve the solid was then added. Addition of an equal volume of concentrated hydrochloric acid to the hot filtered solution gave, on

cooling, a 50% yield of the required *dihydrochloride* as white plates, readily soluble in water (Found: As, 21·7; N, 8·1; Cl, 41·0. $C_6H_7ON_2Cl_2As,2HCl$ requires As, 21·9; N, 8·1; Cl, 41·5%).

To this chloro-compound (5 g.) in water (50 c.c.), hydriodic acid (*d* 1·7; 30 c.c.) was added; the solid was collected, washed with alcohol and ether, and dried in a vacuum over caustic soda and calcium chloride, 3 : 5-*diamino*-4-*hydroxyphenyldi-iodoarsine dihydriodide* being thus obtained as yellow prisms, readily soluble in water (yield, 7 g.) (Found: As, 10·7; I, 72·0. $C_6H_7O_2N_2I_2As,2HI$ requires As, 10·1; I, 72·0%).

3-*Amino*-5-*acetamido*-2-*hydroxyphenylarsine Derivatives*.—The *di-iodoarsine hydriodide* was obtained by the general method as yellow, boat-shaped crystals (Found: As, 11·9; N, 4·6; I, 62·1%), soluble in water to give a yellow solution, which slowly deposits crystals of the oxide hydriodide.

The *arsenoxide hydriodide* forms white prisms, soluble in water only after shaking for a few seconds (Found: As, 19·6; I, 33·0%).

3 : 5-*Diacetamido*-2- *and* -4-*hydroxyphenyldichloroarsines*.—These were obtained by the general method, or by the action of alcoholic hydrogen chloride on the corresponding arsenoxide, as clusters of needles readily soluble in water, by which they were slowly hydrolysed. They could not be obtained sufficiently pure for analysis.

3 : 5-*Diacetamido*-4-*hydroxyphenylarsinous acid* was obtained (1) by hydrolysis of the dichloro-arsine; (2) by acetylation of 3-amino-5-acetamido-4-hydroxyphenyldichloroarsine hydrochloride as described under 5-acetamido-2-hydroxyphenylarsenoxide (see below); or (3) by acetylation of 3 : 5-diamino-4-hydroxyphenyldichloroarsine dihydrochloride. It was purified by solution in caustic alkali and acidification by hydrochloric acid (Congo-red), and consisted of white plates or needles, insoluble in water, dilute mineral acids, or sodium bicarbonate solution, but soluble in aqueous solutions of sodium hydroxide, sodium carbonate, or dilute ammonia (Found: As, 23·8; N, 8·9. $C_{10}H_{13}O_5N_2As$ requires As, 23·7; N, 8·9%).

3 : 5-*Diacetamido*-2-*hydroxyphenylarsenoxide*, obtained by aqueous hydrolysis of the corresponding dichloro-arsine, is an amorphous, white solid with solubilities identical with the above arsenious acid. It was purified similarly, and dried at 100° (Found: As, 24·8; N, 9·4. $C_{10}H_{11}O_4N_2As$ requires As, 25·1; N, 9·4%).

Derivatives of 3-*Amino*-4-*hydroxyphenylarsine*.—The dichloroarsine was obtained by the general method as a monohydrate. On treatment of its aqueous solution with excess of hydriodic acid, it gave the corresponding *di-iodoarsine hydriodide*, which was also obtained by the general method; this formed yellow prisms, giving a yellow solution in water. The iodine attached to the arsenic atom

showed some resistance to the action of hot 8*N*-nitric acid, only one-third of the total iodine being removed (Found: As, 13·5; I, removed by concentrated nitric acid, 68·0. $C_6H_6ONI_2As,HI$ requires As, 13·3; I, 67·5%).

The hydrolysis of the dichloro-arsine hydrochloride was accomplished by dissolution in water (3 g. in 10 c.c.); the solution deposited the crude oxide hydrochloride, whilst the filtrate contained approximately two-thirds of the total chlorine introduced.

3-*Acetamido*-4-*hydroxyphenylarsenoxide*. This compound was obtained by the methods since given in E.P. 254,186 and F.P. 606,238, but is best obtained as follows: To 3-amino-4-hydroxyphenyldichloroarsine (25 g.), dissolved in water (80 c.c.), acetic anhydride (37·5 c.c.) is added, followed at once by sodium acetate until the mixture no longer reacts acid to Congo-red. After acidification (Congo-red) by 25% sulphuric acid, the crude acetyl derivative is collected and washed. The *oxide*, purified by acidification of its solution in sodium hydroxide by 25% sulphuric acid, forms a tetrahydrate consisting of white prisms, which lose water at 100°. It is insoluble in water, sodium bicarbonate, or sodium carbonate solution, but soluble in excess of caustic alkalis and in large excess of ammonia (Found: H_2O lost at 100°, 23·1. Calc.: H_2O, 23·0. Found, in dried material: As, 30·9; N, 5·7. Calc.: As, 31·1; N, 5·8%).

Derivatives of 5-*Amino*-2-*hydroxyphenylarsine*.—Sulphur dioxide was passed for 90 minutes through a solution of 20 g. of 5-amino-2-hydroxyphenylarsinic acid in water (60 c.c.) and hydrochloric acid (200 c.c.). The precipitated 5-*amino*-2-*hydroxyphenyldichloroarsine hydrochloride*, purified by solution in water (80 c.c.) and reprecipitation by 160 c.c. of hydrochloric acid (yield, 15·5 g.), consisted of anhydrous, white prisms, soluble in four parts of water (Found: As, 25·5; N, 4·8; Cl, 37·0. $C_6H_6ONCl_2As,HCl$ requires As, 25·7; N, 4·8; Cl, 36·8%); the basified solution is much more stable to aerial oxidation than that of its isomeride.

5-*Amino*-2-*hydroxyphenylarsenoxide hydrochloride*, white prisms soluble in water, was obtained by dissolving the above dichloroarsine hydrochloride (2 g.) in water (8 c.c.) and collecting the crystals which separated after some hours (Found: As, 31·5; Cl, 15·1. $C_6H_6O_2NAs,HCl$ requires As, 31·9; Cl, 15·1%).

5-*Amino*-2-*hydroxyphenyldi-iodoarsine hydriodide*, made by the general methods, consisted of yellow prisms, soluble in water to give a yellow solution (Found: As, 13·5; N, 2·7. I, removed by hot 8*N*-nitric acid, 22·8; I, removed by concentrated nitric acid, 67·7. $C_6H_6ONI_2As,HI$ requires As, 13·3; N, 2·5; I, 67·5%).

5-*Amino*-2-*hydroxyphenylarsenoxide hydriodide* was obtained as

stout, white prisms, by shaking the above di-iodoarsine hydriodide (1 g.) with water (10 c.c.); it resembles its isomeride in properties and solubilities (Found: As, 22·7; I, 40·0. $C_6H_6O_2NAs,HI$ requires As, 22·9; I, 38·9%).

5-*Acetamido*-2-*hydroxyphenylarsenoxide* was best prepared by dissolving the corresponding aminodichloroarsine hydrochloride (15 g.) in water (50 c.c.), cooling during addition of acetic anhydride (25 c.c.), and adding sodium acetate. The acetyl compound which separated was purified as in the case of its isomeride, and formed white anhydrous prisms having similar solubilities (Found: As, 31·3; N, 5·7. $C_8H_8O_3NAs$ requires As, 31·1; N, 5·8%).

3-*Acetamido*-4-*hydroxy- and* 5-*Acetamido*-2-*hydroxy-phenyldichloroarsines*.—These derivatives were obtained by trituration of the corresponding arsenoxide with excess of alcoholic hydrogen chloride. On spontaneous evaporation, crystals of the dichloro-arsine were obtained, which were purified by solution in alcohol and precipitation by ether. They formed white or pale yellow needles, soluble in cold alcohol and in cold water; the latter hydrolysed them slowly to give the corresponding arsenoxide (Found, for 3-*acetamido*-4-*hydroxyphenyldichloroarsine*: As, 25·1; N, 4·7; Cl, 24·1; for 5-*acetamido*-2-*hydroxyphenyldichloroarsine*: As, 25·1; N, 4·8; Cl, 24·0. $C_8H_8O_2NCl_2As$ requires As, 25·1; N, 4·75; Cl, 24·0%).

3-*Nitro*-4-*hydroxy*-5-*aminophenyldi-iodoarsine hydriodide*, made from the corresponding arsinic acid (compare Fourneau, *loc. cit.*) by the general method, consisted of yellow prisms, dissolving in water to give a yellow and in alkali carbonate or hydroxide to give red solutions (Found: As, 12·1; N, 5·0; I, 58·5. $C_6H_5O_3N_2I_2As$ requires As, 12·3; N, 4·6; I, 62·4%). On acetylation in alkaline solution, it gave 3-*nitro*-4-*hydroxy*-5-*acetamidophenylarsenoxide*, an amorphous, white solid, insoluble in water and giving deep red solutions with caustic alkalis (Found: As, 25·8. $C_8H_7O_5N_2As$ requires As, 26·2%).

3-*Acetamido*-4-*hydroxy- and* 5-*Acetamido*-2-*hydroxy-phenylmethoxychloroarsines*.—To the corresponding arsenoxide (4·8 g.), dissolved at room temperature in methyl alcohol (90 c.c.), 15% methyl-alcoholic hydrogen chloride (2·4 c.c.) was added, the solution kept for 30 mins., and concentrated under reduced pressure to 10 c.c.; the methoxychloro-compound then crystallised out (yield, 70% in each case). 3-*Acetamido*-4-*hydroxyphenylmethoxychloroarsine* (Found: As, 25·8; N, 4·8; Cl, 12·2%) and 5-*acetamido*-2-*hydroxyphenylmethoxychloroarsine* (Found: As, 25·7; N, 5·0; Cl, 12·2; MeO, 10·3. $C_9H_{11}O_3NClAs$ requires As, 25·7; N, 4·8; Cl, 12·2; MeO, 10·6%) each consisted of white prisms, readily converted by warm water into the corresponding arsenoxide.

3-*Acetamido*-4-*hydroxyphenylarsine*.—A mixture of 3 : 3′-diamino-4 : 4′-dihydroxyarsenobenzene (5 g.) and zinc dust (16 g.) was added to concentrated hydrochloric acid (70 c.c.) and water (50 c.c.) at 90—100°; after cooling, the clear supernatant liquid was filtered into a solution of sodium acetate (20 g.) in water (20 c.c.) containing acetic anhydride (15 c.c.) in suspension. On shaking, 3-*acetamido*-4-*hydroxyphenylarsine* separated in 90% yield (Found: As, 33·0; N, 6·3. $C_8H_{10}O_2NAs$ requires As, 33·0; N, 6·2%); it formed white plates, insoluble in water but soluble in excess of caustic alkalis.

5-*Acetamido*-2-*hydroxyphenylarsine*, similarly prepared from the corresponding arsenobenzene, also forms white plates (Found: As, 32·8; N, 6·3%). Both arsines are readily oxidised by air to the corresponding arseno-compound.

CCCXV.—*The Apparent Hydration of Ions. Part II. The Densities and Viscosities of some Mixed Aqueous Solutions of Lithium Chloride and Hydrochloric Acid.*

By JOHN WILLIAM INGHAM.

THE methods described in Part I (this vol., p. 1917) for the investigation of the hydration of potassium and sodium chlorides in concentrated aqueous solutions containing hydrochloric acid have now been applied to certain mixed solutions of lithium chloride and hydrochloric acid. The densities and viscosities at 25° have been determined for a series of solutions containing different proportions of the acid and the salt with approximately the same total solute concentration as a saturated solution of sodium chloride, such a concentration being chosen so that a direct comparison might be made of the behaviour of the two salts under similar conditions.

The experimental work was carried out in the same way as for Part I, but, since the solutions were not saturated, they were made by mixing stock solutions of known concentration. The opportunity was taken of further testing the Scarpa method for measuring the viscosities by carrying out determinations in an Ostwald tube upon the same solutions. The same viscometers were used as for Part I. The results confirmed the previous conclusions as to the accuracy of the Scarpa method. In Table I, col. 1 shows the densities calculated from the formula

$$d_4^{25°} = 0{\cdot}99707W'/W - 0{\cdot}0012(W' - W)/W;$$

cols. 2 and 3 the coefficients of viscosity in c.g.s. units; cols. 4, 5, and 6 the concentrations (mols./litre) of acid, salt, and water, respectively; and col. 7 the hydration numbers, x. The total solute concentrations varied between 5·459 and 5·402, that previously found for saturated sodium chloride solution at 25° being 5·4325.

TABLE I.

$d_{4^\circ}^{25^\circ}$.	η (Scarpa).	η (Ostwald).	HCl.	LiCl.	H_2O.	x.
1·1176	0·01951	0·01944	0	5·407	49·20	2·49
1·1147	0·01849	0·01839	0·546	4·913	49·20	2·36
1·1116	0·01748	0·01746	1·091	4·364	49·20	1·81
1·1087	0·01667	0·01664	1·635	3·799	49·29	2·12
1·1050	0·01581	0·01579	2·176	3·248	49·29	1·91
1·1019	0·01509	0·01508	2·702	2·708	49·34	1·89
1·0985	0·01440	0·01435	3·246	2·160	49·32	1·72
1·0957	0·01384	0·01384	3·789	1·635	49·30	1·82
1·0920	0·01320	0·01318	4·330	1·072	49·34	1·80
1·0893	0·01267	0·01263	4·890	0·540	49·29	

Except in the case of the first two solutions, the agreement between the viscosities obtained by the different methods was good. The viscosity of the stock lithium chloride solution (5·407M) as found by the Scarpa method was in better agreement with Green's data for that salt (J., 1908, **93**, 2023) than was the value given by the Ostwald method. Any errors in density determinations are reflected in the latter method and do not affect the Scarpa values.

Discussion of Results.

Densities and Solution Volumes.—It is found that, although the densities can be calculated by means of the formula $d_{4^\circ}^{25^\circ} = K + k_1a + k_2b$ previously applied to the potassium chloride (or sodium chloride)–hydrochloric acid solutions, yet some adjustment of the constants is required. The solution volume of either the acid or the water is different, and if the value of K is retained at 1·01275, the expression

$$d_{4^\circ}^{25^\circ} = 1{\cdot}01275 + 0{\cdot}01355a + 0{\cdot}0193b \quad . \quad . \quad . \quad \text{(i)}$$

gives fair agreement for the calculated densities (see below). The corresponding solution volumes of the acid and the salt are 22·62 and 22·80, and the lithium ions show only a small apparent volume in solution. The apparent density of the water in the solutions is then the same as in those containing sodium chloride or potassiun chloride. This result, in the light of Masson's work (J., 1911, **99**, 1132), can only be regarded as conclusive if no other constants satisfy the expression. Examination of the data shows that the solution volumes of the lithium chloride and the acid are nearly equal. Assuming equality, and taking the value HCl = 22·43 as found in Part I, the values of the constants for the density expression may be deduced from this value together with that obtained for the water

from the equation $w\gamma + a\alpha + b\beta = 1000$, where α, β, and γ are the molar solution volumes of acid, salt, and water, and a, b, and w the molar concentrations per 1000 c.c. (Masson, *loc. cit.*). The mean value of γ is 17·82 ($\alpha = \beta = 22{\cdot}43$), and hence $K = d_w = 1{\cdot}0110$; k_1 and k_2 are then calculated from $k_1 = (M_a - \alpha d_w)/1000$ and $k_2 = (M_b - \beta d_w)/1000$, M_a being the molecular weight of the acid, and M_b that of the salt, and it is found that $k_1 = 0{\cdot}0138$ and $k_2 = 0{\cdot}0197$. The equation

$$d_4^{25^\circ} = 1{\cdot}0110 + 0{\cdot}0138a + 0{\cdot}0197b \quad . \quad . \quad . \quad \text{(ii)}$$

gives at least as good agreement as is obtained with the other values for the constants, as is shown by the following comparison.

$d_4^{25^\circ}$ (obs.)	1·1176	1·1147	1·1116	1·1087	1·1050
(calc., i)	1·1171	1·1150	1·1116	1·1082	1·1049
(calc., ii)	1·1175	1·1153	1·1118	1·1084	1·1050
$d_4^{25^\circ}$ (obs.)	1·1019	1·0985	1·0957	1·0920	1·0893
(calc., i)	1·1016	1·0984	1·0957	1·0921	1·0894
(calc., ii)	1·1016	1·0984	1·0955	1·0919	1·0891

It seems that this type of calculation is in the nature of a compromise, involving an assumption of constant solution volumes for the series of solutions, which is probably not strictly justifiable. The variations in the solution volumes, as calculated from the different constants, are, however, not very great, and are unimportant for the subsequent discussion of viscosities. The solution volumes may now conveniently be reviewed in tabular form and compared with values calculated from ionic radii. Calculations have been made in two ways: (1) The expression $\frac{4}{3}\pi r^3 N$ is used to obtain the ionic volume for the g.-ion, r being the radius as given by Wasastjerna (*Soc. Sci. Fenn. Comm. Phys. Math.*, 1923, **38**, 1) and N the Avogadro number. (2) It is assumed that the ionic volumes bear the same relationship to the solution volumes as does the bivalent oxygen atom (or ion) O″ to the water molecule, taken as 18; the molar volumes are then obtained by summing the ionic volumes. Conversely, the experimental solution volumes of the salts and the acid may be divided into the respective ionic solution volumes, the hydrogen ion in the case of the acid having no appreciable volume.

Ionic volumes.

	Li·.	Na·.	K·.	Cl′.	O″ (H_2O).
r, in Å.U.	0·72	1·01	1·30	1·72	1·32
r^3, ,, ...	0·373	1·030	2·197	5·088	2·300
$\frac{4}{3}\pi r^3 N$, in c.c.	0·946	2·616	5·578	12·92	5·84
$r^3 \times 18/2{\cdot}300$	2·921	8·063	17·60	39·83	18·00
ϕ (found) (i)	0·18	—	—	22·62	—
(ii)	0·0	—	—	22·43	17·82
(iii)	—	1·58	12·25	22·43	17·795
(iv)	0·33	—	—	22·58	17·795

The solution volumes found (ϕ) are those obtained according to the values adopted for the constants in the density calculations; thus (i) and (ii) are based on the values used in equations (i) and (ii) respectively, (iii) is based on the values used in Part I, and (iv) on the values $K = 1{\cdot}01275$, $k_1 = 0{\cdot}0136$, $k_2 = 0{\cdot}0192$.

Molar volumes.

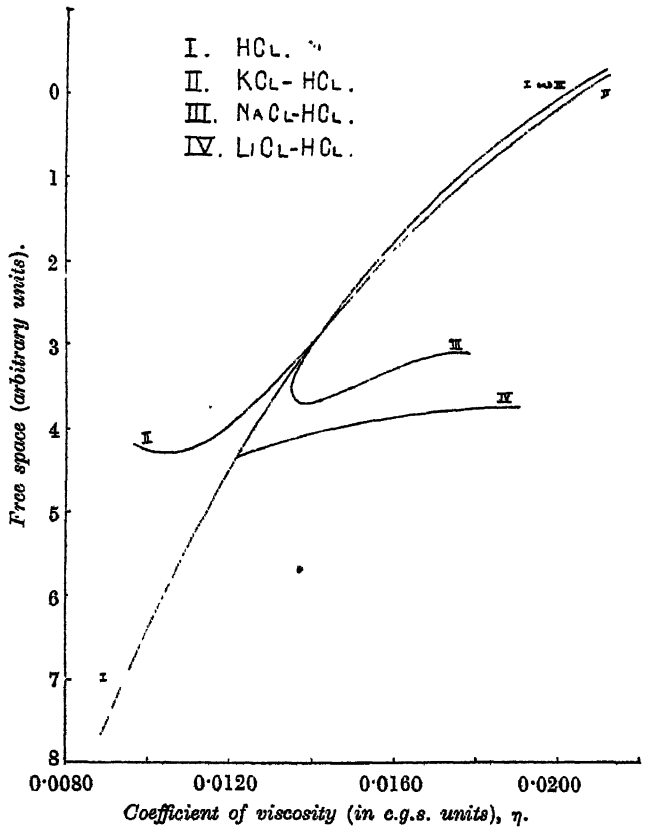
ϕ for solids	—	20·54	26·96	37·44	—

The values for the solids are derived from density data due to Baxter (*Amer. Chem. J.*, 1904, **31**, 558). Green (*loc. cit.*) obtained values for the solution volume of lithium chloride ranging from 17·53 to 20·94 according to the concentrations, the values in concentrated solution being in close agreement with Baxter's figure for the solid. Since Green's calculations involve the use of the density of pure water, no change in this value being allowed for in the concentrated solutions, it need not necessarily be concluded that the actual solution volume is the same as the solid volume. On the other hand, it is difficult to see why the solution volume obtained by the author (22·43) is higher than that of the solid—in the case of sodium and potassium chlorides the solution volumes are less than the solid volumes. The table shows also that the volumes deduced from the lattice radii are considerably less than the apparent solution volumes.

Viscosities.—The empirical method of calculating the degree of hydration of ions, as used in Part I, has been applied to the results for lithium chloride and leads to values which are comparable with those obtained for potassium and sodium. As expected, lithium chloride is more highly hydrated and the generally accepted series relationship $Li^{\cdot} > Na^{\cdot} > K^{\cdot}$ is indicated. The fall in viscosity which occurs when hydrochloric acid replaces lithium chloride is accounted for by assuming that the lithium ions are hydrated, whilst the hydrogen and chlorine ions are not solvated to any marked extent. Changes of viscosity due to changes of chlorine-ion concentration are expressed by the equation $\eta_1 - \eta_2 = \frac{1}{2}(\eta_1 + \eta_2) \times 2{\cdot}5\phi$, where ϕ is the volume of ions added to or removed from 1 c.c. of solution, and is given by $\phi = (C_2 - C_1) \times 22{\cdot}43/1000$. The volume 22·43 is that of the chlorine ion in solution. If the hydrogen ions have no specific effect, as appears to be the case for solutions of pure acid, then on comparing a solution of hydrochloric acid with one of lithium chloride of equal chlorine-ion concentration, complete dissociation

being assumed, any difference in viscosity may be attributed to the solvated lithium ions. It is further assumed that their effect is proportional to their volume, as with the chlorine ions, and the volume of hydrated lithium ions is calculated from the above equation. The ϕ value so obtained is divided by the concentration of lithium chloride in solution, and this gives the effective volume of 1 g.-ion of lithium ions, from which the volume of water accompanying the 1 g.-ion is deduced. From the following data, *viz.*, $C = 5{\cdot}407$, $\eta(\mathrm{LiCl}) = 0{\cdot}01951$, $\eta(\mathrm{HCl}) = 0{\cdot}01220$ (from Green's data), $\phi = 0{\cdot}1829$ c.c. (or 182·9 c.c. per litre), one obtains in this way 33·82 c.c. per g.-ion of lithium, corresponding to a hydration with practically the same amount of water, since the lithium ion has an almost negligible solution volume; thus x, the hydration number, is 1·88. This value is decidedly higher than that obtained for sodium ions ($x = 1{\cdot}44$) in the same way and at practically the same concentration.



A more trustworthy result is probably obtained by calculating the hydration numbers for each successive pair of solutions in the series of salt and acid mixtures. The values so obtained are given in the last column of Table I. Any changes of chlorine-ion concentration are allowed for in making the calculations.

The above methods of calculating the degrees of hydration can only be regarded as trustworthy if it is shown that viscosity changes can be related to changes in the mean sizes of the molecules composing a liquid mixture. The original equation of Einstein $\eta = \eta_0(1 + 2{\cdot}5\phi)$ is not concerned with the actual size of the suspended particles, but deals with their total volume. Smoluchowski's extension of this equation (*Kolloid-Z.*, 1916, **18**, 194), introducing a correction for the charge upon the suspended particle, involves the radius; but in the present state of the knowledge of the applicability of this formula, it seems hardly possible to extend its use to the salt and acid solutions here considered. The problem may be approached from another point of view. Dunn (*Trans. Faraday Soc.*, 1926, **22**, 401) has developed a kinetic theory of viscosity of liquids, which, whilst it is primarily concerned with the effect of change of temperature, is of interest in that it deals with the attractive forces between the molecules and the factors governing the slipping between the planes. One of these factors is the possession by some of the molecules of a certain critical energy in virtue of which they are subject to negligible cohesion, and hence represent "loose spots" in the adjacent planes. It seems that the number of such molecules in a given liquid will depend partly upon the amount of free space. The question of the relation between free space and viscosity has been investigated by McLeod (*ibid.*, 1923,

19, 6), who suggested that for normal liquids viscosity should be inversely proportional to free space. It is of interest, therefore, to see how this bears upon the problem of the salt and acid solutions. It is essential to show that the variations of free space alone cannot account for the viscosity effects.

The molar volumes obtained by calculation from the lattice radii are taken as the limiting volumes of the various species, and for a

FIG. 1.

given solution the free space is calculated from the molar concentrations of salt, acid, and water (*i.e.*, 1000 — space occupied). Even if the resulting values are not numerically equal to the actual free space, they should be comparable amongst themselves. They are plotted against the viscosities in Fig. 1, the curve for hydrochloric acid being derived from Green's data (*loc. cit.*). The curves are very similar to those obtained by plotting total solute concentration against viscosity (see Fig. 3, Part I).

If the free space alone governed the viscosity, the changes would be in the direction of lower viscosity for greater free space. As acid displaces salt in the sodium chloride–acid solutions, the free space increases at first and the viscosity falls. The rate of fall is, however, much more rapid than for corresponding free-space change in pure acid solutions. At a later stage in the mixed solutions, free space decreases with increase of total solute concentration, and the curve finally becomes identical with that for pure acid.

The curve for the potassium chloride–acid mixtures shows that the free space at first increases whilst viscosity rises, and this is in accord with the idea that the latter effect is partly due to the substitution of larger water molecules for smaller potassium ions. The subsequent increase of viscosity may be more largely due to the decrease in free space.

Lithium chloride solutions have much higher viscosities than potassium chloride solutions of equal free space. The total solute concentrations are, however, also higher in this case.

When lithium chloride is compared with sodium chloride, it is seen that whilst the viscosities are comparable for solutions of approximately the same total concentration and the same relative amounts of salt and acid, yet those containing lithium chloride have more free space. The effect of the greater free space has been more than counterbalanced by the presence of the more highly hydrated lithium ions.

Summary and Conclusions.

1. Densities and viscosities have been determined at 25° for a series of concentrated mixed aqueous solutions of lithium chloride and hydrochloric acid. The methods of Scarpa and Ostwald for measuring viscosities have been again compared and found to agree.

2. Formulæ of the type $d = K + k_1a + k_2b$ can be used to calculate the densities with fair accuracy. The assumption of the strict constancy of the molar solution volumes is not, however, justifiable. The packing of the ions amongst the water molecules may be supposed to involve a reduction of the free space depending upon the numbers and sizes of the various ions. The apparent volume of the water in solution may therefore vary from one solution to another.

3. The replacement of lithium chloride by hydrochloric acid results in a fall in viscosity which is interpreted as being due to the higher hydration of the lithium ions than of the hydrogen ions. Hydration numbers are calculated which indicate (i) a greater degree of hydration for lithium than sodium under similar conditions, (ii) a fall in the degree of hydration as the proportion of acid in the solution increases.

4. The influence of "free space" upon the viscosities in mixed solutions of lithium, sodium, or potassium chloride and hydrochloric acid is discussed.

The author wishes to record his thanks to Professor A. A. Boon for his kind interest and encouragement during these researches.

CCCXVI.—*The Reduction of Selenious Acid.*

By LESLIE MARSHALL CLARK.

IT has long been known that when selenious acid is reduced in the presence of copper or other heavy metals, the precipitate obtained does not consist of selenium alone but contains in addition some metallic compound of selenium (compare Keller, *J. Amer. Chem. Soc.*, 1897, **19**, 773). This point has been particularly exemplified by examination of the solutions obtained after estimation of nitrogen by the Kjeldahl method in certain organic selenium compounds, copper having been added in the sulphuric acid–potassium sulphate treatment as usual to aid the destruction of the organic material. It was found if the alkaline solutions remaining after the distillation of ammonia were made very slightly acid with hydrochloric acid and reduced with sulphurous acid, a black precipitate was obtained which had the composition of cuprous selenide. Moreover, it is of interest that in all cases a very considerable loss of selenium had occurred during the destruction of the organic matter.

The reaction has now been further examined by reducing selenious acid by sulphurous acid in solutions containing copper sulphate and hydrochloric acid. The precipitate obtained varies from pure selenium, in solutions containing much hydrochloric acid, to cuprous selenide in dilute acid solutions, a mixture of the element and salt being formed intermediately (see table, p. 2391). The hydrochloric acid concentration is evidently the factor determining the composition of the precipitate (Expt. A). As a possible explanation of this phenomenon the following has to be considered. Selenious acid may be reduced by sulphurous acid with intermediate formation of hydrogen selenide, which reacts with a further amount of unchanged selenious acid to give selenium:

$$2H_2Se + SeO_2 = 2H_2O + 3Se \quad . \quad . \quad . \quad . \quad (1)$$

In the presence of cuprous ions, the hydrogen selenide will form cuprous selenide, but the amount of this compound formed will

depend on the hydrogen-ion concentration of the solution. This is largely determined by the hydrochloric acid concentration, which will also affect the rate of the reaction (1), increase of acid favouring the separation of selenium. The suggested intermediate reaction has been found to take place, for when hydrogen selenide is passed into an aqueous solution containing selenious acid, selenium is precipitated in the amount required by equation (1) (Expt. D). The mechanism which has been suggested above for the reduction of selenious acid may therefore be the correct one, but the experiment on the reaction between selenious acid and hydrogen selenide is not crucial, for the following reason. When finely ground metallic selenium is kept in contact with a hot solution of sulphurous acid containing copper sulphate, the selenium increases in weight owing to the formation of cuprous selenide (Expt. B). It has not been found possible to achieve complete conversion of the element into cuprous selenide, presumably owing to the arrest of further chemical action by the formation of a coating of selenide on the individual grains of selenium.

There is thus a secondary reaction between selenium, sulphurous acid, and copper sulphate in which cuprous selenide can be formed, and this makes it unnecessary to postulate the intermediate formation of hydrogen selenide when selenious acid is reduced. The fact that complete conversion of selenium into cuprous selenide cannot be brought about in Expt. B, whereas the theoretical amount of cuprous selenide can be obtained in the reduction of selenious acid when the proper hydrochloric acid concentration is present (see table), cannot be used as an argument against the hypothesis of this secondary reaction, for the red modification formed by the reduction of selenious acid possesses a higher degree of chemical reactivity than the metallic selenium powder used in Expt. B and is, moreover, in a much more finely divided condition.

Reinsch (Fresenius, " Qualitative Chemical Analysis," 10th Edtn., p. 118) observes that " metallic copper when placed in a warm solution of selenious acid containing hydrochloric acid becomes immediately coated black; if the solution remains long in contact with the copper it turns light red from the separation of selenium." These results are explicable on the theory that selenious acid is reduced to selenium by the cuprous ions formed at the copper–hydrochloric acid interface, and that this selenium is further reduced by cuprous ions to give cuprous selenide, the dark coating referred to by Reinsch. These reactions may be represented by the equations

$$SeO_2 + 2Cu_2Cl_2 + 4HCl = Se + 4CuCl_2 + 2H_2O \quad . \quad (2)$$

$$Se + 2Cu_2Cl_2 = Cu_2Se + 2CuCl_2 \quad . \quad . \quad . \quad (3)$$

The experiments on the formation of cuprous selenide already described suggested that the nature of the deposit produced on the copper would depend on the hydrochloric acid concentration. This was found to be the case (Expt. C), since when strips of copper are immersed in selenious acid solutions containing varying amounts of hydrochloric acid, the precipitate formed varies from pure selenium in high concentrations of acid to a black deposit of cuprous selenide adhering to the copper in low concentrations. The selenium formed in the most concentrated hydrochloric acid solution examined was slowly reduced to cuprous selenide, evidently by the cuprous chloride present.

The facts described in this communication may therefore be explained as follows: when selenious acid is reduced by sulphurous acid, reduction to the element probably occurs without intermediate formation of hydrogen selenide. The selenium so formed can be further reduced to cuprous selenide should cuprous ions be present in the solution, but the extent to which this can take place is determined by the hydrochloric acid concentration. It is probable that the hydrochloric acid affects the cuprous chloride concentration by formation of the known cuprous chloride–hydrochloric acid complex.

Evidently there is a close parallelism between these experiments and those described by Wardlaw and Pinkard (J., 1922, **121**, 216), who found that, in the reaction between sulphur dioxide and cuprous chloride dissolved in hydrochloric acid, there is some definite concentration of acid above which cuprous chloride and sulphur dioxide react with the separation of sulphur only, an intermediate concentration of acid in which both sulphur and cuprous sulphide are precipitated, and a stage in which sulphide only is produced. These authors also showed that if the concentration of hydrochloric acid fell below 35 c.c. of concentrated acid to 215 c.c. of water, no reduction of sulphur dioxide by cuprous chloride took place. In the present case, however, reduction of selenious acid was found even when less than 1 c.c. of concentrated acid was present in 75 c.c. of water [Expt. C (1)].

It had been intended to obtain further tests of the theory now put forward (*e.g.*, by studying the reduction of selenious acid by various concentrations of cuprous chloride), but the work has had to be abandoned.

EXPERIMENTAL.

Expt. A.—To a solution of sodium selenite (5·000 g.) in boiled, distilled water, 10 c.c. of concentrated hydrochloric acid were added, and the volume was made up to 500 c.c.; 25 c.c. of this solution gave 0·1053 g. of selenium when reduced with sulphurous

acid in the presence of hydrochloric acid according to the usual method. Copper sulphate (1·25 g.) in water (75 c.c.) was added to each of a number of 25 c.c. portions of the selenite solution together with various amounts of hydrochloric acid; 30 c.c. of freshly prepared, saturated aqueous solution of sulphur dioxide were then slowly poured into the hot mixture, which was kept gently boiling for ½ hour. Almost immediate precipitation occurred in each case, the colour of the precipitate with the higher concentrations of hydrochloric acid being reddish brown, changing to black. A further 30 c.c. of sulphurous acid solution was added, and the mixture kept on the steam-bath for ½ hour longer. The precipitate was filtered on an asbestos mat in a Gooch crucible, well washed with sulphurous acid and water, dried in the steam oven, and weighed. (Moist cuprous selenide is quite stable to such a drying process, since when 0·2778 g. of the pure compound was moistened with water and dried as described, the residue was unchanged in weight.) The results are shown in the following table:

25 C.c. of the solution contain 0·1053 g. Se, equivalent to 0·2740 g. Cu_2Se.

HCl added, c.c.	Wt. of ppt., g.	Cu_2Se in ppt., %.	HCl added, c.c.	Wt. of ppt., g.	Cu_2Se in ppt., %.
1	0·2712	99	5	0·1680	61
2	0·2240	86	10	0·1266	27
3	0·2099	81	20	0·1076	3·5
4	0·1827	69	30	0·1050	0

Expt. B.—*Reaction between selenium, copper sulphate, and sulphurous acid.* Finely powdered selenium (0·1500 g.) was gently boiled for ½ hour with copper sulphate (2·0 g.) in water (100 c.c.) to which hydrochloric acid (1 c.c.) and saturated sulphurous acid (30 c.c.) had been added, 3 c.c. of ethyl alcohol having been added before addition of the sulphurous acid, so that the solution could wet the selenium powder, which otherwise made a film on the surface. Another 30 c.c. of sulphurous acid were added, and the mixture was kept on the steam-bath for 1 hour. The residue after filtration and drying weighed 0·3054 g. (Calc. for complete conversion into Cu_2Se, 0·3900 g.). A qualitative test showed that the precipitate contained selenium and copper, but no sulphur.

No change in the weight of another sample of selenium was observed when the above experiment was repeated without addition of sulphurous acid.

Expt. C.—*Reduction of selenious acid by cuprous chloride.* 25 C.c. portions of a solution of 5·00 g. of sodium selenite in 250 c.c. of water containing 10 c.c. of hydrochloric acid were diluted with 50 c.c. of water, and varying amounts of hydrochloric acid were added. A piece of thin copper sheet (about 4 cm. square) was then introduced,

into each solution; reaction began almost immediately, but the delay was longest in the solution containing least hydrochloric acid:

(1) No extra hydrochloric acid added. The copper was rapidly completely coated with a black film.

(2) 1 C.c. of acid added. A black film was formed which flaked away after standing for some hours. After 24 hours some selenium was also being deposited.

(3) 5 C.c. of acid added. A reddish-brown deposit was formed, which clearly contained some red selenium, as well as cuprous selenide.

(4) 20 C.c. of acid added. Selenium was precipitated in a red cloud at the copper surface, but did not adhere thereto. After 24 hours the precipitate had darkened in colour, and then contained copper, but the filtered solution contained no selenium, complete reduction having been effected.

The formation of a mixture of red selenium and cuprous selenide described in Expts. C (2) and (3) would not be expected were the solution homogeneous. If the hydrochloric acid–cuprous chloride concentrations were such that selenium was partially reduced to cuprous selenide, then each particle of selenium would have a coating of the selenide and no red selenium would be distinguished. In the experiments in question, the results are ascribed to the presence of layers of solution which are not homogeneous in the vicinity of the copper plate. The hydrochloric acid and cuprous chloride contents of such layers will naturally vary with the distance of the layer from the metal and with time. The product of the reduction may then be non-homogeneous as described.

Expt. D.—*Reaction between selenium dioxide and hydrogen selenide.* A carefully dried, round-bottomed flask containing aluminium selenide was fitted with a funnel incorporating a three-way tap in order that water or hydrogen might be admitted at will. A tube from this flask dipped below a solution of selenium dioxide in cold, dilute, oxygen-free hydrochloric acid contained in a conical flask, from which a tube passed to a trap containing cadmium acetate solution for removal of uncombined hydrogen selenide. Dry hydrogen was passed through the apparatus for an hour to remove air, the gas was cut off, and cold, boiled, distilled water was admitted to the aluminium alloy. When sufficient water had been added, a slow stream of hydrogen was started to sweep the evolved gas through the reaction flask and thence into the cadmium acetate trap. Immediate reaction took place and selenium was deposited in the reaction flask. A rather colloidal precipitate of red selenium formed at first, but this slowly coagulated, leaving a clear aqueous

liquid in which flocculent masses of the element were suspended. After 1¾ hours, the selenium formed was rapidly filtered through a Gooch crucible, washed with water, dried, and weighed.

The reaction flask initially contained 60 c.c. of water, 10 c.c. of concentrated hydrochloric acid, and selenium dioxide corresponding to 0·0696 g. of selenium, and at the conclusion of the experiment 0·2168 g. of selenium was obtained from it. According to equation (1), selenious oxide corresponding to 0·0696 g. of selenium should react with hydrogen selenide to produce 0·2088 g. of the element. The error in other similar experiments was never greater than 4% and the agreement between the calculated and observed figures is sufficiently close to be accepted as confirmation of the equation.

I wish to thank Mr. G. C. H. Jenkins for assistance in some of the experiments described in this communication.

NORTHWICH RD., WEAVERHAM. [*Received, February 22nd*, 1928.]

CCCXVII.—*The Formation of 2-Substituted Benziminazoles.*

By MONTAGUE ALEXANDRA PHILLIPS.

IT has been shown (Phillips, this vol., p. 172) that 2-methylbenziminazoles are readily formed by the action of boiling dilute hydrochloric acid on mono- or di-acetyl-*o*-diamines and by the action of acetic anhydride and hydrochloric acid on *o*-phenylenediamines, and it was suggested that hydrolysis of the diacetyl to the monoacetyl compound constituted a stage in the formation of the ring compound from the former.

These reactions have now been extended to the formation of other 2-substituted benziminazoles, and it has been shown that *o*-phenylenediamine on condensation with formic, acetic, propionic, glycollic, lactic, and mandelic acids in the presence of boiling dilute hydrochloric acid gives good yields of the corresponding cyclic compound.

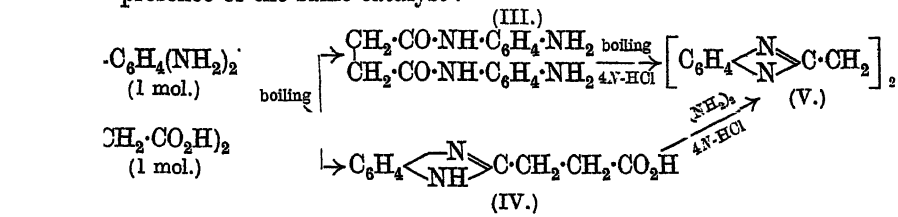
In view of the general nature of this reaction, it now seems possible, as an alternative to the above suggestion, that the mechanism of the formation of 2-substituted benziminazoles from mono- and di-acyl-*o*-diamines involves hydrolysis to the diamine with subsequent formation of the ring. Since traces of 4-nitro-*o*-phenylenediamine always seem to accompany 5-nitro-2-methylbenziminazole in the formation of the latter compound from 4-nitrodiacetyl-*o*-phenylenediamine (compare Phillips, *loc. cit.*) and the amount of diamine seems to be greater if the heating is not pro-

longed, it would seem that, in this case at least, the second view is the more correct. Experiments are contemplated which may decide between these two views.

The reduction of *o*-nitroacetanilide by iron and dilute acetic acid (a method which is generally employed for the production of *o*-aminoacylanilides) gives benziminazole only. The effect of a *p*-cyanomethyl group in stabilising the *o*-aminoformamido-structure is shown by the reduction of 3-nitro-4-formamidobenzyl cyanide by this method (Maron, Kontorowitsch, and Bloch, *Ber.*, 1914, **47**, 1377; D.R.-P. 283,448).

3-Amino-4-formamidobenzyl cyanide, 3-amino-4-acetamidobenzyl cyanide, and 3-amino-4-lactamidophenetole, which were shown by Maron and his co-workers (*loc. cit.*; *Ber.*, 1914, **47**, 718) to pass into the corresponding benziminazoles by prolonged treatment with formic or glacial acetic acid, readily give the same ring compounds by boiling with dilute hydrochloric acid. 3 : 4-Diformamidobenzyl cyanide also gives the benziminazole readily by similar treatment.

The condensation of *o*-phenylenediamine and oxalic, malonic, and succinic acids requires special notice. *o*-Phenylenediamine and oxalic acid in the presence of boiling dilute hydrochloric acid give a quantitative yield of 2 : 3-*dihydroxyquinoxaline*, no benziminazole derivative being detected, whilst malonic acid and *o*-phenylenediamine give a mixture of *o*-phenylenemalonamide (I) (compare Meyer and co-workers, *Annalen*, 1906, **347**, 17) and 2-*aminomalonanilic acid* (II), which readily passes into the heterocyclic compound on further treatment with boiling dilute mineral acid. No benziminazole-2-acetic acid was detected.



$$C_6H_4(NH_2)_2 + CH_2(CO_2H)_2 \longrightarrow$$

$$\text{(I.)}\ C_6H_4\begin{<}NH\cdot CO\\NH\cdot CO\end{>}CH_2 + C_6H_4(NH_2)\cdot NH\cdot CO\cdot CH_2\cdot CO_2H\ \text{(II.)}$$

2 : 3-Dihydroxyquinoxaline and *o*-phenylenemalonamide resemble each other in their insolubility in water and organic solvents, in their high melting points, and in the formation of very sparingly soluble monosodium salts.

From succinic acid and *o*-phenylenediamine (1 mol. of each) 2 : 2′-diaminosuccinanilide (III) and benziminazole-2-propionic acid (IV) were isolated, whilst with double the proportion of the diamine, αβ-dibenziminazolylethane (V) and traces of benziminazole-2-propionic acid were found. αβ-Dibenziminazolylethane, originally obtained by Walther and von Pulawski (*J. pr. Chem.*, 1899, **59**, 249) by the action of succinic anhydride on *o*-phenylenediamine at high temperatures, was also obtained from 2 : 2′-diaminosuccinanilide by treatment with hot dilute hydrochloric acid and by condensation

of benziminazole-2-propionic acid and *o*-phenylenediamine in the presence of the same catalyst:

The synthesis of 2-phenylbenziminazole by the above methods has not proved practicable, only traces of this compound having been isolated as picrate by treatment of *o*-aminobenzanilide and dibenzoyl-*o*-phenylenediamine with boiling dilute hydrochloric acid. The condensation of *o*-phenylenediamine with benzoic acid, benzoic anhydride, or benzoyl chloride in the presence of the above catalyst was also unsuccessful (compare, however, Walther and von Pulawski, *loc. cit.*).

That these reactions are not confined to the aromatic diamines is suggested by the ready conversion of $\alpha\alpha'$-diacetylethylenediamine into 2-methyl-4 : 5-dihydroglyoxaline by boiling with dilute hydrochloric acid; it is proposed to study the formation of glyoxalines from diacylethylenediamines by the above methods.

EXPERIMENTAL.

Condensation of o-Phenylenediamine and Organic Acids in Presence of Boiling 4N-Hydrochloric Acid.

o-Phenylenediamine (0·02 mol.), the requisite acid (0·03 mol.), and 20 c.c. of 4*N*-hydrochloric acid were boiled for 30—40 minutes under reflux. On neutralisation of the filtered solution with ammonia, the benziminazole separated. In no case except that of lactic acid was the benziminazole isolated readily when the condensation was attempted in the absence of the mineral acid.

All the benziminazoles described in the following table are readily soluble in dilute mineral acids and in excess of dilute caustic alkalis. They were recrystallised from water except where otherwise indicated.

Acid.	Benziminazole.	Crystalline form.	M. p.	Yield, %.	N, %. Found.	Calc.

* Recrystallised from 50% alcohol.

† Compare Bistrzycki and Przeworski, *Ber.*, 1912, **45**, 3483.

Benziminazole was also obtained by reduction of *o*-nitroformanilide, using the method described for the preparation of *o*-aminoacetanilide (Phillips, *loc. cit.*) (Found : N, 23·5%), and by the action of boiling 4*N*-hydrochloric acid on *o-phenylenediamine monoformate* (Found : N, 23·6%).

3-Nitro-4-lactamidophenetole was obtained by warming a mixture of 5 g. of 4-*l*-lactamidophenetole (lactophenin) and 10 c.c. of 16% nitric acid for 5 minutes at 40°; the gum formed was poured into water (100 c.c.) and the resulting solid crystallised from 50% alcohol (4·5 g., yellow needles, m. p. 115°). The nitro-compound was reduced by iron and boiling dilute acetic acid as described previously; the amino-compound (yield 60%) crystallised from water in needles, m. p. 135—136° (compare Maron and Bloch, *Ber.*, 1914, **47**, 718). 5-Ethoxy-2-(α-hydroxyethyl)benziminazole was obtained in 50% yield by treating the above amino-compound (2 g.) with boiling 4*N*-hydrochloric acid (10 c.c.) for 30 minutes, with subsequent neutralisation. It forms white plates, m. p. 170—171°, from water, and is readily soluble in dilute mineral acids and in excess of dilute caustic alkali (Found: N, 13·5. Calc. for $C_{11}H_{14}O_2N_2$: N, 13·6%).

3-Nitro-4-formamidobenzyl cyanide was made by cautiously adding 4-formamidobenzyl cyanide to ten times its weight of nitric acid (*d* 1·5) at 5—6°. The nitration mixture on being poured on crushed ice deposited the nitro-compound, which was collected and washed within ten minutes to avoid hydrolysis of the formyl group; it crystallised from 60% alcohol in yellow prisms, m. p. 151—152° (yield 86%). On reduction with iron and acetic acid (Phillips, *loc. cit.*), a 50% yield of 3-amino-4-formamidobenzyl cyanide was obtained; white needles, m. p. 124°, from water (Found : N, 23·8. Calc. for $C_9H_9ON_3$: N, 24·0%).

3 : 4-*Diformamidobenzyl Cyanide.*—3-Amino-4-formamidobenzyl cyanide (1·5 g.) and formic acid (98%, 2 c.c.) were heated under reflux for 20 minutes. After removal of excess formic acid, the gum was dissolved in alcohol, and the filtered solution allowed to evaporate in a vacuum. The semi-solid mass left was crystallised from alcohol–ether, 3 : 4-*diformamidobenzyl cyanide* being obtained as a hygroscopic, micro-crystalline solid, m. p. 92—95°, readily soluble in water, ethyl and methyl alcohols, and acetic and formic acids, but insoluble in ether or benzene (Found : N, 20·5. $C_{10}H_9O_2N_3$ requires N, 20·7%).

Nitration of 4-Acetamidobenzyl Cyanide.—This nitration was studied by Gabriel (*Ber.*, 1882, **15**, 836), who isolated only the 3-nitro-derivative; the following method led to the production of 4-acetamidophenylacetamide in addition. 4-Acetamidobenzyl cyan-

ide (8 g.) was fed slowly into nitric acid (*d* 1·5, 50 c.c.) at 5—10°, and then poured on ice; the gummy solid obtained was collected, dried at 50° (7 g.), and crystallised from 300 c.c. of 50% alcohol, 3 g. of crude 4-acetamidophenylacetamide, m. p. 212—215°, being obtained; further crystallisation gave the pure amide, m. p. 231° (compare Purgotti, *Gazzetta*, 1890, **20**, 599) (Found: N, 14·8. Calc.: N, 14·6%). The mother-liquors on concentration to half bulk gave deep golden-yellow plates of the nitro-compound, m. p. 112—113° (2 g.) (Found: N, 19·3. Calc.: N, 19·2%), slowly soluble in excess of dilute caustic alkalis to give an orange solution. 3-Amino-4-acetamidobenzyl cyanide was obtained by reduction of the above nitro-compound by iron and boiling dilute acetic acid. It forms white needles from hot water, m. p. 140° (compare Maron, Kontorowitz, and Bloch, *loc. cit.*) (Found: N, 22·4. Calc.: N, 22·2%).

5-*Cyanomethylbenziminazole.*—3-Amino-4-formamidobenzyl cyanide (1·5 g.) or 3 : 4-diformamidobenzyl cyanide (1·5 g.) was boiled under reflux with 4*N*-hydrochloric acid (10 c.c.) for 20 minutes. The crystals which separated on neutralisation and cooling were collected, washed, and crystallised from hot water. The yield was approximately 1·0 g. in either case (80%); 5-cyanomethylbenziminazole crystallises from hot water as anhydrous, diamond-shaped plates, m. p. 158—159° (compare Maron, Kontorowitz, and Bloch, *loc. cit.*) (Found: N, 26·8. Calc.: N, 26·7%).

5-*Cyanomethyl*-2-*methylbenziminazole.*—3-Amino-4-acetamidobenzyl cyanide (3 g.) was refluxed for 20—30 minutes with 20 c.c. of 4*N*-hydrochloric acid; on neutralisation and cooling, 5-cyanomethyl-2-methylbenziminazole separated (yield 65%); it crystallises from hot water in prisms, m. p. 206° (compare Maron, Kontorowitz, and Bloch, *loc. cit.*).

Condensation of o-*Phenylenediamine and Dibasic Organic Acids in Presence of Boiling* 4N-*Hydrochloric Acid.*

Oxalic acid. o-Phenylenediamine (5·5 g.), oxalic acid (dihydrate, 6·5 g.), and 4*N*-hydrochloric acid (30 c.c.) were heated to boiling, and a crystalline solid formed. After 10 minutes' further boiling, the reaction mixture was cooled and the solid, consisting of almost pure 2 : 3-dihydroxyquinoxaline, was collected, washed with water, and dried (yield, 8 g.) (Found: N, 17·4%). The *sodium* salt was obtained as white prisms, sparingly soluble in hot water (Found: N, 15·5; Na, 12·15. $C_8H_5O_2N_2Na$ requires N, 15·2; Na, 12·5%), and, on acidification with hydrochloric acid, it gave the pure *quinoxaline* as white needles, insoluble in hot water or the ordinary solvents and not melting below 350° (Found: N, 17·4%).

$C_8H_6O_2N_2$ requires N, 17·3%). That this compound is not the isomeric benziminazole-2-carboxylic acid is indicated by its weak acidity and by the sparing solubility of its sodium salt. Moreover, benziminazole-2-carboxylic acid has been obtained by oxidation of 2-methylbenziminazole (Bistrzycki and Przeworski, *loc. cit.*). The analogous 2 : 3-dihydroxyquinoxaline-6-arsinic acid, made from 3 : 4-diaminophenylarsinic acid by the above method, gives an arseno-compound which is insoluble in caustic alkali or alkali carbonate solutions, showing that this cannot be a benziminazole derivative (unpublished work).

Malonic acid. *o*-Phenylenediamine (5 g.), malonic acid (5 g.), and 4*N*-hydrochloric acid (30 c.c.) were boiled under reflux for 30 minutes. A white crystalline precipitate which had separated from the hot solution was collected after cooling (A); the filtrate on being made alkaline to litmus with 50% sodium hydroxide solution gave a crystalline precipitate (B). The solid A was further purified by means of its *mono-sodium* salt (compare dihydroxyquinoxaline, above), white, sparingly soluble cubes (Found : N, 14·5; Na, 11·4. $C_9H_7O_2N_2Na$ requires N, 14·1; Na, 11·6%), and was proved to be *o*-phenylenemalonamide (Found : N, 15·9. Calc. : N, 15·9%), white prisms, m. p. over 300°, insoluble in boiling water and the ordinary solvents, resembling dihydroxyquinoxaline in these particulars. The solid B (1·5 g.) crystallised from boiling water as white prisms of *2-aminomalonanilic acid*, m. p. 175—176° (Found : N, 14·4. $C_9H_{10}O_3N_2$ requires N, 14·4%), an amphoteric substance; when its solution in dilute hydrochloric acid is boiled for ½ hour, *o*-phenylenemalonamide is formed in quantitative yield.

Succinic acid. (i) *o*-Phenylenediamine (8 g.), succinic acid (10 g.), and 4*N*-hydrochloric acid (60 c.c.) were boiled under reflux for 40 minutes. On cooling, a crystalline solid (A) separated. The filtrate on basification with 50% sodium hydroxide gave an amorphous precipitate (B); the filtrate from this, on neutralisation to Congo-red with hydrochloric acid, gave a crystalline precipitate (C). The last precipitate (4·5 g.) was further crystallised from hot water and shown to be benziminazole-2-propionic acid, white prisms, m. p. 224°, sparingly soluble in cold but readily soluble in boiling water, in dilute mineral acids, and in ammonia, sodium carbonate, etc. The solid A (9 g.) consisted of a mixture of succinic acid with the hydrochloride of the base B. The latter (2 g.) was found to be 2 : 2′-diaminosuccinanilide (compare Meyer, *Annalen*, 1903, **327**, 1), a white, amorphous solid, m. p. above 300°, insoluble in boiling water and in the ordinary solvents; its hydrochloride is sparingly soluble in cold water, from which it forms white, hexagonal plates (Found : N, 15·3; Cl, 19·1. Calc. : N, 15·1; Cl, 19·1%).

No trace of *o*-phenylenesuccinamide or of 2-aminosuccinanilic acid was detected.

(ii) *o*-Phenylenediamine (4·2 g., 2 mols.) and succinic acid (2·3 g., 1 mol.) were boiled for 1 hour with 4*N*-hydrochloric acid (30 c.c.). The solid which was precipitated on cooling was collected and crystallised from hot water (A); the filtrate on neutralisation to litmus gave 0·5 g. of benziminazole-2-propionic acid. The solid A (1·5 g.) was shown to be αβ-dibenziminazolylethane dihydrochloride (Found: N, 16·5; Cl, 20·9. Calc.: N, 16·7; Cl, 21·2%), white needles, sparingly soluble in water; this was also obtained by boiling for 1 hour under reflux a mixture of benziminazole-2-propionic acid (2 g.), *o*-phenylenediamine (1 g.), and 4*N*-hydrochloric acid (14 c.c.), and cooling (Found: N, 16·3; Cl, 20·9%), or by treatment of 2 : 2′-diaminosuccinanilide with boiling 4*N*-hydrochloric acid. The base is a white amorphous solid, m. p. above 300°.

2-*Methyl*-4 : 5-*dihydroglyoxaline*.—Diacetylethylenediamine, made by reduction of aminoacetonitrile hydrochloride (Fargher, J., 1920, **117**, 1351), followed by acetylation, was boiled for 30 minutes with five times its weight of 4*N*-hydrochloric acid and gave a 55% yield of the above glyoxaline, m. p. 107° (Found: N, 33·0. Calc.: N, 33·3%).

RESEARCH LABORATORIES, MESSRS. MAY AND BAKER, LTD.,
WANDSWORTH, S.W. 18. [*Received, June 16th*, 1928.]

CCCXVIII.—*The Influence of Intensive Drying on Inner Equilibria. Part III.*

By ANDREAS SMITS.

THE author's theory of allotropy (*Chem. Weekblad*, 1910, **7**, 79, 155; *Versl. Akad. Wetensch. Amsterdam*, 1910, **18**, 808; *Z. physikal. Chem.*, 1911, **76**, 421) is based on a hypothesis consisting of two parts. The first part states that every phase, and therefore also every crystalline phase, of an allotropic substance is a state which in certain circumstances can behave as a poly-component phase. The second part states that this behaviour must be attributed to complexity, *i.e.*, to the existence of different molecular species; when these are in inner equilibrium, however, the behaviour of the system is unary, *i.e.*, it behaves as a one-component system.

When this theory was published, it was pointed out that such a single substance would be expected to behave as a poly-component phase under two conditions, *viz.*, during rapid working or by use of a negative catalyst.

In 1912 (J., **101**, 2339) H. B. Baker and Mrs. Baker showed that intensive drying had the effect of raising the boiling points of nitrogen trioxide and nitrogen tetroxide by 44° and 47° respectively. These results, which were unknown to me until 1921, seemed to indicate that in the moist liquid an inner equilibrium exists between different species of molecules (simple and complex molecules), and that either this inner equilibrium was fixed or the inner transformations were retarded by intensive drying.

In these experiments it seemed therefore that we had a very distinct confirmation of the theory of allotropy, and that intensive drying was an excellent method of proving the complexity of a so-called single substance (*Z. physikal. Chem.*, 1922, **100**, 477). The results published by Baker (J., 1922, **121**, 568), showing a great elevation of boiling point in ten liquids that had been intensively dried for several years, supplied a further confirmation of the theory, since several of these liquids were regarded as quite normal, single substances. This increase in boiling point might possibly have been ascribed to great superheating (rendered possible in some unknown way by intensive drying, see p. 2407), had not Baker found exactly parallel effects in the surface tension and vapour density, the latter being 2—3 times that found with moist liquids (this vol., p. 1051).

These results seemed to point to an inner equilibrium between different species of molecules in the moist liquid, as postulated by the theory. To explain the behaviour of the intensively dried substances as a whole, the author assumed that intensive drying causes first a retardation of the velocity of the establishment of, and possibly also a displacement of, the inner equilibrium, and finally a fixation of it ("The Theory of Allotropy," 1922, p. 310; J., 1924, **125**, 1068).

Although this hypothesis was very probable, it still lacked a direct proof. The author therefore studied the influence of intensive drying on the vapour pressure. If the establishment of inner equilibrium is retarded, it will be manifested by a retarded change of the vapour pressure with temperature and by a temporary decrease of the vapour pressure after partial distillation.

A displacement of the inner equilibrium, however, will be revealed by a change of the vapour pressure at constant temperature, whilst a fixation of the inner equilibrium, as the final state of the process of intensive drying, should enable us to separate completely the different molecular species of the so-called single substance.

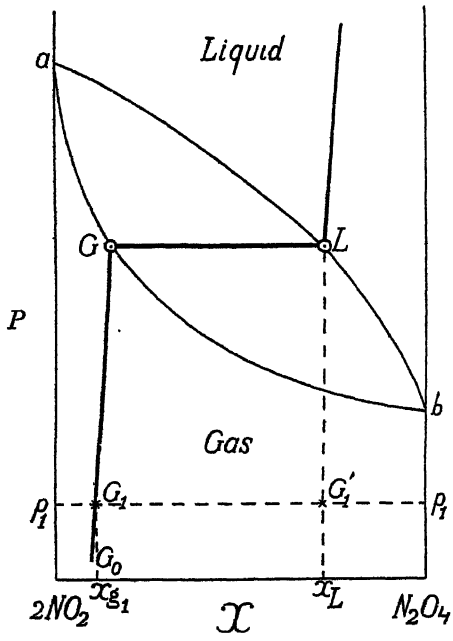
I wish to state emphatically that these studies can give us a proof of the explanation of the intensive drying which I have advanced. These considerations explain the behaviour of dried substances without making any special assumptions about the "mechanism"

of the action of the water molecules, as indeed every thermodynamical consideration does. A theory about that "mechanism" will undoubtedly be advanced before very long; it will not displace the present theory, however, but will complete it. It is necessary to emphasise this point because it seems that some confusion still exists on the matter.

(1) *Discussion of Vapour-density and Vapour-pressure Determinations.*

In an earlier paper we showed that intensively dried hexane in rapid evaporation behaved as a mixture, and we will shortly publish a detailed confirmation of this fact. Also, changes of vapour pressure at constant temperature, and without distillation, have been found in some cases, but even after several years' drying these changes are relatively small. On the other hand, Baker's experiments on the abnormally high vapour densities (*loc. cit.*) seem to contradict these results.

It was most unlikely that our carefully purified liquids, dried in either small or large apparatus for 2—5 years with a relative very large quantity of purest distilled phosphorus pentoxide, would be less completely dried than those of Baker; and it was therefore probable that there was some simple explanation of this apparent contradiction. Since studies of "velocity" phenomena, such as rapid distillation and rapid heating, showed rather large effects, whilst "equilibrium" phenomena, such as the vapour pressure, revealed little or no effect, it was obvious that the anomaly would disappear if the properties studied by Baker were actually velocity phenomena.



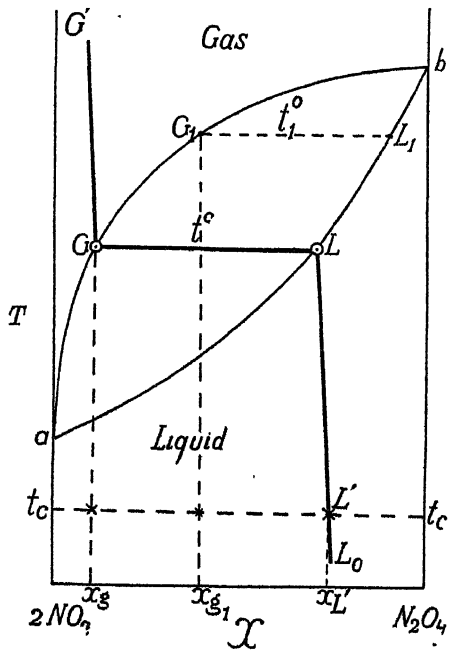
In reviewing Baker's experiments, we will discuss first his determination of the vapour density by the method of Victor Meyer, taking a simple example, such as nitrogen tetroxide; the P–x diagram of the pseudo-system at the temperature at which the experiment is carried out is given in Fig. 1 (see *op. cit.*, p. 24, Fig. 32).* Supposing now that, if in inner equilibrium at the given temperature, the coexisting phases are L and G, these phases will be present if the little bulb, used in Victor Meyer's method, is filled with moist nitrogen tetroxide. Further, we will suppose that the horizontal line p_1p_1 corresponds with a pressure of 1 atmosphere. If the bulb is broken, the liquid evaporates, but that evaporation is accompanied by a chemical transformation, namely, $N_2O_4 \longrightarrow 2NO_2$, and the unsaturated vapour formed is given by the point G_1, lying on the vapour curve GG_0 of the unary figure, so that the composition

* The only difference is that the temperature corresponding with Fig. 32 is above the critical temperature of the pseudo-component α.

of the vapour formed is not x_L but x_{G_1}, and it is to this composition that the vapour density found corresponds.

If, however, the nitrogen tetroxide is so intensely dried that, although the inner equilibrium is not yet fixed, the inner transformations are distinctly retarded, the result of the vapour-density determination will now be quite different. This time, when the little bulb is broken, the liquid will to some extent behave as a mixture. Let us suppose, on the one hand, that the liquid behaves as a real mixture; in this case the reaction $N_2O_4 \longrightarrow 2NO_2$ will not take place, and if all the liquid is evaporated, a gas phase G_1' will be formed, the composition of which is equal to the composition of the liquid before the bulb was broken. Consequently, the vapour density found will then correspond with the composition x_L. On the other hand, it is now evident that, if the inner equilibrium is not yet fixed but the inner transformations are only retarded, the composition of the gas phase, at the moment of the reading, will be given by a point between G_1 and G_1'; consequently in this case the vapour density will show an abnormally high value, notwithstanding that the inner transformations are not yet stopped, but only retarded. If it had been possible to wait until the slow substance had reached inner equilibrium before the readings were taken, the ordinary vapour density would have been found, but in this method readings had to be taken quickly, so as to avoid errors due to the diffusion of the vapour into the air column.

FIG. 1.



Hence, we see that vapour density, as determined by the Victor Meyer method, gives a value corresponding to a velocity phenomenon and that this method makes it possible to obtain large changes of the vapour density, since it enables us to find *temporary changes* which disappear if one waits until inner equilibrium in the gas phase is established. Similar results would be obtained by Dumas' method.

The vapour pressure of the same dried liquid, at constant temperature, however, is an equilibrium phenomenon, and is still completely unchanged.

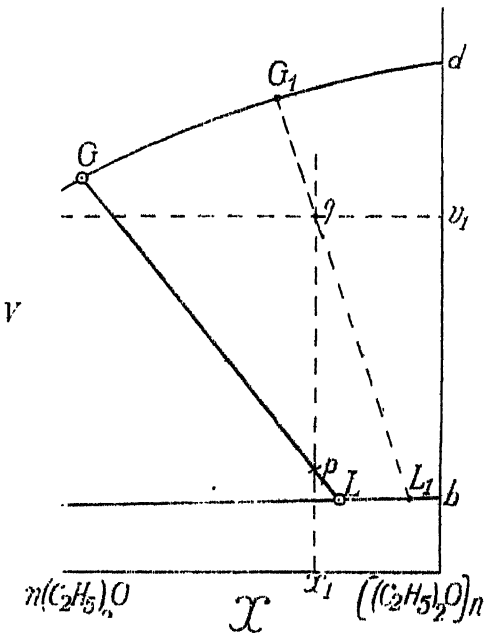
It is evident that the determination of the latent heat of vaporisation or condensation is the determination of the effect of a velocity phenomenon, and, indeed, it seems one of the best methods for finding whether a retardation of the inner transformation has already occurred. Considering a T–x diagram for constant pressure, say 1 atm. (Fig. 2; see also *op. cit.*, p. 27, upper part of Fig. 38), we see that in the pseudo-diagram the unary figure is given by the curves L_0L and GG' and the horizontal line GL; consequently L and G are the coexisting liquid and gas phases at the boiling point.

FIG. 2.

Suppose now that we determine the heat of condensation, and the temperature of the calorimeter corresponds with the horizontal line t_ct_c, we have to consider two cases. (1) If the substance behaves in a unary manner, the vapour phase G will be transformed into the liquid phase L', lying on the curve LL_0, and the heat of condensation therefore contains an exothermic heat of reaction corresponding with the change of composition from x_g to $x_{L'}$. (2) If, however, the substance has become slow, by intensive drying, and therefore behaves to some extent as a mixture, the point representing the boiling liquid will move along the curve Lb and that of the vapour phase along the curve Gb in such a way that the coexisting phases always lie on the same horizontal line—if the boiling point is increased, for instance, from t° to t_1°, the coexisting phases are L_1 and G_1. Now it is evident that the condensation of the vapour phase G_1 in the calorimeter will give rise to a smaller heat of condensation, since the composition of this vapour phase x_{g_1} is nearer to $x_{L'}$ than is x_G, so that, although the composition of the condensed vapours lies between x_g and x_{g_1}, the exothermal chemical reaction is smaller than

in the first case, in which the substance was assumed to behave in a unary manner.

The following observations may be made on the enormous increase in the boiling points of intensively dried liquids observed by Baker. The apparatus contained two distilling flasks, each with two side tubes, and to one of these tubes was sealed the side piece of the other. In the determination of the boiling point, the liquid was distilled by heating the containing flask in an oil-bath, the other flask being cooled in water or in ice. When sufficient liquid had collected in the second flask, this was heated in the oil-bath while the first was cooled. That, after ten years' drying, the inner equilibrium was not yet fixed and the liquid behaved, on evaporation, as a mixture, follows from a remarkable fact mentioned by Baker himself (J., 1922, **121**, 568), namely, that when the condensed liquid from the distillation was again heated, it did not enter into a state of ebullition until the abnormally high temperature had been reached. Further, speaking of his result obtained with benzene, he says (*loc. cit.*), "The liquid boiled at 106° quite steadily. Some of the liquid was distilled from the apparatus into a distilling flask and left for a day exposed to moist air. Its boiling point was found to be 105°." The boiling point of the distillate was consequently the same as that of the residue and was still unchanged after a day in contact with moist air. If the inner equilibrium had been fixed, a distillate with abnormally low boiling point would have been formed, whereas both experiments indicate that just the opposite occurred, thus proving that the inner transformations had been merely retarded, so that the liquid on distillation behaves as a mixture. But since the transformations are not stopped, the inner equilibrium will after some time be re-established in the distillate, which will then show the same behaviour as the initial liquid. The second experiment proves that, notwithstanding the contact with moist air, the liquid was still slow.



The following experiment indicates the same thing.

I wrote to Prof. Baker that I was very anxious to know what the vapour pressures of his dried liquids were, and he kindly determined that of dried ether, using a dried barometer tube of mercury, surrounded by a water jacket. On being admitted to the tube, the ether gave at 20° a vapour pressure of 374 mm. Hg instead of 442 mm., but this value rose slowly. This also is completely in agreement with a slow establishment of the inner equilibrium, which can be understood most easily by using a diagram (Fig. 3) in which the molecular volume V is plotted against the composition x (expressed, for instance, as mols.%). The temperature considered is that at which the vapour-pressure determination is carried out.

At this temperature, a is the volume of n g.-mols. of pure liquid

$(C_2H_5)_2O$, *i.e.*, liquid consisting only of the first pseudo-component [the single molecules $(C_2H_5)_2O$], or the completely dissociated second pseudo-component, under its own vapour pressure, and c is the volume of n g.-mols. of gaseous $(C_2H_5)_2O$ in equilibrium with this liquid phase. The points b and d have the same significance with respect to 1 g.-mol. of the second pseudo-component, $[(C_2H_5)_2O]_n$. The vapour pressure of pure liquid $(C_2H_5)_2O$ will be much larger than that of pure liquid $[(C_2H_5)_2O]_n$, and the molecular volume of the coexisting vapour is therefore much smaller than that of the vapour coexisting with $[(C_2H_5)_2O]_n$. In Fig. 3 it is supposed that the difference is so large (which is quite possible) that n times the molecular volume of the vapour coexisting with liquid $(C_2H_5)_2O$ is even smaller than the molecular volume of the vapour coexisting with liquid $[(C_2H_5)_2O]_n$, but this is not essential. The line ab, the binodal for the liquids, gives the molecular volumes of the liquid mixtures, whilst cd, the binodal for the vapours, gives the molecular volumes of the gaseous mixtures of the pseudo-system. If the system of all these liquids and vapours behaves in a unary manner only one liquid and one vapour coexist, namely those given by the points L and G. From the situation of these coexisting phases we see that the liquid phase is rich in the polymeric or complex molecules, whilst the vapour phase is rich in the single molecules. This coexistence corresponds to a definite pressure, the vapour pressure of the liquid in inner equilibrium.

FIG. 3.

Suppose now that the bulb with dried ether was nearly completely filled, *i.e.*, the volume of vapour was relatively very small. Drawing the nodal line LG, we can conclude from this that the state of the mixture must be represented by a point on this line and quite near to L, so that the total composition corresponds with x_1, for in this

case the quantities of the phases L and G, which together form the system are in the ratio Gp/Lp. After the bulb is broken, the system attains a relatively large volume, given, say, by the horizontal line v_1v_1; then we see that, if in the first moments the substance behaves as a mixture, owing to its sluggishness caused by intensive drying, the point q can tell us what the state of the coexisting phases will be during the first moments. For the state of a mixture of composition x_1 at a volume v_1 is given by the point q on the nodal line L_1G_1, and from the position of this point we see that the quantities of the coexisting phases are largely changed and the the ratio has now become G_1q/L_1q. This nodal line is situated in the region of lower pressures, so that the vapour pressure will be abnormally low. But as the inner equilibrium is not yet fixed, the inner transformations, which are only strongly retarded, are taking place in the direction of the inner equilibrium, which will be reached after some time, *i.e.*, the vapour pressure will increase.

In the experiments of Prof. and Mrs. Baker on nitrogen trioxide and nitrogen tetroxide a similar phenomenon took place. Directly after the bulb is broken the liquid must evaporate strongly, changing the composition of the coexisting phases in the direction of lower vapour pressure, *i.e.*, higher boiling points, and as the boiling liquid slowly distils, the behaviour as a mixture is continued.

(2) *Discussion of Surface-tension Determinations.*

We have now to deal with the determination of the surface tension; it is true that this is not a velocity phenomenon but this property is not trustworthy in this case for the following reasons. Baker (this vol., p. 1055) describes experiments in which a tube of 1 cm. diameter was prepared with two platinum plates 7 cm. long fixed facing each other at the lower end of the tube, and having a thermometer placed between them. Benzene was introduced just to cover the plates, which were connected with a 400-volt battery for some hours, and its boiling point was thus raised to 91°. This effect was not destroyed when the apparatus stood for a few days with the plates disconnected from the battery—the boiling point was 88° and the boiling was steady, not violent. While the boiling was proceeding, the voltage was again applied and within 2 minutes the evolution of bubbles was stopped. Measurements of the surface tension of the liquid indicated a 2—3-fold increase in molecular weight.

I had previously carried out sparking experiments and had been impressed by the efficiency of strong electric fields in drying dielectrics, but had delayed their application in this direction. I therefore repeated Baker's experiment (in collaboration with my

assistant Mr. Bruin), using an apparatus of exactly the same dimensions. Before the platinum plates were connected with the 400-volt battery, the boiling point of the benzene was 80·5°, and after the current had passed for 4 hours the boiling point had risen to 95° but then sank to 88° under steady boiling, even if the platinum plates were disconnected from the battery. The electrodes were now connected together, and after 2 days the boiling point was again determined, without applying an electrical field: it was still high (*viz.*, 93°), but sank again to 88° under steady boiling. The bubbles originated from a small part of the platinum wire, fixed to one of the plates.

Now it is known that the most favourable condition for superheating is to heat in a bath, and the best way to prevent superheating is to heat with a small flame applied at a point on the bulb containing the liquid. When heating was effected in the latter way, with application of the electrical field, the benzene boiled at 80·5° and the phenomenon mentioned by Baker had disappeared completely, thus showing that his high boiling points may be affected to an unknown degree by superheating.

At the same time we determined the influence of an electrical field on the vapour pressure, since if such a field had any influence on the position of the inner equilibrium, it would also change the vapour pressure. A similar tube with platinum plates was connected to a glass-spring indicator and to a little bulb containing phosphoric oxide. Benzene was introduced in the tube so as just to cover the plates. The apparatus was highly evacuated, and, without application of an electrical field, the vapour pressure was determined over the range 40—90°. The experiment was then repeated, applying an electrical field, first of 400 volts and then of 800 volts. The result was that the vapour-pressure lines coincided *completely*. From this we may conclude that the electrical field does not effect any change in the inner equilibrium, and that the increase in boiling point is most probably due to the removal of electrically charged dust particles by the field, in which case superheating occurs more easily when heating is carried out in a bath. Hence we must infer that, had Baker heated the liquid with a very small flame (micro-burner), instead of in a bath, he would have found a normal boiling point for his dust-free liquid.

From his surface tension measurements, Baker calculated that the molecular weight was 2—3 times the normal, but the vapour-pressure determination, and, we may now add, also the boiling-point measurements, showed that the inner state of the liquid is not changed at all. Therefore it seems most probable that, if a liquid by long standing in a sealed tube has become free from dust particles

the surface tension may be changed, and is therefore no longer a trustworthy criterion as to the state of the inner equilibrium.

Conclusions.

Consequently, my conclusions are : (1) That as yet neither Baker nor I have stopped the inner transformations in the *liquid* phase of a single substance but we have succeeded, as shown especially by Baker's determination of vapour density and latent heat, in retarding the velocity of the inner transformations by intensive drying of liquids, so that the substance behaves as a mixture with regard to what we have termed velocity phenomena. (2) Moreover, we have realised a fixation of the inner equilibrium in the *solid* phase and in the coexisting gas phase of a single substance by intensively drying sulphur trioxide, and our continued investigation of phosphoric oxide points to the same result. (3) With regard to the *gas* phase of a single substance, it is most probable that Baker, using small quantities, has realised a fixation.

In answer to the question whether intensive drying can effect a displacement of the inner equilibrium, we can say that in some cases relatively small displacements are found with liquids, that Baker most probably has realised a very strong displacement with gases, and that we have found a very distinct change in the case of ammonium chloride (preliminary paper, *Rec. trav. chim.*, 1927, **46**, 445).

Summary.

The present state of our knowledge of intensive drying is discussed. It is pointed out that intensively dried hexane in rapid distillation behaves as a mixture, but that the changes of vapour pressure at constant temperature, without distillation, are relatively small even after several years' drying. This appears to be in conflict with experiments in which Baker obtained abnormally high vapour densities for perfectly dry liquids. In seeking an explanation of this anomaly, it is seen that rapid evaporation and distillation are "velocity" phenomena, whereas vapour pressure is an "equilibrium" phenomenon, and that large effects are to be expected in the former case and negligible or zero effects in the latter. The two types of result are therefore reconciled.

Baker's surface-tension experiments alone appeared to present a difficulty, but it has now been shown that this property is not a trustworthy criterion for internal equilibrium, for it may be altered by removal of dust particles from a liquid during long standing.

Further, it has been demonstrated experimentally that an electric field has no influence on the vapour pressure of benzene or on its

[*To face p.* 2409.]

boiling point, provided that, during the determination of the latter, superheating be avoided by the use of a small flame instead of a bath.

Our recent results will be published shortly.

UNIVERSITY, AMSTERDAM. [*Received, June 25th*, 1928.]

CCCXIX.—*The Densi-Tensimeter.*

By ANDREAS SMITS.

EVER since Abegg (*Z. physikal. Chem.*, 1908, **61**, 455) emphasised the anomaly that ammonium chloride has the same sublimation pressure when perfectly dry as when moist, whilst the dried vapour was found undissociated and the moist almost completely dissociated, I have desired to repeat Johnson's experiments (*ibid.*, p. 457), but in a more trustworthy apparatus. The problem was to measure the vapour pressure and the vapour density simultaneously, but the insertion of a small baroscope into a vapour-pressure apparatus, with a glass-spring indicator, appeared to present insuperable difficulties, and it was not until the need for such an apparatus became imperative during our experiments on intensive drying, that one of my glass-blowers succeeded in the task. He introduced a quartz baroscope with a quartz knife-edge and also a graduated glass scale into a bulb of high-melting Jena glass of about 10 cm. diameter, so that this bulb formed part of a vapour-pressure apparatus having a glass-spring indicator, and a preliminary investigation was conducted on the "ammonium chloride" problem (*Rec. trav. chim.*, 1927, **46**, 445).

The apparatus has now been improved in certain directions. In the first place the pan on which the knife-edge rests was made from a tube which was cut in two lengthwise and turned up at the ends, to prevent the knife from slipping from the pan. This is seen in Fig. 1, which also shows a cross-piece in the right arm of the baroscope, the vertical tube of which is provided with a small steel rod embedded in powdered iron oxide; this steel rod serves to make the baroscope swing with the aid of a magnet, whereby it can be seen whether the deviation is reproducible.

The difficulty, however, was that in this form of the apparatus the pan could not be ground, whereas the knife-edge was. This was unfavourable, and I therefore changed the construction slightly (see Fig. 2).

Just above the knife-edge two thin quartz arms were sealed and bent down, so that these little arms prevented the baroscope from slipping from the pan, and consequently the pan could have an open V-form and thus be well ground, which was a great advantage. (The firm of Beckerson, Dièren, Holland, carried out the grinding

the knife-edges and pans very efficiently.) The baroscope moved as regularly as a fine balance, and the calibration showed that the readings were exactly reproducible.

Another improvement was then made to ensure that, on cleaning, the baroscope is not removed from its place and made to float on the cleaning liquid. For this purpose the ends of the two little side arms, mentioned above, are bent horizontally, and a glass rod is sealed to the pan holder in such a way that, if the bulb of the baroscope is lifted by the cleaning liquid, the horizontal ends of the side arms are caught by this rod; the knife-edge now cannot be lifted up from the pan and the baroscope remains in the right position (see Fig. 2).

Although the apparatus was now very satisfactory, I thought that possibly the accuracy could be increased a little by changing the baroscope once more. In order to eliminate a possible source of slight error, caused by adsorption of vapour on the quartz surface of the baroscope, it was necessary to have, as accurately and symmetrically as possible, the same area of quartz surface on each side of the knife-edge. To ensure this, the baroscope of the latest construction contains two bulbs, but whilst the left one is closed, the right one has two or more holes, so that it can serve to enlarge the surface of the right part of the baroscope without impairing its function in the apparatus; moreover, since both the inner and the outer surface of the open bulb are exposed to the vapour, this bulb must be smaller than the other.

This principle is embodied in the baroscope shown in Fig. 3, from which we see also that the tube with the small iron rod is now sealed into the open bulb, that the needle is sealed at the middle of the arm of the baroscope, and that the scale is at the upper part of the apparatus.

Fig. 4 shows the bulb, containing the baroscope, sealed to the glass-spring indicator. The whole apparatus has been called a "Densi-Tensimeter."

CCCXX.—*The Action of Substituted Aromatic Amines on Camphoric Anhydride. Bromo- and Iodo-camphoranilic Acids and Camphoro-bromo- and iodo-phenylimides.*

By MAHAN SINGH, RAM SINGH AHUJA, and KISHEN LAL.

WHEN a substituted aniline is condensed with camphoric anhydride, a camphoranilic acid and the corresponding imide are formed, the relative quantities depending on the nature of the substituent (R)

and its position in the amine (Singh and Singh, J., 1927, 1994; see also J., 1925, **127**, 1966). The order in which the *o*-, *m*-, and *p*-substituted amines affect the yield of the camphorimide is, however, not consistent for R = Cl, Br, I, Me, and CO_2H.

The results obtained from the condensation products of camphoric anhydride with bromoanilines and iodoanilines are now reported. Table I gives the approximate percentage yields of the respective camphorimides, formed together with carboxy-, methyl-, chloro-, bromo-, and iodo-camphoranilic acids.

TABLE I.

Percentage yields of the imides.

	CO_2H.	Me.	Cl.	I.	Br.
p	Nil	Traces	15—20	25—30	40
m	,,	—	6	31	25
o	,,	—	5	—	5—10

Except for the position of chlorine, the order for the *p*-substituted amines corresponds to the order which indicates the relative influence of the substituents on the nitration of a monosubstituted benzene. The ratio acid/imide produced is also dependent on the temperature at which the reaction is carried out, though the order in which the substituents affect the ratio is the same as that given in Table I. All the condensations except that of *o*-iodoaniline (*vide infra*) were carried out at a temperature between 145° and 150° and the reaction mixture was heated for 3—4 hours.

With regard to the optical rotations of these compounds, (*a*) the *o*-bromo- and *o*-iodo-acids give negative values in acetone and methyl ethyl ketone; (*b*) the *p*-isomeride has in all cases the maximum rotation, which is in accordance with Frankland's rule (J., 1896, **69**, 1583). These observations also support Cohen's rule (Frankland, J., 1912, **101**, 667) "that the rotatory effect of the ortho-grouping differs more from that of the phenyl than do those of the meta- and para-groupings"; (*c*) the molecular rotatory powers of the acids do not follow the order of the dielectric constants of the solvents used.

Table II gives the molecular rotatory powers of camphoranilic acid and some of its 2′-substituted derivatives in methyl alcohol, ethyl alcohol, acetone, and methyl ethyl ketone.

As regards their effect in diminishing the molecular rotatory power in acetone and in methyl ethyl ketone, the order of the substituents is that of their effect on the optical activity of menthyl and *sec.*-β-octyl esters of monosubstituted acetic acids and benzoic acids (Rule and Smith, J., 1925, **127**, 2188; Rule and Mitchell, J., 1926, 3202; Rule and collaborators, this vol., p. 178). This

corresponds to the relative polarity of the groups as deduced from molecular inductive capacities. For methyl- and ethyl-alcoholic solutions there is a small displacement in the order of the substituents.

It is remarkable that the above order of substituents is followed when the solvents are ketones and not when they are alcohols. The substances examined by Rule and his collaborators (*loc. cit.*) were all liquids and the question of the effect of solvents did not arise. The authors have not been able to find in the literature mention of any series of optically active, ortho-substituted substances examined in ketonic solution with a view to correlating the molecular rotation with the nature of the *o*-substituent. It seems probable that such optically active substances show the same relative changes in rotatory power in ketonic solvents and in the pure state. Work is in progress to determine whether the effect on the optical activity of substituents in the ortho-position follows the above order only when the substances are dissolved in ketones.

For the meta- and the para-substituted derivatives the effect of the substituents accords with what Rule and others (*loc. cit.*) have called their general effect, *i.e.*, CO_2H>halogens>Me>H.

EXPERIMENTAL.

Condensation of Camphoric Anhydride with Bromo- and Iodoanilines.—The method was that described for the condensation of *o*-chloroaniline (J., 1927, 1995). Sodium carbonate was used to separate the camphoranilic acid from the imide. They can also be separated by fractional crystallisation from alcohol.

Camphoro-*o*-bromophenylimide crystallised in short needles, m. p. 142° (Wootton, J., 1910, **97**, 415, gives 139—140°) (Found: Br, 23·9. Calc.: Br, 23·85%), and the *m*-bromo-isomeride in silky needles, m. p. 190° (Wootton gives 184—185°) (Found: Br, 23·9%).

2′-Bromocamphoranilic acid crystallised in silky needles, m. p. 168°, $[M]_D$ − 61·1° in acetone (Wootton gives m. p. about 78°,

$[M]_D$ — 41·1°) (Found Br, 22·8; equiv., by titration with NaOH, 353·3. Calc.: Br, 22·6%; equiv., 354). The 3′-bromo-acid crystallised in prisms, m. p. 224° after shrinking at 220° (Wootton, 215—217°) (Found: Br, 22·8%; equiv., 353·4).

4′-Bromocamphoranilic acid crystallised in stout needles, m. p. 206—207° (Found: Br, 22·7%; equiv., 352·5), and *camphoro-p-bromophenylimide* in prismatic needles, m. p. 182·5° (Found: Br, 23·9%).

The condensation of camphoric anhydride and *o*-iodoaniline was carried out at 115°; at higher temperatures a viscous oil was obtained and the yield of the acid was seriously diminished. The alcoholic solution of the condensation product was precipitated with water, and the acid dissolved by addition of dilute aqueous ammonia. The residue was probably unchanged material containing a small quantity of camphoro-*o*-iodophenylimide, which could not be separated and purified. The ammoniacal solution was acidified, yielding an amorphous spongy mass, which was redissolved and reprecipitated several times. *2′-Iodocamphoranilic acid* was thus

obtained as a somewhat sticky powder, which was dried in a vacuum desiccator for 48 hours; m. p. 147—149° (Found: I, 31·2; equiv., 400. $C_{16}H_{20}O_3NI$ requires I, 31·7%; equiv., 401).

Camphoro-m-*iodophenylimide* crystallised as a light fluffy mass, m. p. 172° (Found: I, 33·0. $C_{16}H_{18}O_2NI$ requires I, 33·2%), and 3′-*iodocamphoranilic acid* in light prismatic needles, m. p. 226—227° (Found: I, 31·7%; equiv., 402, 406).

Camphoro-p-*iodophenylimide* crystallised in needles, m. p. 197° (Found: I, 33·1%), and 4′-*iodocamphoranilic acid* in short needles, m. p. 221° (Found: I, 31·8%; equiv., 399).

In general, the preceding imides are readily soluble in acetone and methyl ethyl ketone, fairly readily soluble in methyl alcohol, and sparingly soluble in ethyl alcohol, and the acids are soluble in the common organic solvents.

4′-Methylcamphoranilic acid (compare Wootton, *loc. cit.*; Singh and Puri, J., 1926, 504) and only a trace of the imide were obtained by the general method.

The rotatory power of 2′-methoxycamphoranilic acid was determined in methyl ethyl ketone for comparison: 0·1989 g. dissolved in 25 c.c. gave α_D — 0·50°, whence $[M]_D$ — 90·75°.

The authors wish to express their indebtedness to Professor H. B. Dunnicliff for his interest and advice in this work.

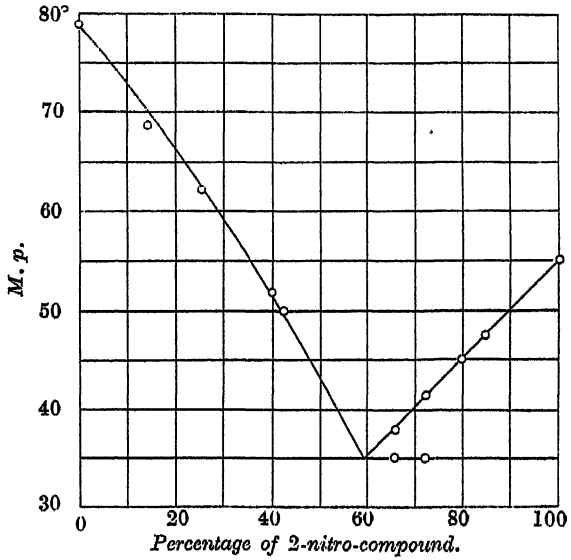
CCCXXI.—*Studies in the Nitration of Substituted Tertiary Aromatic Amines.*

By GEORGE ROGER CLEMO and JAMES MUIR SMITH.

ALTHOUGH the literature contains a great number of papers on the subject of nitration, this major reaction is still imperfectly understood. The preliminary experiments which led to this investigation were carried out several years ago by one of us (G. R. C.) and C. M. McLeod, but at the time it was not possible to pursue the subject. It has been pointed out by, amongst others, Noelting and Collin (*Ber.*, 1884, **17**, 261) and Pinnow (*Ber.*, 1894, **27**, 3161), that the products of the nitration of certain aniline derivatives vary with the amount of concentrated sulphuric acid used to dissolve the base.



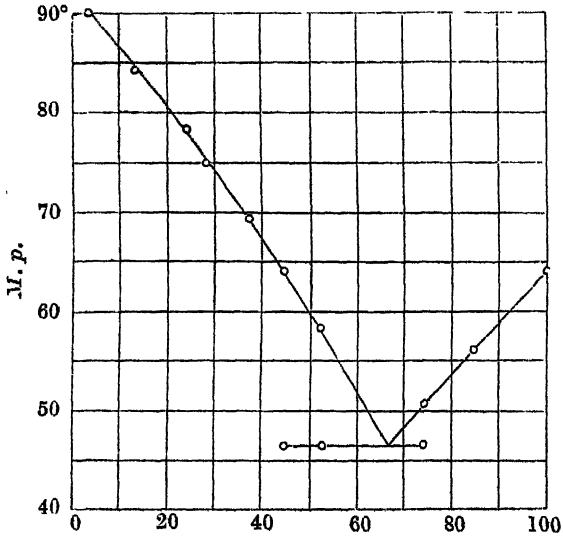
It has now been found that variation of the strength of the sulphuric acid used as the medium for the nitration has in many cases a striking effect on the particular nitro-compound formed.

The experiments of Flürscheim and Holmes on the nitration of benzyldiethylamine (J., 1926, 1562), and of Pollard and Robinson on benzylpiperidine (J., 1927, 2770), which showed that the addition of certain salts to the reaction medium had a marked effect in reducing the proportion of the *m*-nitro-compound formed, are of interest in this connexion.

The bases selected for our experiments were, in the first instance, *p*-chloro-, *p*-bromo-, and *p*-methyl-dimethylaniline, and subsequently more complicated dialkylanilines, including tetramethylbenzidine and 4 : 4′-tetramethyldiaminodiphenylmethane, were employed.

FIG. 1.

Composition–melting point curve for mixtures of 4-chloro-2-nitro- and 4-chloro-3-nitro-dimethylaniline.



Thus, *p*-chlorodimethylaniline on nitration in concentrated sulphuric acid gives a good yield of the almost pure *m*-nitro-derivative (*Ber.*, 1898, **31**, 2984), whilst in dilute sulphuric acid (75% H_2SO_4 by weight) a good yield of the pure *o*-nitro-compound results—this compound was prepared by Heidlberg (*Ber.*, 1887, **20**, 151) by the action of nitrous acid on the base. With *p*-bromodimethylaniline, approximately parallel results have been obtained, and in both cases the presence of urea inhibits ortho-nitration in dilute sulphuric acid, whilst improving the purity of the *m*-nitro-derivative when concentrated sulphuric acid is used. That the ortho- and meta-nitrations involve essentially different mechanisms for the two reactions is seen also from the fact that, in the latter case, when the

nitration mixture is removed from the cooling bath, the temperature quickly rises some degrees above that of the room, during which time the reaction is completed, whilst, in the former, nitration only occurs with rapid rise of temperature and slight effervescence some 1—4 hours after room temperature has been attained.

It was then decided to submit *p*-chloro- and *p*-bromo-dimethylanilines to a series of nitration experiments in sulphuric acid of various strengths. The analyses of the resulting nitration products were carried out according to the well-known method of Holleman (see Figs. 1 and 2), and, contrary to expectations, it has been found

FIG. 2.

Composition–melting point curve for mixtures of 4-bromo-2-nitro- and 4-bromo-3-nitro-dimethylaniline.

that the change over from the *o*- to the *m*-nitro-compound is not a gradual process. Thus the chloro-base in sulphuric acid (86% H_2SO_4) gives a product containing 92% of the *o*-compound, whilst in 92% acid a theoretical yield of the *m*-nitro-compound results. With 88 and 90% acid, however, the product is an oil containing both of the nitro-compounds and unchanged base (eutectic temperature of the two nitro-compounds, 35·1°).

The pure materials necessary for the construction of Figs. 1 and 2 were made by the above methods and crystallised from alcohol. The results of the nitrations are summarised in the following tables.

Nitration of 4-Chlorodimethylaniline in Sulphuric Acid of Various Concentrations.

Conc. of H_2SO_4 (% by weight).	Total yield of nitro-compound from 6·2 g. of base.	Proportion of 2- to 3-nitro-compound in product.

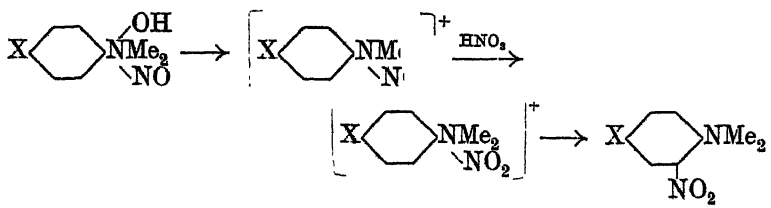
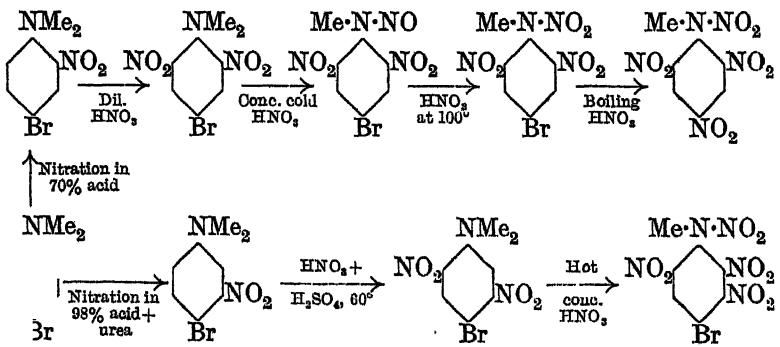
98·0 (Urea present)	7·0	4 : 96



Although no special accuracy is claimed for the figures in column 3 of the above tables, a test in which known amounts of one of the pure isomerides were added to the product of nitration gave composition values from the graph which were within 0·5% of the calculated ones. In marked contrast to the two previous cases, however, *p*-methyldimethylaniline gives a good yield of *o*-nitro-product (*Ber.*, 1895, **28**, 3041; 1897, **30**, 3119) in dilute sulphuric acid in the presence of urea, whilst nitration in concentrated acid gives the normal *m*-nitro-derivative (D.R.-P. 69188; *J. pr. Chem.*, 1902, **65**, 247). It is therefore clear that the nature of the para-substituent plays an important part in ortho-nitration.

Attention was then turned to bases having a para-substituent more powerfully *op*-directing than either Cl, Br, or CH_3, and *p*-dimethylaminobenzyl alcohol was the first selected for study. A difficulty was encountered here, however, as the literature records no suitable method for its preparation (see, however, following paper), and hence a detailed study of its nitration has not yet been carried out. Nevertheless, it has been found in preliminary exp[illegible]

ments that this alcohol undergoes nitration in 70% sulphuric acid in presence of urea so readily that the reaction is difficult to control at $-5°$. The benzoyl derivative of *p*-dimethylaminobenzyl alcohol, on the other hand, is recovered largely unchanged under these conditions. Tetramethylbenzidine readily undergoes ortho-nitration in 70% sulphuric acid in the presence of urea (*Ber.*, 1881, **14**, 2164; J., 1926, 2712), whilst in concentrated sulphuric acid meta-nitration proceeds equally easily (*Ber.*, 1904, **37**, 29), and parallel results are obtained with 4:4′-tetramethyldiaminodiphenylmethane (*Ber.*, 1894, **27**, 3161).



The explanation at present accepted for the meta-nitration of bases dissolved in concentrated sulphuric acid is that it is the kation of the ionised ammonium salt, $[R{\cdot}NMe_2H]^+$, which undergoes nitration. It is somewhat difficult to understand, however, why such a reaction should proceed smoothly in 92% sulphuric acid, but not in 90 or 88% acid, whilst with 86% acid ortho-nitration occurs, involving a different mechanism. The above explanation, if correct, leads to the curious inference that no ammonium ions are present in the 86% acid (H_2SO_4,H_2O corresponds to 84·5% H_2SO_4), since it has been shown for *p*-chloro- and *p*-bromo-dimethylaniline that the meta-nitration is more rapid than the ortho.

The inhibition by urea in the cases of the two bases just mentioned suggests strongly that nitrous acid plays a fundamental part in the nitration process. This contention is supported by the fact that many such nitro-compounds have been prepared by the action of nitrous acid on a dilute acid solution of the para-substituted dialkylaniline (*Ber.*, 1887, **20**, 151, 2460; 1898, **31**, 2982; 1918, **51**, 1036; J., 1926, 1896). In these cases, however, it is usual to obtain considerable quantities of nitrosoamines on account of the partial dealkylation of the tertiary amino-group, and the fact that these products are not formed in the cases under consideration seems to preclude the explanation that ortho-nitration is due solely to the action of nitrous acid. The best explanation which can be offered is that shown by the following scheme, which involves the prior addition of nitrous acid, followed by ionisation to give the ammonium ion, and oxidation of the nitroso- to the nitro-group, which then migrates into an unoccupied ortho-position.

The fact that urea prevents the reaction when X is Cl or Br, but not when it is $\cdot CH_3$, $\cdot CH_2\cdot OH$, $\cdot CH_2\cdot C_6H_4\cdot NMe_2(p)$, or $\cdot C_6H_4\cdot NMe_2(p)$, may be ascribed to the more acid character of the first two bases, as it is probable that urea will not react with concentrations of nitrous acid sufficient to start the process of ortho-nitration for the other (stronger) bases.

Attention was turned finally to the problem of the further nitration of some of the aforementioned mono-ortho- and -meta-nitro-compounds, and it has been found that, generally, a second nitro-group can be introduced into the *m*-nitro-derivative by nitration in sulphuric acid at 60°, and that the same dinitro-compound is formed directly when the base is treated in concentrated sulphuric acid at 60° with 2 mols. of nitric acid. In the case of *p*-bromodimethylaniline, the resulting dinitro-compound has the same melting point as the compound obtained by the bromination of 3 : 6-dinitrodimethylaniline (Forster and Coulson, J., 1922, **121**, 1995), and hence the second nitro-group in all probability occupies the 6-position. The final stage of the reaction is the production of a trinitro-nitroamine as shown below. The further nitration of the *o*-nitro-derivatives also results in the introduction of a second nitro-group in the 6-position, and the end stage in the nitration of 4-bromo-2-nitrodimethylaniline is tetryl, whilst with the corresponding chloro-base the last stage of the above reaction cannot be carried out, for the chlorine atom is not removed by boiling with fuming nitric acid.

EXPERIMENTAL.

The following general method of nitration was used in the experiments recorded in the tables on p. 2417, with the exception that all the nitration mixtures were allowed to stand together over-night at room temperature, before being poured on ice and worked up.

4-*Chloro*-2-*nitrodimethylaniline*.—4-Chlorodimethylaniline (6·2 g.;

0·04 mol.) was dissolved in sulphuric acid (20 c.c.; 75% H_2SO_4 by weight*), cooled in an ice-bath, and stirred whilst a mixture of nitric acid (2·9 c.c.; 66% HNO_3) and sulphuric acid (10 c.c.; 75% H_2SO_4) was run in during ½ hour, the temperature meanwhile being kept at 3—5°. The reaction mixture was allowed to warm to room temperature (21°), and then about 4½ hours later a rapid rise of temperature to 35° occurred, whereupon nitration took place with slight effervescence. After the temperature had fallen again, the mixture was poured on ice, neutralised with caustic soda, the red precipitate collected, well washed with water, and dried in a vacuum (6·5 g.; m. p. 56°). The product was crystallised from methyl alcohol, giving 5 g. of red prisms, m. p. 56° (corr.). If urea (2 g.) was added to the above experiment, and the nitration mixture left overnight at room temperature, 5·8 g. of chlorodimethylaniline were recovered unchanged. *4-Chloro-2-aminodimethylaniline* was obtained as an oil, b. p. 158°/22 mm., by reducing the nitro-compound with iron and hydrochloric acid (Found: N, 16·6. $C_8H_{11}N_2Cl$ requires N, 16·5%); it forms an *acetyl* derivative, colourless plates from ligroin, m. p. 90° (Found: N, 12·9. $C_{10}H_{13}ON_2Cl$ requires N, 13·1%).

4-Chloro-3-nitrodimethylaniline.—This compound was prepared by substituting an equal volume of concentrated sulphuric acid for the 75% acid used above, and nitration was completed with slight rise of temperature as soon as the mixture had reached room temperature. The yield from 6·2 g. of 4-chlorodimethylaniline was 7·5 g., which gave yellow needles (7 g.) from methyl alcohol, m. p. 79° (corr.). The same yield of rather purer nitro-compound was formed when urea was present. *4-Chloro-3-aminodimethylaniline*, obtained by the reduction of the nitro-compound with iron and hydrochloric acid, forms colourless plates from ligroin; m. p. 54° (Found: N, 16·3. $C_8H_{11}N_2Cl$ requires N, 16·5%); this compound, which darkens after a time in air, forms an *acetyl* derivative, colourless prisms, m. p. 97° (Found: N, 13·0. $C_{10}H_{13}ON_2Cl$ requires N, 13·1%).

4-Bromo-2-nitrodimethylaniline.—4-Bromodimethylaniline (8 g.; 0·04 mol.), when nitrated as described above for the corresponding chloro-base, gave 7·2 g. of product containing 92% of the 2-nitro-compound, which crystallised from methyl alcohol in orange-coloured prisms, m. p. 64° (*Ber.*, 1887, **20**, 2460) (Found: N, 11·6. Calc. for $C_8H_9O_2N_2Br$: N, 11·4%). In this case reaction set in one hour after the nitration mixture had reached room temperature (21°), but if urea was present nitration was inhibited. *4-Bromo-2-aminodimethylaniline* was obtained as an oil, b. p. 165°/23 mm., by

* All subsequent acid percentages are by weight.

reduction of the nitro-compound with iron and hydrochloric acid (Found: N, 13·05. $C_8H_{11}N_2Br$ requires N, 13·0%); its *acetyl* derivative formed colourless, glistening prisms from ligroin, m. p. 111° (Found: N, 10·7. $C_{10}H_{13}ON_2Br$ requires N, 10·9%).

4-*Bromo*-3-*nitrodimethylaniline*.—Nitration was carried out in the presence of urea as for the corresponding chloro-compound, and the product gave orange-coloured needles from methyl alcohol, m. p. 93·5° (Found: N, 11·5. $C_8H_9O_2N_2Br$ requires N, 11·4%).

3 : 3′-*Dinitro*-4 : 4′-*tetramethyldiaminodiphenylmethane*.—4 : 4′-Tetramethyldiaminodiphenylmethane (10·2 g.) and urea (4 g.) were dissolved in sulphuric acid (60 c.c.; 70%), and a mixture of nitric acid (5·8 c.c.; 66%) and sulphuric acid (20 c.c.; 70%) was added at − 5°. After standing for 1 hour at room temperature, the mixture was worked up in the usual way and gave 9·2 g. of red prisms, m. p. 121° after crystallising from acetic acid.

3 : 3′-*Dinitrotetramethylbenzidine*.—Tetramethylbenzidine (9·6 g.) was nitrated as in the preceding case and gave 7·4 g. of red needles, m. p. 188°, from acetic acid.

4-*Bromo*-2 : 6-*dinitrodimethylaniline*.—4-Bromo-2-nitrodimethylaniline (3 g.) was added in portions to nitric acid (35 c.c.; 52% HNO_3), the temperature being maintained meanwhile at 10°, and subsequently raised to 35° for ½ hour. The resulting acid solution was then gradually diluted with water until the dinitro-compound began to separate, and when precipitation was complete the solid was collected and recrystallised from alcohol, giving orange-coloured diamond-shaped plates (1 g.), m. p. 118° (Found: N, 14·2. $C_8H_8O_4N_3Br$ requires N, 14·4%). 4-Bromo-2 : 6-dinitrophenylmethylnitrosoamine (see below) was also isolated from this reaction.

4-*Bromo*-2 : 6-*dinitrophenylmethylnitrosoamine*.—4-Bromodimethylaniline (14 g.) was dissolved in sulphuric acid (56 c.c.; 50%) by warming on a water-bath. Water (48 c.c.) was then added, the solution cooled to 12°, and a mixture of nitric acid (80 c.c.; 66% HNO_3) and sulphuric acid (120 c.c.; 96%) added. After a short time a vigorous reaction set in, and the temperature was kept under 40° by cooling; the nitrosoamine then separated as small, pale yellow needles, which were collected and recrystallised from alcohol (18 g.; m. p. 124°) (Found: C, 27·9; H, 1·55; N, 18·7. $C_7H_5O_5N_4Br$ requires C, 27·6; H, 1·6; N, 18·4%).

4-*Bromo*-2 : 6-*dinitromonomethylaniline*.—This was prepared as orange-coloured needles, m. p. 104—105°, by refluxing the above nitrosoamine for 6 hours with methyl-alcoholic hydrogen chloride (Found: N, 15·8. $C_7H_6O_4N_3Br$ requires N, 15·2%).

4-*Bromo*-2 : 6-*dinitrophenylmethylnitroamine*.—4-Bromo-2 : 6-dinitrophenylmethylnitrosoamine (1 g.) was dissolved in fuming nitric

acid (15 c.c.) and heated on a water-bath for ten minutes. Water was then added, and the precipitated nitroamine collected and recrystallised from alcohol, giving pale yellow needles, m. p. 113—114°; yield 0·8 g. (Found: C, 26·3; H, 1·9. Calc. for $C_7H_5O_6N_4Br$: C, 26·2; H, 1·6%) (Blanksma, *Rec. trav. chim.*, 1902, **21**, 272).

2 : 4 : 6-*Trinitrophenylmethylnitroamine* (*Tetryl*).—4-Bromo-2 : 6-dinitrophenylmethylnitrosoamine (3 g.) was boiled under reflux with fuming nitric acid (25 c.c.) for 5½ hours, and the resulting solution cooled and poured into water. The yellow solid was collected and crystallised from alcohol, 1 g. of diamond-shaped plates being obtained, m. p. 127°, not depressed when mixed with an authentic specimen of tetryl. The compound gave 2 : 4 : 6-trinitroaniline (m. p. 186°) when treated with ammonia.

4-*Bromo*-3 : 6-*dinitrodimethylaniline*.—4-Bromodimethylaniline (6 g.) was dissolved in sulphuric acid (20 c.c.; 96%) at 40°, the solution stirred, and a mixture of nitric acid (4 c.c.; 66%) and concentrated sulphuric acid (10 c.c.) slowly added. The reaction mixture was allowed to stand over-night, then poured on ice, and neutralised with caustic soda. The precipitate consisted of a mixture of the 3-nitro- and the 3 : 6-dinitro-compound, and was separated by dissolving it in concentrated hydrochloric acid and gradually diluting the solution with water, the less basic dinitro-compound being precipitated; it crystallised from alcohol in deep red plates, m. p. 107° (compare Forster and Coulson, J., 1922, **121**, 1995).

4-*Bromo*-2 : 3 : 6-*trinitrophenylmethylnitroamine*.—Fuming nitric acid (20 c.c.) was added all at once to 4-bromo-3-nitrodimethylaniline (3 g.); a vigorous reaction took place, and when it had subsided the solution was heated for ½ hour on a water-bath and then poured on ice with stirring. The resulting yellow solid was collected, extracted with a small volume of alcohol, and the residue recrystallised from alcohol, pale yellow needles being obtained, m. p. 158° (Found: N, 19·2. Calc. for $C_7H_4O_8N_5Br$: N, 19·1%) (compare Forster and Coulson, *loc. cit.*, who, however, give m. p. 165°).

The authors are indebted to the Research Fund of the Chemical Society for a grant towards the expenses of this investigation.

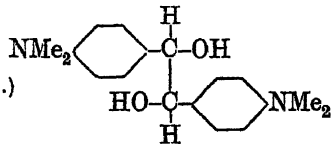
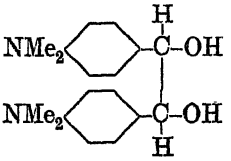
CCCXXII.—*The Reduction of* p-*Dimethylaminobenzaldehyde, and the Preparation of* p-*Dimethylaminobenzyl Alcohol.*



By GEORGE ROGER CLEMO and JAMES MUIR SMITH.

IN the course of the experiments described in the preceding paper, *p*-dimethylaminobenzyl alcohol was needed, but it was found that there is some confusion in the literature dealing with this compound, and that no satisfactory method is recorded for its preparation. Thus, Rousset (*Bull. Soc. chim.*, 1894, **11**, 318) claimed to have prepared the alcohol, colourless needles, m. p. 63°, by refluxing the corresponding aldehyde with caustic potash. Braun and Kruber (*Ber.*, 1912, **45**, 2978), however, could not repeat this work, and the present authors have also failed to obtain the alcohol by this means. Geigy and Co. (D.R.-P., 105,105) state that *p*-dimethylaminobenzyl alcohol can be isolated from the action of formaldehyde on dimethylaniline, but Cohn (*Chem.-Ztg.*, 1900, **24**, 564) contradicts the claim. Braun and Kruber, however, uphold Geigy and state that they have thus isolated the alcohol in a 2% yield as an oil which gave an oily benzoyl derivative; a *m*-nitrobenzoyl derivative, m. p. 51°; a methiodide, m. p. 126°; a picrate, m. p. 130°; and a chloroplatinate, m. p. 181°.



Rousset (*loc. cit.*) investigated the reduction of the aldehyde by sodium amalgam in alcohol, but instead of the alcohol obtained a solid, m. p. 155°. It has now been found that this solid is a mixture of two stereoisomeric s-*bis*(p-*dimethylaminophenyl*)*ethylene glycols* (I and II), one constituting about two-thirds; and that p-*dimethylaminobenzyl alcohol* can also be isolated from the reaction mixture in a 20% yield of the theoretical. The derivatives of *p*-dimethylaminobenzyl alcohol given by Braun and Kruber do not correspond in a single instance with those now obtained. Thus, it is found that the *benzoyl* derivative has m. p. 91°, the m-*nitrobenzoyl* derivative m. p. 76°, the *methiodide* 232°, and that the *chloroplatinate*, which these authors state to be insoluble in alcohol, crystallises from this medium with solvent of crystallisation, m. p. 100° (decomp.). It has not been found possible to prepare a crystalline picrate from the alcohol, but it is significant (see below) that dimethyl-*p*-toluidine gives a picrate corresponding in properties and m. p. to that given by Braun and Kruber for *p*-dimethylaminobenzyl alcohol.

The action of acids on the stereoisomeric glycols is of a complex nature and the pinacolin transformation has not yet been effected. Further, it has not been possible to prepare acetyl or benzoyl derivatives from (I) and (II). The glycol produced in greater

amount, m. p. 113°, gives a *dimethiodide*, whilst the other, m. p. 178°, under similar conditions, gives only a *monomethiodide*. No resolution experiments, however, have been attempted with a view to settling which glycol has the racemic and which the *meso*-structure.

(I.)

(II.)

The electrolytic reduction of *p*-dimethylaminobenzaldehyde has been described by Schepss (*Ber.*, 1913, **46**, 2574), who claims to have thus obtained a 41% yield of *p*-dimethylaminobenzyl alcohol as an oil which solidifies on cooling. It has now been found that in this reduction a mixture of at least the four following compounds is formed: dimethyl-*p*-toluidine, 15% of the theoretical; *p*-dimethylaminobenzyl alcohol, 20%; 4 : 4′-tetramethyldiaminodiphenylmethane; and the glycol, m. p. 178°. In all probability the glycol of m. p. 113° is also formed, but it has not been possible to isolate it from the reaction mixture.

Experimental.

p-*Dimethylaminobenzyl Alcohol.*—*p*-Dimethylaminobenzaldehyde (10 g.) was dissolved in ethyl alcohol (50 c.c.), sodium amalgam (150 g.; 4% Na) added, and the mixture refluxed for 4 hours on the water-bath. The colourless alcoholic solution was decanted into ice and water (250 g.), and the resulting colourless solid (A) was then collected, washed with water, and dried in a vacuum (7·8 g.). The filtrate was saturated with sodium chloride, extracted with ether, and after separation, drying, and fractionation, gave an almost colourless oil (1·6—1·8 g.), b. p. 123°/1 mm. (Found: C, 71·2; H, 8·65; N, 9·4. $C_9H_{13}ON$ requires C, 71·5; H, 8·6; N, 9·3%). p-*Dimethylaminobenzyl alcohol* is somewhat soluble in water, and when treated with benzoyl chloride in presence of caustic soda gives a *benzoate*, colourless prisms from ligroin, m. p. 91° (Found: C, 75·3; H, 6·9; N, 5·7. $C_{16}H_{17}O_2N$ requires C, 75·3; H, 6·7; N, 5·5%). The m-*nitrobenzoate*, on the other hand, can only be prepared by reaction in pyridine, and is obtained as pale yellow plates, m. p. 76°, by crystallising rapidly from ligroin (80°) (Found: C, 64·1; H, 5·6. $C_{16}H_{16}O_4N_2$ requires C, 64·0; H, 5·3%); it is easily soluble in dilute acids, but when its ligroin solution is heated for a short time decomposition occurs. The *methiodide* is easily formed by treating an acetone solution of the alcohol with methyl iodide, and crystallises from ethyl alcohol, in which it is sparingly

soluble, in colourless plates, m. p. 232° (decomp.) (Found : C, 41·4; H, 5·6; I, 43·4. $C_{10}H_{16}ONI$ requires C, 40·9; H, 5·5; I, 43·3%). The *chloroplatinate* forms pale brown leaflets from alcohol, containing solvent of crystallisation, m. p. 100° (decomp.) (Found : Pt, 24·8. $C_{18}H_{28}O_2N_2Cl_6Pt,2C_2H_5{\cdot}OH$ requires Pt, 24·3%).

Solid A. The combined material from three experiments (23·4 g.) was extracted with ether, leaving a solid (8 g.) which crystallised from alcohol in colourless prisms, m. p. 178° (Found : C, 72·1; H, 8·2; N, 9·2. $C_{18}H_{24}O_2N_2$ requires C, 72·0; H, 8·0; N, 9·3%). This *glycol* is sparingly soluble in alcohol, and both its alcoholic and acetic acid solutions show a blue fluorescence, whilst it gives a blood-red solution in sulphuric acid. When a hot acetone solution of the compound is treated with methyl iodide, a *monomethiodide* crystallises, and after recrystallisation from aqueous alcohol (1 : 5) gives colourless prisms, m. p. 232° (decomp.) (Found : C, 51·9; H, 6·3; I, 28·6. $C_{19}H_{27}O_2N_2I$ requires C, 51·7; H, 6·12; I, 28·8%).

On evaporation of the above ethereal extract, a colourless crystalline solid resulted (15 g.), which crystallised from alcohol–ligroin (80°) (1 : 9) in colourless needles, m. p. 113° (Found : C, 72·5; H, 8·0; N, 9·0. $C_{18}H_{24}O_2N_2$ requires C, 72·0; H, 8·0; N, 9·3%). This *glycol* is easily soluble in most organic solvents, giving blue fluorescent solutions, and a blood-red solution in sulphuric acid. When its acetone solution is treated with methyl iodide, the *dimethiodide* separates, which crystallises from alcohol in colourless plates with one molecule of alcohol of crystallisation, m. p. 97° (decomp.) (Found : I, 40·4; 40·0. $C_{20}H_{30}O_2N_2I_2,C_2H_5{\cdot}OH$ requires I, 40·3%).

Electrolytic Reduction of p-*Dimethylaminobenzaldehyde.*—A solution of *p*-dimethylaminobenzaldehyde (10 g.) in sulphuric acid (100 c.c., 20% H_2SO_4) was subjected to a current of 3 amps. in the electrolytic cell described in J., 1918, **113**, 764. The resulting colourless acid solution was made strongly alkaline, extracted with ether, and the extract left over-night, whereupon the glycol, m. p. 178° (0·5 g.), crystallised. When the ether was removed from the filtrate, and the residual oil steam-distilled, an oil rapidly passed over. This was extracted with ether, and the solution dried and fractionated, a colourless, strongly basic oil (1·3 g.) distilling at 70°/1 mm. (*p*-Dimethylaminobenzyl alcohol is but slightly volatile in steam.) The compound forms a picrate, yellow needles from alcohol, m. p. 130°, and a methiodide, colourless prisms from alcohol, m. p. 222°, and the melting points are not depressed when mixed with authentic specimens of the corresponding dimethyl-*p*-toluidine derivatives. The aqueous solution in the steam-distillation flask was decanted from the viscid oil, which was again extracted with water, the combined extract being saturated with sodium chloride and extracted

with ether. On fractionation, *p*-dimethylaminobenzyl alcohol (2·0 g.) passed over at 123°/1 mm. On cooling the viscid oil in ice for some time, a solid crystallised out and was collected and recrystallised from ligroin, forming colourless plates, m. p. 88°, not depressed by admixture with 4 : 4′-tetramethyldiaminodiphenylmethane.

NEWCASTLE-UPON-TYNE. [*Received, July 3rd*, 1928.]

CCCXXIII.—*Trypanocidal Action and Chemical Constitution. Part VIII. Derivatives of β-Aminoethyl- and γ-Aminopropyl-arsinic Acids.*

By GEORGE ALECK CROCKER GOUGH and HAROLD KING.

THE great success which has attended the treatment of diseases of protozoal and allied origin with aromatic arsenic compounds arose essentially from Ehrlich's discovery that trypanocidally active atoxyl contains arsenic directly linked to the aromatic nucleus, and is, in fact, *p*-aminophenylarsinic acid. From this starting point many aromatic arsenic compounds may be readily synthesised, and since these often show the active properties of the parent substance in an enhanced degree, the attention of chemists and pharmacologists has been directed almost exclusively to this type of compound. In the aliphatic series, the position is quite different. Apart from the work of the early pioneers, which had no primary therapeutic aim, only two important attempts have been made to develop this field—one by the French firm of Poulenc Frères and the other by R. Adams and his co-workers in America. The position, however, is still unsatisfactory, since the aliphatic compounds which have been hitherto examined for trypanocidal action are without the amphoteric characteristics which so often accompany activity in the aromatic series. Thus it is important that any new investigation in this field should include the synthesis of a series of amino-aliphatic arsinic acids, which, by reason of their small molecular weight and their similarity to the amino-acids derived from the tissues, should possess a greater power of penetration and a more favourable distribution. It was therefore decided to prepare a series of compounds of the general type $R_1R_2N\cdot[CH_2]_n\cdot AsO_3H_2$, where R_1 and R_2 are hydrogen, aliphatic, or alicyclic radicals. Two methods of synthesis of such compounds suggest themselves: (*a*) the action of sodium arsenite on chloroamines of the type $R_1R_2N\cdot[CH_2]_n\cdot Cl$ (Meyer's reaction), and (*b*) the action of amines on chloro-acids of the type $Cl\cdot[CH_2]_n\cdot AsO_3H_2$. Since no acids of the latter type have been described, an initial examination of the first method was made,

but the use of β-chloroethyldiethylamine, $CH_2Cl\cdot CH_2\cdot NEt_2$, β-bromoethyldiethylamine, and *methyl-β-chloroethyldiethylammonium chloride*, $[CH_2Cl\cdot CH_2\cdot NMeEt_2]Cl$, under various conditions, gave no indication of the formation of arsinic acids. It occurred to us, however, in view of the similarity between *p*-toluenesulphonic esters of aliphatic alcohols and the corresponding halide esters, exemplified from several aspects by Ferns and Lapworth (J., 1912, **101**, 285; compare Kenyon, Phillips, and Turley, J., 1925, **127**, 405) and by Clemo and Walton's extension (this vol., p. 723) of their use to the Friedel–Crafts reaction, that the reactivity of aliphatic toluenesulphonic esters might be applied to the preparation of aliphatic arsinic acids by treatment with sodium arsenite. Such indeed has proved to be the case, for methyl *p*-toluenesulphonate and sodium arsenite give a small yield of methylarsinic acid. In order to extend the scope of the reaction to two cases in which we were interested, an attempt was made to prepare the *p*-toluenesulphonyl ester of diethylaminoethanol and the mono-ester from trimethyleneglycol. In the first case the only product isolated was *tetraethylpiperazinium di*-p-*toluenesulphonate*,

$$\left[\begin{matrix}Et\\Et\end{matrix}\!\!>\!N\!<\!\!\begin{matrix}CH_2\cdot CH_2\\CH_2\cdot CH_2\end{matrix}\!\!>\!N\!<\!\!\begin{matrix}Et\\Et\end{matrix}\right](C_7H_7SO_3)_2,$$

characterised as its *di-iodide* and *dichloroaurate*, products which were identical with those prepared from the product of the polymerisation of β-chloroethyldiethylamine. In the second case the chief products were *trimethyleneglycol di*-p-*toluenesulphonate* and *propane-αγ-dipyridinium di*-p-*toluenesulphonate*,

$$[C_5H_5N\cdot CH_2\cdot CH_2\cdot CH_2\cdot C_5H_5N](C_7H_7SO_3)_2,$$

the latter being characterised as its *dichloride*, *dichloroaurate*, *tetramercurichloride*, and *dipicrate*. Meanwhile, further examination of this extension of the Meyer reaction has been postponed, as the synthesis of the required arsinic acids by method (*b*) has given the desired products.

This alternative method of preparation raised the problem of the synthesis of the chloro-aliphatic arsinic acids. By the interaction of ethylene and arsenious chloride in the presence of aluminium chloride, Renshaw and Ware (*J. Amer. Chem. Soc.*, 1925, **47**, 2991) prepared β-chloroethyldichloroarsine, $CH_2Cl\cdot CH_2\cdot AsCl_2$. The yield obtained by following their directions is poor and the method, although capable of improvement, was not found convenient for our purpose. As an alternative method, and one which would give access to the higher homologues, the synthesis of hydroxyalkylarsinic acids of the type $CH_2OH\cdot[CH_2]_n\cdot AsO_3H_2$ was investigated. β-Hydroxyethylarsinic acid has been prepared by the action of sodium arsenite on ethylenechlorohydrin (Poulenc Frères,

B.P. 191028, 1922; Edee, *J. Amer. Chem. Soc.*, 1928, **50**, 1394) and the reaction is also applicable to the preparation of *γ-hydroxypropylarsinic acid*. When these syrupy acids were dissolved in concentrated hydrochloric acid and reduced with sulphur dioxide in presence of hydrogen iodide, yellow oils separated which, when allowed to react with a petroleum solution of thionyl chloride, gave β-chloroethyldichloroarsine and γ-chloropropyldichloroarsine, respectively. The intermediate yellow oils were purified for chemical examination by distillation at 0·02 mm., and were then found to be the complex arsenious esters resulting from the intermolecular condensation of the primarily formed hydroxyalkyldichloroarsines. In particular, the di-ester of *γ-hydroxypropyldichloroarsine* and *γ-hydroxypropylarsinous acid* was obtained pure,

$$OH{\cdot}C_3H_6{\cdot}As\langle^{O{\cdot}C_3H_6{\cdot}AsCl_2}_{O{\cdot}C_3H_6{\cdot}AsCl_2}.$$

The higher-boiling fractions, which could not be purified, were found to contain an even larger proportion of arsenic to chlorine, and thus were probably still more highly condensed compounds of the general formula $H(OC_3H_6As)_{2n-1}Cl_{2n}$, where n is the number of times that the condensation has been effected (*e.g.*, in the above case, 2; in the compound containing 7 arsenic atoms, 3). Analysis of a sample of the freshly-prepared oil, which had not been subjected to any heat treatment, showed that the first stage of the condensation had already taken place to a large extent.

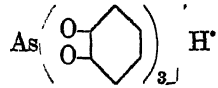
The interaction of γ-chloropropylarsinic acid and aliphatic or alicyclic amines proceeds normally to yield the corresponding substituted aminopropylarsinic acids. In this way, the arsinic acids produced by the action of ammonia, di- and tri-methylamine, *n*-propylamine, *n*-hexylamine, piperidine, 2 : 2 : 6-*trimethylpiperidine*, 3-carbethoxypiperidine, 4-hydroxy-2 : 2 : 6-trimethylpiperidine, *l*-α-phenylethylamine, and piperazine were prepared, and from these a number of substitution products. Owing to the extreme solubility of these simple arsinic acids or their hydrochlorides in water, their isolation has proved a difficult problem, but almost all have been obtained crystalline by the use of appropriate organic solvents. A common impurity which complicated the isolation is probably the corresponding non-crystalline γ-hydroxypropylarsinic acid.

The reactions of β-*chloroethylarsinic acid* were found to be in striking contrast to those of its homologue. With an excess of sodium hydroxide, dimethylamine, or any other strong base, the acid decomposes completely, forming ethylene and the corresponding arsenate and hydrochloride of the base. In the case of ammonia, where the reaction was investigated in some detail, the same decom-

position occurred in aqueous and alcoholic solution at the ordinary temperature and at 100°. When, however, ammonia or the amine was added in sufficient amount to maintain the reaction mixture neutral to litmus, normal, and generally exhaustive, substitution took place without the formation of any arsenic acid. Thus, although it was not possible to obtain such amino-acids as β-aminoethylarsinic acid, the completely substituted compounds, *triethylamine-ββ'β''-triarsinic acid*, $N(CH_2\cdot CH_2\cdot AsO_3H_2)_3$, and *methyldiethylamine-ββ'-diarsinic acid*, $NMe(CH_2\cdot CH_2\cdot AsO_3H_2)_2$ were easily obtained. In the preparation of the former compound, it was found that the ammonia could be conveniently supplied by conducting the reaction in the presence of aqueous solutions of carbamide, acetamide, or ammonium acetate, which slowly yielded the ammonia by hydrolysis. The reactive character of β-chloroethylarsinic acid is shown by the fact that some of the quaternary compound, *dimethyldiethylammonium chloride ββ'-diarsinic acid*,

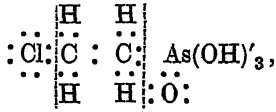
$$\left[\begin{matrix}Me\\Me\end{matrix}\!\!>\!N\!<\!\!\begin{matrix}CH_2\cdot CH_2\cdot AsO_3H_2\\CH_2\cdot CH_2\cdot AsO_3H_2\end{matrix}\right]Cl\,,$$

is formed in the preparation of *β-dimethylaminoethylarsinic acid*. The substituted arsinic acids from trimethylamine, piperidine, and piperazine were also prepared, the last forming the disubstituted piperazine,



$$AsO_3H_2\cdot CH_2\cdot CH_2\cdot N\!<\!\!\begin{matrix}CH_2\cdot CH_2\\CH_2\cdot CH_2\end{matrix}\!\!>\!N\cdot CH_2\cdot CH_2\cdot AsO_3H_2\,.$$

Whilst β-chloroethyldichloroarsine and γ-chloropropyldichloroarsine are oils, many of the amphoteric arsinic acids of both series (ethyl and propyl) form crystalline dichloroarsine hydrochlorides when sulphur dioxide is passed into a solution of the amphoteric arsinic acid in concentrated hydrochloric acid in the presence of a little hydriodic acid.



The instability of β-chloroethylarsinic acid towards bases recalls the reactions of β-chlorovinylarsinic acid (Mann and Pope, J., 1922, **121**, 1754), in which acetylene and sodium chloride and arsenate are formed by the action of sodium hydroxide. Since the use of caustic alkali in the hydrolysis of γ-chloropropylarsinic acid yields no arsenic acid, the ease of decomposition must be connected in some way with the presence of the chloro-group in the β-position to the arsinic acid grouping. This particular case of instability may be explained as an example of a general tendency of all arsinic acids. It seems probable that in alkaline solution the arsenic atom in arsinic acids tends to exert a higher co-ordination number than the normal (four), and yields complex ions by combination with one or two hydroxyl ions in which it has an outer electron shell of 10 or 12:

$$[R\cdot As\rightarrow O(OH)_3]' \text{ and } [R\cdot As\rightarrow O(OH)_4]''$$

Examples of the formation of stable compounds of a similar type are well known; *e.g.*, tripyrocatechylarsinic acid

(Rosenheim and Plato, *Ber.*, 1925, **58**, 2000). In such complex ions the arsenic–carbon linking will be weakened owing to the drift towards the carbon atom of the electron pair constituting that linking, caused by the negatively charged arsenic atom. If some decomposition can now take place which will result in the loss of two electrons from the alkyl radical (*e.g.*, the removal of a negative ion), then the two electrons forming the arsenic–carbon linking will move into the position between the α- and β-carbon atoms, with the resultant production of a double linking at this point. In the case of β-chloroethylarsinic acid, at this stage the hypothetical co-ordination compound,

consists virtually of intramolecularly ionised ethylene (Lowry, J., 1923, **123**, 822) combined with a chlorine ion and electrically neutral arsenic acid—a system which may easily become arranged into its components when the chlorine ion is removed under the influence of the sodium ions present in the solution. A similar explanation applies to the decomposition of β-chlorovinylarsinic acid.

In the case of γ-chloropropylarsinic acid, although the complex ion may be formed and the chlorine ion removed from it, the electron pair between the arsenic and the α-carbon atoms cannot move along the carbon chain to complete the octet of the terminal carbon atom, since that movement would involve the formation of a ten-electron system around the β-carbon atom. Completion of the γ-carbon octet therefore takes place in the normal way by the addition of a hydroxyl ion, with the consequent formation of γ-hydroxypropylarsinic acid.

Therapeutic Results and Considerations.

Out of more than two dozen compounds described in this communication, all of which contain one of the groups

$>N\cdot CH_2\cdot CH_2\cdot AsO_3H_2$ or $>N\cdot CH_2\cdot CH_2\cdot CH_2\cdot AsO_3H_2$,

only two proved to have any therapeutic activity, and that of a trivial nature, when tested on experimental infections of *Trypanosoma equiperdum* in mice. These were triethylamine-ββ′β″-tri-

arsinic acid, $N(CH_2 \cdot CH_2 \cdot AsO_3H_2)_3$, and γ-piperidinopropylarsinic acid, $C_5H_{10}N \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot AsO_3H_2$. For the former the maximum tolerated dose is 2·5 mg. per g. of mouse, and with a dose of 2·0 mg. the trypanosomes disappear from the peripheral blood of infected mice, but relapse occurs in 6 days; whereas for the latter the tolerated dose is 1·0 mg., and with 0·75 mg. a similar temporary "cure" is followed by relapse in 7 days. The latter compound lends itself to chemical development, but although piperidine was replaced by 2 : 2 : 6-trimethylpiperidine, 3-carbethoxypiperidine, 4-hydroxy-2 : 2 : 6-trimethylpiperidine, and piperazine, and the propyl group by the ethyl group, producing structures of similar build, there was no sign of any therapeutic activity. The results are surprising, for the majority of the compounds prepared and tested were amphoteric and extremely soluble in water—properties which should have ensured a favourable distribution in the mammalian tissues.

In seeking to arrive at some interpretation of this lack of activity, many possibilities arise, but two seem to us to be of predominant importance. Accepting the postulate that the main trypanocidal activity of active arsinic acids is due to their reduction to the corresponding oxides by the tissues, it was pointed out in Part V of this series, where another inactive series was encountered (Hewitt, King, and Murch, J., 1926, 1355; compare also Durham, Marchal, and King, *J. Pharm. Exp. Ther.*, 1926, **28**, 349), that the evidence was all in favour of the view that the inactivity of a series of aromatic arsinic acids containing the sulphonamide group, when compared with their analogously constituted active acids containing the amide group, was due to their non-reduction by the tissues to the corresponding oxides. In other words, these sulphonamide acids lay outside the zone of reduction potential of the tissues. In fact, our view is that variation of the chemotherapeutic index of derivatives of phenylarsinic acid is in part due to the variation in reduction potential produced by various substituents in the *o*-, *m*-, and *p*-positions, just as Conant and Fieser (*J. Amer. Chem. Soc.*, 1924, **46**, 1881) found that the reduction potential of quinones varies with introduction of substituents. All the acids described in this communication contain aliphatically bound arsenic with a chain of at least two methylene groups attached to the arsinic acid, and it may be that such acids are inherently difficult to reduce and that the effect on the reduction potential of wide variation of the remainder of the molecule is lost by the buffering effect of the ethylene or propylene chains.

The other possibility is that these acids are excreted from the system too readily, owing in part to their strikingly great aqueous

solubility, and in part to their lack of substantive properties for the tissues. This substantive effect of efficient medicaments, which keeps them in the body for long periods and allows them to exert a persistent and continuous action, has been emphasised in the case of Bayer 205 and its analogues (Balaban and King, J., 1927, 3078), and it undoubtedly plays an important part in the action of arsenicals (Durham, Marchal, and King, *loc. cit.*). Thus the superior activity of arseno-compounds over arsinic acids, of silver salvarsan over salvarsan, and of zinc sulpharsenol over sulpharsenol, on experimental trypanosome infections in mice, is possibly associated with such longer persistence in the body. The activity of aromatic arsinic acids and the inactivity of aliphatic arsinic acids may be due to an inherently great substantivity of the aromatic nucleus. It may be, on the other hand, that the substantivity of aromatic arsinic acids arises from the fact that, as previously suggested, they come within the zone of reduction potential of the tissues, and are accordingly reduced to the reactive oxides, and stored as such by condensation in a reversible form, whereas the aliphatic arsinic acids are non-substantive because they are outside the reduction potential of the tissues, and cannot therefore be stored as the potentially active oxides.

It is of interest that Castelli (*Arch. Schiff. Trop. Hyg.*, 1912, **16**, 605), working in Ehrlich's laboratory, found mono- and di-methylarsinic acids inactive on experimental trypanosomiasis in mice, a fact confirmed for methylarsinic acid in our laboratories, and that Ritz (*Arch. Internat. Pharmacodyn.*, 1923, **27**, 67) found allylarsinic acid to have no curative action on trypanosome infections in mice. On the other hand, Ritz found that the latter effected a temporary disappearance of *Trypanosoma brucei* in rats, on which methyl- and dimethyl-arsinic acids were inactive, whereas Voegtlin and Smith (*J. Pharm. Exp. Ther.*, 1920, **16**, 449) found methyl- and ethylarsinic acids to possess a definite action on *T. equiperdum* in rats.

We are deeply indebted to Miss F. M. Durham and Miss M. Hill, of this Department, for the painstaking care with which they have carried out the whole of the biological experiments on the toxicities of the individual arsinic acids.

Experimental.

β-*Chloroethylarsinic Acid and Derivatives.*

β-*Hydroxyethylarsinic Acid*, $CH_2OH{\cdot}CH_2{\cdot}AsO_3H_2$. — Ethylene chlorohydrin (80 g.) was slowly added to a solution of arsenious oxide (100 g.) and sodium hydroxide (120 g.) in water (300 c.c.) (compare B.P., 191028, 1922; Adams and Quick, *J. Amer. Chem. Soc.*, 1922, **44**, 811; Edee, *ibid.*, 1928, **50**, 1394). The mixture was

cooled and shaken during the addition in order to avoid loss of the chlorohydrin as ethylene oxide. After standing for 12 hours, the whole was warmed on the water-bath for 30 minutes, diluted with water (1500 c.c.), rendered acid with hydrochloric acid (Congo paper), and evaporated until a copious deposit of salt and arsenious oxide had separated. The solid was removed, washed twice with 96% alcohol, the united filtrates evaporated to dryness at 50°, and the residue extracted with alcohol (100 c.c.). On removal of the alcohol, a viscous syrup of crude β-hydroxyethylarsinic acid was left. Contrary to the statement of Edee (*loc. cit.*), this acid on treatment with a hot ammoniacal solution of calcium chloride yields a sparingly soluble *calcium* salt, crystallising from dilute solution in hexagonal leaflets (Found: Loss at 100°, 9·0; Ca, 17·1; As, 32·7, 33·6, 33·7. $C_2H_5O_4AsCa,H_2O$ requires H_2O, 8·0; Ca, 17·7; As, 33·2%).

β-*Chloroethyldichloroarsine*, $CH_2Cl{\cdot}CH_2{\cdot}AsCl_2$.—Crude β-hydroxyethylarsinic acid, prepared from 100 g. of ethylene chlorohydrin, was dissolved in concentrated hydrochloric acid (350 c.c.), potassium iodide solution (4 c.c. *N*) added, and the solution treated with sulphur dioxide below 50° until saturated. After standing for 48 hours, the lower layer was removed and dried by solution in carbon tetrachloride, followed by removal of the solvent by distillation. The crude oil (140 g.) was then mixed with an equal volume of light petroleum, and thionyl chloride (127 c.c.) added slowly. When the reaction ceased, the product was distilled first at ordinary pressure and finally under reduced pressure. In this manner there were obtained arsenious chloride, b. p. 39—41°/30 mm. (44 g.), and β-chloroethyldichloroarsine, b. p. 92—93°/32 mm. (60 g.). Renshaw and Ware (*J. Amer. Chem. Soc.*, 1925, **47**, 2991) give b. p. 90—93°/30 mm.

In repeating the preparation of β-chloroethyldichloroarsine from ethylene and arsenious chloride by the method of Renshaw and Ware (*loc. cit.*), it was found that the yield of product was very sensitive to slight alterations in the conditions of experiment. In one case in which freshly-distilled arsenious chloride (220 g.) and powdered, freshly sublimed aluminium chloride (29 g.) were treated with ethylene at 0°, an increase in weight of 27 g. was recorded with formation of β-chloroethyldichloroarsine (15 g.). Similar experiments were tried (*a*) with twice the above amount of aluminium chloride, and (*b*) with absorption of the ethylene at 50—60°. Whilst in both these cases a larger increase in the volume and weight was observed, the yield when the product was worked up by Renshaw and Ware's method was not appreciably altered. It was found, however, that a consistent yield (30 g.) could be obtained by using

the condition (*b*), provided the method of isolation was modified (compare Green and Price, J., 1921, **119**, 449). The reaction mixture was poured into ice-cold 4*N*-hydrochloric acid and evaporated under reduced pressure, the excess of arsenious chloride and the dichloroarsine volatilising without hydrolysis. The last portions of the dichloroarsine (often considerable) may be removed from the tarry residue by distillation in a current of the vapour of 4*N*-hydrochloric acid at 100° and 30 mm. The carbon tetrachloride extract of the total distillate was distilled to remove traces of water, and the residue distilled in a vacuum. The carbon tetrachloride extracts and the arsenious chloride underwent the curious sequence of colour changes noted by Renshaw and Ware; it is of interest that no trace of these coloured compounds was formed in the preparation of β-chloroethyldichloroarsine from β-hydroxyethylarsinic acid.

β-*Chloroethylarsinic Acid.*—Oxidation of the above dichloroarsine with nitric acid, by the method used by Pope and Mann (J., 1922, **121**, 1754) for the corresponding vinyl derivative, caused considerable decomposition; oxidation with chlorine in the presence of water, however, gave the chloro-acid in good yield. β-Chloroethyldichloroarsine (57 g.) was suspended in water (228 c.c.) and dissolved by the passage of chlorine below 50°. On repeated evaporation of this solution with water at 60°, followed by crystallisation of the residue from acetone, β-*chloroethylarsinic acid*, m. p. 134—135° (35 g.), was obtained as pearly plates (Found: As, 39·5. $C_2H_6O_3AsCl$ requires As, 39·8%). The maximum tolerated dose per g. of mouse is 0·2 mg.

Triethylamine-ββ′β″-triarsinic Acid.—β-Chloroethylarsinic acid (5 g.) and carbamide (6·3 g.) were heated on the water-bath with sufficient water to render the whole liquid. More water was added from time to time to liberate ammonia by hydrolysis of the carbamide. The reaction was discontinued when a sample contained no un-ionised chlorine (detected by treating a sample with excess of silver nitrate and nitric acid, filtering from silver chloride, and boiling the filtrate with excess of potassium hydroxide to hydrolyse any unreacted chloro-acid; this test was employed throughout the preparations). After excess of carbamide had been removed by extraction with boiling ethyl alcohol (30 c.c.), the residue was dissolved in water (15 c.c.) and made neutral to Congo paper. On cooling, clusters of needles of *triethylamine-ββ′β″-triarsinic acid*, m. p. 184—185°, separated (4·1 g.) (Found: As, 47·7; N, 2·7. $C_6H_{18}O_9NAs_3$ requires As, 47·6; N, 2·9%). The acid yields crystalline *calcium* and *barium* salts on treatment in ammoniacal solution with calcium and barium chlorides; the *magnesium* salt is more soluble and is amorphous. The acid is also obtained by the use of acetamide or ammonium acetate as sources of ammonia.

Methyldiethylamine-ββ′-diarsinic Acid.—β-Chloroethylarsinic acid (3 g.) and water (2 c.c.) were heated to 100°, and methylamine (33% aqueous solution) added from time to time to keep the whole neutral. When all the chlorine was ionised (15 hours), the mixture was neutralised with hydrochloric acid (Congo paper), evaporated to dryness, and freed from methylammonium chloride by boiling with ethyl alcohol. The residual gum solidified after prolonged manipulation and was crystallised from a mixture of water and alcohol. *Methyldiethylamine-ββ′-diarsinic acid*, m. p. 192—194°, thus obtained forms rectangular plates (1·9 g.) (Found: As, 42·5; N, 3·8; loss on heating at 90°, 5·2, 5·1. $C_5H_{15}O_6NAs_2,H_2O$ requires As, 42·5; N, 4·0; H_2O, 5·1%). The maximum tolerated dose is 1·5 mg.

β-*Dimethylaminoethylarsinic Acid* and *Dimethyldiethylammonium Chloride ββ′-Diarsinic Acid.*—β-Chloroethylarsinic acid (6 g.) was treated with dimethylamine in a similar manner to that employed in the previous preparation. When the reaction was complete (20 hours), the mixture was acidified with hydrochloric acid, evaporated, and freed from dimethylammonium chloride by boiling with chloroform. The residue was dissolved in the minimum volume of water, and alcohol added so long as a precipitate formed. Crystallisation of this precipitate (0·5 g.) from a mixture of alcohol and water yielded compact masses of *dimethyldiethylammonium chloride ββ′-diarsinic acid*, m. p. 178° (Found: N, 3·8; Cl, 9·4. $C_6H_{18}O_6NAs_2Cl$ requires N, 3·8; Cl, 9·2%). The maximum tolerated dose is over 3 mg.

The alcoholic filtrate from the above was concentrated to a small volume (10 c.c.), and acetone (120 c.c.) slowly added. The precipitate, on crystallisation from ethyl alcohol, yielded β-*dimethylaminoethylarsinic acid hydrochloride*, m. p. 138—140° (4·9 g.) (Found: N, 6·0; Cl, 15·2. $C_4H_{12}O_3NAs,HCl$ requires N, 6·0; Cl, 15·2%).

The above quaternary ammonium compound is more readily prepared by the direct interaction of the appropriate reagents. β-Dimethylaminoethylarsinic acid (0·23 g.) and β-chloroethylarsinic acid (0·4 g.) were melted together at 100° by the addition of a few drops of alcohol and heated for 2 days. Solution of the melt in water, followed by the addition of alcohol, yielded the required compound (0·3 g.), identical with that previously prepared.

β-*Dimethylaminoethylarsinic Acid Methochloride.*—β-Chloroethylarsinic acid (4·9 g.) was treated with trimethylamine according to the method used above. When the reaction was complete, the mixture was dried, the trimethylammonium chloride removed by boiling ethyl alcohol (20 c.c.), and the residue crystallised from methyl alcohol. β-*Dimethylaminoethylarsinic acid methochloride*, m. p. 187—188° (evolution of gas), thus obtained forms elongated

plates (Found: N, 5·7. $C_5H_{15}O_3NAsCl$ requires N, 5·7%). The maximum tolerated dose is less than 0·05 mg.

β-*Piperidinoethylarsinic Acid.*—β-Chloroethylarsinic acid (7 g.) was dissolved in ethyl alcohol (15 c.c.), and piperidine added until the mixture was neutral to litmus; it was then refluxed, and after 3 hours the reaction again adjusted to neutrality. When interaction had ceased (6 hours), the excess piperidine was removed by basification with sodium hydroxide, followed by evaporation under reduced pressure at 50° until the distillate contained no amine. The residue was made acid with hydrochloric acid, dried, and extracted with boiling ethyl alcohol. Upon concentration of the extract, β-*piperidinoethylarsinic acid hydrochloride*, m. p. 155—157°, separated as lustrous plates (7·5 g.) (Found: Cl, 13·0; N, 5·2. $C_7H_{16}O_3NAs,HCl$ requires Cl, 13·0; N, 5·1%).

For the preparation of the corresponding dichloroarsine, the piperidino-acid (1·5 g.) was dissolved in concentrated hydrochloric acid (4 c.c.) containing a trace of potassium iodide and reduced by passing in sulphur dioxide for 15 mins. The copious precipitate was removed and recrystallised from 2*N*-hydrochloric acid. β-*Piperidinoethyldichloroarsine hydrochloride* thus obtained forms square plates, m. p. 126—127° (evolution of gas), soluble in water and in ethyl alcohol (Found: As, 26·1. $C_7H_{15}NAsCl_3$ requires As, 25·5%). By treatment of this dichloroarsine, dissolved in water (0·9 c.c.), with a saturated aqueous solution of potassium iodide (2·5 c.c.), added drop by drop, bright yellow crystals of β-*piperidinoethyldiiodoarsine hydriodide*, m. p. 158—159°, were obtained (Found: As, 13·1. $C_7H_{15}NAsI_3$ requires As, 13·2%). This substance dissolves in either water or ethyl alcohol with formation of a colourless solution.

NN′-*Piperazinedi-ββ′-ethylarsinic Acid.*—β-Chloroethylarsinic acid (3 g.) was treated with piperazine hydrate until neutral to litmus, and the resulting mixture heated on the water-bath. The reaction was readjusted to neutrality after 5 hours. A slight trace of un-ionised chlorine persisted after 20 hours' heating. The liquid was concentrated to 10 c.c. and acidified with hydrochloric acid. When the sides of the vessel were rubbed, hexagonal plates of NN′-*piperazinedi-ββ′-ethylarsinic acid dihydrochloride* separated. For analysis and physiological assay, they were recrystallised from 15 c.c. of boiling water; yield, 2·3 g. (Found: As, 32·2; Cl, 15·4. $C_8H_{20}O_6N_2As_2,2HCl$ requires As, 32·4; Cl, 15·3%). This salt is unmelted at 280°, but darkens progressively from 220° upwards. The maximum tolerated dose is 2·5 mg.

β-*Chloroethyldiethylamine*, $CH_2Cl{\cdot}CH_2{\cdot}N(C_2H_5)_2$, was prepared by a modification of the method given in B.P., 167781 of 1921.

β-Diethylaminoethanol (59 g.), dissolved in chloroform (100 c.c.), was added slowly to a mixture of thionyl chloride (120 g.) and chloroform (500 c.c.) cooled to −5°. After standing for an hour, most of the chloroform was removed on the water-bath, and the residue evaporated twice with alcohol under reduced pressure. Crystallisation of the product from alcohol–ether gave stout needles of β-chloroethyldiethylamine hydrochloride, m. p. 210—211° (69 g.). Concentration of the mother-liquors gave a further quantity (13 g.). Treatment of the amine hydrochloride (0·5 g.) in water (5 c.c.) with a hot saturated solution of picric acid (0·68 g.) in water yielded the *picrate*, m. p. 116—117°, which crystallised in a compact form from hot solutions, and in needles from cooler solutions. The *chloroaurate*, m. p. 68—71° (somewhat indefinite), crystallises from *N*-hydrochloric acid in hexagonal tablets (Found: Au, 41·1. $C_6H_{14}NCl,HAuCl_4$ requires Au, 41·4%). When the free amine, b. p. 51—52°/16 mm., was kept with an equal volume of absolute alcohol, crystals of 1 : 4-tetraethylpiperazinium dichloride (1 g.) separated, which, when treated with saturated potassium iodide solution (2·5 g. KI), yielded elongated plates of the corresponding di-iodide, identical with that obtained by the interaction of β-diethylaminoethanol and *p*-toluenesulphonyl chloride (see below). No indication of the formation of arsinic acids was obtained by the treatment of β-chloroethyldiethylamine with sodium arsenite under the conditions employed for the preparation of β-hydroxyethylarsinic acid (see above). The amine was largely unattacked, but small amounts of β-diethylaminoethanol and of an unsaturated amine were detected.

Methyl-β-chloroethyldiethylammonium Iodide.—Upon mixing β-chloroethyldiethylamine (26·3 g.) with methyl iodide (3·5 g.) an immediate turbidity was produced and after ½ hour the whole became solid. The excess of methyl iodide was then removed and the residue (51 g.) crystallised from methyl alcohol. *Methyl-β-chloroethyldiethylammonium iodide* thus prepared crystallises in colourless plates, m. p. 219—220°, which are slightly deliquescent and tend to become yellow or red on exposure to air, when wet with solvent (Found: I, 46·1. $C_7H_{17}NClI$ requires I, 45·7%). When treated with sodium hydroxide solution (50%), a concentrated solution of the quaternary salt (80%) yielded an oil, which became solid when the alkali was added in excess. This was found to be the original quaternary iodide liberated unchanged from solution by the "salting out" effect of the sodium hydroxide. Saturated solutions of sodium carbonate and of potassium acetate, but not those of calcium or barium chloride, exert a similar effect.

Methyl-β-chloroethyldiethylammonium chloride was prepared by treating a solution of the iodide (23·5 g.) in water (100 c.c.) with

freshly prepared silver chloride (28 g.) for 20 minutes. The silver iodide was then removed and the liquid stirred with a further quantity of silver chloride (12 g.) for 1 hour to ensure complete conversion. Removal of the water and the silver halides yielded the *chloride* as a mass of highly deliquescent needles, part of which was converted into the *chloroaurate*, m. p. 202—204°, which crystallised from 0·5*N*-hydrochloric acid in fine needles (Found: Au, 40·3. $C_7H_{17}NCl,AuCl_4$ requires Au, 40·3%). No arsinic acid could be isolated by interaction of this chloride and sodium arsenite.

Reaction between Sodium Arsenite and Methyl p-*Toluenesulphonate.*—Methyl *p*-toluenesulphonate (14·2 g.) was stirred at 100° with arsenious oxide (7·2 g.) dissolved in 22 c.c. of 10*N*-sodium hydroxide for 3 hours. When cool, the sodium *p*-toluenesulphonate was removed, and the filtrate treated with just insufficient alcohol to precipitate an oil. On keeping, a small crop of sodium methylarsinate separated in rhombs mixed with fine needles of sodium toluenesulphonate. These could be separated mechanically, and the sodium methylarsinate agreed in all its properties with a specimen prepared from methylarsinic acid. It is, however, preferable to isolate methylarsinic acid as its calcium salt. After removal of sodium toluenesulphonate, the reaction mixture was made slightly acid to Congo paper and evaporated to dryness. On dissolving the residue in water, arsenic trioxide remained undissolved and could be completely eliminated by repetition of the process. Wholly crystalline calcium methylarsinate (1·5 g.) could then be precipitated from a hot ammoniacal solution by excess of calcium chloride. For analysis, the product was dissolved in hydrochloric acid, treated with calcium chloride and reprecipitated from hot dilute solution by excess of ammonia. It then crystallised in microscopic plates (Found: Ca, 20·3. Calc. for CH_3O_3AsCa,H_2O: Ca, 20·5%) having the formula given by Klinger and Kreutz (*Annalen*, 1888, **249**, 152).

Interaction of p-*Toluenesulphonyl Chloride and* β-*Diethylaminoethanol.*—Dry diethylaminoethanol (5·8 g.) was treated with a solution of *p*-toluenesulphonyl chloride (9·5 g.) in benzene (30 c.c.) at 0°. After standing over-night, the solid which had separated was removed and crystallised from ethyl alcohol. In this way there were obtained elongated, hexagonal plates of *tetraethylpiperazinium di*-p-*toluenesulphonate*, m. p. 300—301° (decomp.) (Found: N, 5·4. $C_{26}H_{42}O_6N_2S_2$ requires N, 5·2%). Upon treatment of this salt (1 g.) with a saturated solution of potassium iodide (2·5 g.) in water, long needles of the corresponding *di-iodide*, unmelted at 300°, separated (Found: I, 55·7; N, 6·1. $C_{12}H_{28}N_2I_2$ requires I, 56·9; N, 6·2%). Treatment of the di-*p*-toluenesulphonate (0·1 g.), dissolved in hot 2*N*-hydrochloric acid (40 c.c.), with auric chloride

gave large, square plates of *tetraethylpiperazinium dichloroaurate* (Found: Au, 45·0. $C_{12}H_{28}N_2Au_2Cl_8$ requires Au, 44·9%). Both this substance and the iodide were found to be identical with the corresponding derivatives prepared from the tetraethylpiperazinium dichloride (see above) formed by the polymerisation of free β-chloroethyldiethylamine. The specimen of the chloroaurate prepared in this way gave similar figures on analysis (Found: Au, 44·9%).

γ-Chloropropylarsinic Acid and Derivatives.

γ-Trimethylene Chlorohydrin.—Preparation of the chlorohydrin from trimethylene glycol and hydrochloric acid by the method of Hultman, Davis, and Clarke (*J. Amer. Chem. Soc.*, 1921, **43**, 369) was found not as satisfactory as the following process based on the method used by Carius (*Annalen*, 1862, **124**, 257) for the preparation of ethylene chlorohydrin: Sulphur monochloride (2200 g.) was added with vigorous stirring to trimethylene glycol (1000 g.) heated to 70°, at such a rate that the evolved gases could be easily absorbed. After stirring for a further 2 hours, the mixture was cooled and filtered from suspended sulphur. Distillation of the filtrate yielded impure trimethylene dichloride (40 g.) and trimethylene chlorohydrin, b. p. 74—76°/23 mm. (850 g.).

γ-Hydroxypropylarsinic Acid.—Trimethylene chlorohydrin (95 g.) was stirred with sodium arsenite solution (100 g. As_2O_3 and 120 g. NaOH dissolved in 300 c.c. of water) at 50—60° until homogeneous. The liquid was then diluted with an equal volume of water, neutralised to Congo paper, and evaporated to dryness at 50°. Extraction of the residue with hot alcohol (150 c.c.) yielded, after removal of the alcohol, a syrup of impure *γ-hydroxypropylarsinic acid*. This acid yields a crystalline *calcium* salt (Found: As, 33·2. $C_3H_7O_4AsCa$ requires As, 33·8%).

γ-Chloropropyldichloroarsine.—γ-Hydroxypropylarsinic acid (from 95 g. of trimethylene chlorohydrin) was dissolved in concentrated hydrochloric acid (250 c.c.), containing potassium iodide (0·3 g.), and sulphur dioxide passed to saturation, the temperature being kept below 40°. After standing for 2 days, the lower layer (85 g.) was separated and dried by distilling carbon tetrachloride from it. It was then mixed with light petroleum (90 c.c.), and thionyl chloride (56 c.c.) added with cooling and agitation. After refluxing for 2 hours, the petroleum was removed and the residue distilled. In this manner there were obtained arsenious chloride, b. p. 45°/32 mm. (13 g.), and *γ-chloropropyldichloroarsine*, b. p. 120—122°/16 mm. (70 g.) (Found: As, 33·5. $C_3H_6AsCl_3$ requires As, 33·6%).

γ-Chloropropylarsinic Acid.—Chlorine was passed into a suspension of γ-chloropropyldichloroarsine (40 g.) in water (160 g.) until solution

was complete. By repeated evaporation of the solution with water, followed by crystallisation of the residue from water, elongated hexagonal plates of *γ-chloropropylarsinic acid*, m. p. 146—148°, were obtained (Found: As, 37·1. $C_3H_8O_3AsCl$ requires As, 37·0%). This acid yields crystalline *barium* and *calcium* salts with ammoniacal barium and calcium chlorides. The maximum tolerated dose is 0·1 mg.

The Reaction between γ-Hydroxypropylarsinic Acid and Sulphur Dioxide.—The oil which separated when the hydroxy-acid was treated with sulphur dioxide in hydrochloric acid solution was dried as already described. Complete decomposition occurred at 140° when the oil was heated at 15 mm.; at 0·15 mm., however, there was little decomposition and the crude product (15 g.) gave a very volatile substance (arsenious chloride), a light yellow, mobile liquid, b. p. 34—35° (8·5 g.), a darker liquid, b. p. 35—75°, and a residue (5·2 g.). The second fraction was redistilled, b. p. 35°/0·16 mm., and left only a minute residue. Analysis showed it to be the *di-ester* of *γ-hydroxypropyldichloroarsine* and *γ-hydroxypropylarsinous acid*, $(AsCl_2{\cdot}C_3H_6{\cdot}O)_2As{\cdot}C_3H_6{\cdot}OH$ (Found: As, 41·3; Cl, 26·6. $C_9H_{19}O_3As_3Cl_4$ requires As, 41·5; Cl, 26·2. γ-Hydroxypropyldichloroarsine, $C_3H_7OAsCl_2$, requires As, 36·6; Cl, 34·6%). The third fraction and the residue appeared to contain small amounts of more complex condensation compounds (Found: In the third fraction, As, 41·3; in the residue, As, 42·3%). The ester, b. p. 35°/0·16 mm. (10 g.), on treatment with thionyl chloride (8 c.c.) at 0° yielded finally γ-chloropropyldichloroarsine (4·9 g.).

γ-Aminopropylarsinic Acid.—γ-Chloropropylarsinic acid (7 g.) was found to react completely with ammonia (*d* 0·88; 50 c.c.) without the production of arsenic acid, when heated at 110° for 8 hours. After the excess of free ammonia had been removed by warming under reduced pressure, the product was made alkaline with sodium hydroxide and distilled at 50° until the distillate was neutral. The residue was then made acid (Congo paper) with hydrochloric acid, evaporated to dryness, and the organic matter separated from the salt by extraction with alcohol. After removal of the alcohol, the residue was dissolved in water, neutralised to litmus paper with sodium hydroxide, evaporated to dryness, and extracted with pure methyl alcohol. Gradual addition of acetone to the extract yielded the amino-acid which was now sparingly soluble in methyl alcohol. It was freed from a trace of a substance containing ionic chlorine by boiling with a little methyl alcohol. *γ-Aminopropylarsinic acid*, m. p. 212—214° (evolution of gas), obtained in this way, forms compact, microscopic prisms which are extremely soluble in water, but insoluble in ethyl alcohol (Found: N, 7·5. $C_3H_{10}O_3NAs$ requires N, 7·6%). The maximum tolerated dose is 0·4 mg.

γ-Dimethylaminopropylarsinic Acid.—γ-Chloropropylarsinic acid (6 g.) was heated with a methyl-alcoholic solution of dimethylamine (6 c.c. of 33%) at 110° for 8 hours and the excess of amine removed by distillation with sodium hydroxide solution under reduced pressure. The residue was acidified with hydrochloric acid, evaporated to dryness at 50°, and extracted with alcohol. Gradual addition of acetone to this gave a precipitate, which was removed and recrystallised from ethyl alcohol (6 c.c.). *γ-Dimethylaminopropylarsinic acid hydrochloride*, m. p. 108—110°, thus obtained forms slightly deliquescent needles (Found: Cl, 14·4; N, 5·7; As, 30·4. $C_5H_{14}O_3NAs,HCl$ requires Cl, 14·3; N, 5·7; As, 30·3%). The maximum tolerated dose is 0·4 mg.

γ-Dimethylaminopropylarsinic Acid Methochloride.—The chloro-acid (6 g.) was heated with trimethylamine (30 c.c. of 33% aqueous solution) at 100°. After 3 hours the water and excess of amine were removed and the residue extracted with chloroform (30 c.c.) to remove trimethylammonium chloride. The residue, which solidified on being kept for 2 days, was dissolved in the minimum volume of water at 70°, and ethyl alcohol added at that temperature until a turbidity was produced. On cooling, compact prisms of *γ-dimethylaminopropylarsinic acid methochloride* separated, m. p. 174—176° (Found: Cl, 13·5; N, 5·4. $C_6H_{17}O_3NAsCl$ requires Cl, 13·6; N, 5·4%), which did not yield a sparingly soluble picrate or chloroaurate. The maximum tolerated dose is 0·3 mg.

γ-n-Propylaminopropylarsinic Acid.—γ-Chloropropylarsinic acid (6 g.) was refluxed with alcohol (40 c.c.) and *n*-propylamine (10 g.; 6 mols.) for 12 hours. When the reaction was complete, the excess amine and alcohol were removed, first by distillation alone and then with sodium hydroxide under reduced pressure. The residue, when acidified with hydrochloric acid, dried, and extracted with alcohol, yielded *γ-n-propylaminopropylarsinic acid hydrochloride*, m.p. 210—212° (Found: As, 28·2; N, 5·3; Cl, 13·6. $C_6H_{16}O_3NAs,HCl$ requires As, 28·6; N, 5·4; Cl, 13·6%). The maximum tolerated dose is 0·5 mg. The acid, prepared by treatment of the hydrochloride (0·47 g.) with sodium hydroxide (1 mol.) followed by evaporation to dryness, was extracted from the residue with methyl alcohol (2 c.c.); on addition of ethyl alcohol (12 c.c.), in which it is insoluble, needles of *γ-n-propylaminopropylarsinic acid*, m. p. 222—224°, slowly separated (Found: N, 6·1. $C_6H_{16}O_3NAs$ requires N, 6·2%). The acid is neutral to litmus, and yields a white, basic arseno-compound on warming with hypophosphorous acid containing a trace of potassium iodide.

m-Nitrobenzopropylamidopropylarsinic Acid.—*γ-n*-Propylamino-propylarsinic acid hydrochloride (1·5 g.), dissolved in 2*N*-sodium

hydroxide (9 c.c.), was shaken with powdered *m*-nitrobenzoyl chloride (1·45 g.). After 10 minutes equal additional quantities of the latter two reagents were introduced. After further shaking, the mixture was acidified with hydrochloric acid and the resultant system of oil, solid, and water extracted thrice with ether. The oil and the aqueous portion were then evaporated to dryness and extracted with ethyl alcohol. Evaporation of the alcohol left an oil which crystallised after long contact with ethyl acetate. Crystallisation of this solid from aqueous alcohol yielded m-*nitrobenzopropylamidopropylarsinic acid*, m. p. 132—134° (Found: As, 19·9. $C_{13}H_{19}O_6N_2As$ requires As, 20·0%). The corresponding *benzoyl* compound is an oil which could not be crystallised.

γ-n-*Propylaminopropyldichloroarsine Hydrochloride.*—A solution of the amino-acid hydrochloride (1 g.) in concentrated hydrochloric acid (4 c.c.) containing a trace of potassium iodide was treated with sulphur dioxide until saturated. The crystals which separated on chilling were removed and recrystallised from concentrated hydrochloric acid (5 c.c.) with sufficient water to complete solution at the boiling point. γ-n-*Propylaminopropyldichloroarsine hydrochloride*, m. p. 195—196°, thus obtained forms elongated hexagonal tablets, which rapidly reduce a solution of iodine in potassium iodide and yield a yellow solid on treatment with saturated potassium iodide solution (Found: As, 26·4. $C_6H_{14}NAsCl_2,HCl$ requires As, 26·6%). The maximum tolerated dose is 0·0075 mg. It rendered trypanosomes non-infective at a dilution of 1 : 40,000 in horse-serum after 4·5 hours' contact.

γ-n-*Hexylaminopropylarsinic Acid.*—The chloro-acid (6 g.) and *n*-hexylamine (18 g.) were heated at 100° for 20 hours. After removal of the excess of amine, by distillation first under reduced pressure and then in the presence of sodium hydroxide, the residue was acidified with hydrochloric acid, evaporated to dryness, and extracted with ethyl alcohol (15 c.c.). The crystalline product, obtained by cooling the extract in ice, was recrystallised from ethyl alcohol and then yielded short, flat plates of γ-n-*hexylaminopropylarsinic acid hydrochloride*, m. p. 221—223° (6·2 g.). The maximum tolerated dose is 0·025 mg. The m-*nitrobenzoyl* derivative, m. p. 118—120°, prepared from the amino-acid hydrochloride (3·5 g.), *m*-nitrobenzoyl chloride (4·4 g.), and 2*N*-sodium hydroxide (35 c.c.) by the method already described, formed white plates (Found: As, 18·4. $C_{16}H_{25}O_6N_2As$ requires As, 18·0%). The maximum tolerated dose is less than 0·025 mg. The corresponding m-*aminobenzoyl* compound, formed by reduction with ferrous hydroxide, could not be obtained in a crystalline state either free or as the hydrochloride.

γ-Carbethoxy-n-*hexylaminopropylarsinic Acid.*—Ethyl chloroformate (1·2 g.) was added in small amounts with vigorous stirring to an ice-cold solution of the amino-acid (1 g.) in *N*-sodium hydroxide (6 c.c.). When the odour of the chloroformate had disappeared, the solution was acidified with hydrochloric acid and the precipitated oil removed. After prolonged manipulation and keeping at −5°, this solidified and was crystallised from ether–light petroleum. *γ-Carbethoxy*-n-*hexylaminopropylarsinic acid*, m. p. 58—60°, thus obtained, formed long, flat plates (Found: N, 4·1. $C_{12}H_{26}O_5NAs$ requires N, 4·1%). The maximum tolerated dose is 0·005 mg.

γ-Phenylcarbamyl-n-*hexylaminopropylarsinic Acid.*—Phenylcarbimide (4 g.) was added drop by drop to an ice-cold solution of the amino-acid hydrochloride (3 g.) in *N*-sodium hydroxide (25 c.c.) with vigorous stirring. The diphenylcarbamide that separated was removed and the filtrate made acid (Congo paper). The precipitated oil, which solidified after long keeping at 0°, was crystallised from aqueous alcohol and yielded *γ-phenylcarbamyl*-n-*hexylaminopropylarsinic acid*, m. p. 118—124° (indef.). The maximum tolerated dose is 0·01 mg.

γ-n-*Hexylaminopropyldichloroarsine hydrochloride*, prepared in a similar manner to that employed for the corresponding propyl compound from the amino-acid hydrochloride (3 g.) and concentrated hydrochloric acid (30 c.c.), forms large hexagonal plates, m. p. 190—192°, when crystallised from 2*N*-hydrochloric acid (100 c.c.) (Found: As, 23·1. $C_9H_{20}NAsCl_2,HCl$ requires As, 23·1%).

l-*α*-*Phenylethylaminopropyldichloroarsine Hydrochloride.*—The interaction of *l*-*α*-phenylethylamine (3·1 g.) and the chloro-acid (1·5 g.) was carried out in a manner similar to that employed for the preparation of the hexylamino-acid. The product, which remained as a glassy gum, could not be obtained pure and was converted directly into the dichloroarsine by treatment with hydrochloric acid and sulphur dioxide. The precipitate was crystallised from 2*N*-hydrochloric acid and the l-*α*-*phenylethylaminopropyldichloroarsine hydrochloride*, m. p. 194—196°, thus obtained, formed large hexagonal plates (Found: As, 21·9. $C_{11}H_{16}NAsCl_2,HCl$ requires As, 21·8%). The maximum tolerated dose is 0·005 mg.

γ-Piperidinopropylarsinic Acid.—A mixture of the chloro-acid (6 g.) and piperidine (26 g.) was heated for 6 hours at 100°, crystals of piperidine hydrochloride being deposited almost immediately. When the chlorine was completely ionised, the excess of free and combined piperidine was removed, the residue acidified with hydrochloric acid, and evaporated to dryness at 50°. The ethyl-alcoholic extract of the residue, when concentrated and chilled, deposited crystals which were recrystallised from boiling alcohol. *γ-Piperidino-*

propylarsinic acid hydrochloride thus obtained (5 g.) formed square plates, m. p. 162—164° (Found: N, 4·8; Cl, 12·4. $C_8H_{18}O_3NAs,HCl$ requires N, 4·9; Cl, 12·3%).

γ-Piperidinopropyldichloroarsine hydrochloride was prepared by treatment of the acid hydrochloride (3 g.), dissolved in concentrated hydrochloric acid (9 c.c.), with sulphur dioxide. The precipitated solid yielded hexagonal plates, m. p. 194—196° (2·4 g.), when crystallised from 4*N*-hydrochloric acid. The maximum tolerated dose is 0·01 mg.

γ-4-Hydroxy-2 : 2 : 6-trimethylpiperidinopropylarsinic Acid.—The chloro-acid (2 g.) was heated with vinyldiacetonealkamine (6·9 g.) and ethyl alcohol (20 c.c.) for 2 days. After basification with sodium hydroxide, followed by evaporation to dryness, the excess of amine was removed by exhaustive extraction with benzene, and the residue dissolved in water and made neutral to methyl-orange. The liquid was then evaporated to dryness and extracted with boiling methyl alcohol. On concentration of the extract, white, microscopic crystals separated. Recrystallisation of these from methyl alcohol yielded deliquescent *γ-4-hydroxy-2 : 2 : 6-trimethylpiperidinopropylarsinic acid*, m. p. 162° (Found: N, 4·7. $C_{11}H_{24}O_4NAs$ requires N, 4·5%). The maximum tolerated dose is 0·2 mg.

γ-2 : 2 : 6-Trimethylpiperidinopropylarsinic Acid and 2 : 2 : 6-Trimethylpiperidine.—4-Bromo-2 : 2 : 6-trimethylpiperidine hydrobromide (44 g.), prepared from vinyldiacetonealkamine by the method of Pauly and Harries (*Ber.*, 1898, **31**, 667), was reduced by heating with glacial acetic acid (240 c.c.) and zinc dust (66 g.) for 6 hours. The solids were then removed and washed with hot acetic acid. The acid was then removed from the combined filtrates by distillation under reduced pressure, and the basified residue distilled in a current of steam until the distillate was neutral. The ethereal extract of the latter distillate yielded *2 : 2 : 6-trimethylpiperidine*, b. p. 138—139° (20 g.); *hydrochloride*, m. p. 236—237° (Found: Cl, 21·6. $C_8H_{17}N,HCl$ requires Cl, 21·7%). The following characteristic colour reactions are given by addition of this and similar amines (0·02 c.c.) to a 0·5% solution of sodium nitroprusside (20 c.c.) containing acetaldehyde (0·02 c.c.) (Lewin, *Ber.*, 1899, **32**, 3388): piperidine, initially violet-blue, unchanged after 4 hours; 2 : 2 : 6-trimethylpiperidine, initially wine-red, finally magenta; 3-carbethoxypiperidine, initially blue, finally green. The *chloroaurate*, prepared by treating a solution of the amine (0·1 g.) in 2*N*-hydrochloric acid (4 c.c.) with aqueous auric chloride until no further turbidity was produced, followed by crystallisation of the oil from *N*-hydrochloric acid, forms octahedra, m. p. 127—129° (Found: Au, 42·0. $C_8H_{17}N,HAuCl_4$ requires Au, 42·2%). The

picrate, prepared by the action of saturated aqueous picric acid on the amine (0·1 g.), followed by crystallisation of the precipitated oil from water, forms well-developed rhombs, m. p. 195—196°. For the preparation of the substituted aminopropylarsinic acid, γ-chloropropylarsinic acid (2·5 g.) was heated on the water-bath with the amine (10 g.) and alcohol (10 c.c.) for 6 hours. The solvent and free amine were then removed by distillation in the presence of sodium hydroxide, and the residue acidified with hydrochloric acid and evaporated to dryness. The ethyl-alcoholic extract of this yielded the amino-acid hydrochloride, which could not be obtained in a crystalline state; it was therefore converted into the free acid by adjusting the reaction to neutrality to litmus, evaporating the water, and extracting the residue with boiling methyl alcohol. Addition of dry ether to this extract yielded deliquescent, microscopic crystals of *γ-2 : 2 : 6-trimethylpiperidinopropylarsinic acid*, m. p. 150—160° (indef.) (Found: N, 4·4. $C_{11}H_{24}O_3NAs$ requires N, 4·8%). The maximum tolerated dose is 2·0 mg.

γ-Piperazinopropylarsinic Acid.—The product obtained by heating the chloro-acid (4 g.) with piperazine hydrate (24 g.) at 100° for 20 hours, was freed from piperazine by distillation in a current of steam at 100° under reduced pressure in the presence of sodium hydroxide. When the distillate no longer gave a precipitate with picric acid, the residue was acidified with hydrochloric acid (Congo paper), dried, and extracted with boiling ethyl alcohol. Upon concentration and cooling of the extract, a thick syrup separated which slowly solidified. Crystallisation of this from ethyl alcohol (30 c.c.) yielded *γ-piperazinopropylarsinic acid dihydrochloride* (Found: Cl, 21·9. $C_7H_{17}O_3N_2As,2HCl$ requires Cl, 21·8%). The maximum tolerated dose is 2·0 mg. The benzoyl derivative was obtained by the Schotten–Baumann method from the amino-acid hydrochloride (3·3 g.), benzoyl chloride (3·0 g.), and 2*N*-sodium hydroxide (35 c.c.). After the benzoic acid had been removed from the acidified reaction mixture by extraction with ether, the residue was evaporated to dryness and extracted with ethyl alcohol. This extract yielded a white solid which, when crystallised from aqueous acetone, yielded *γ-4-benzoylpiperazinopropylarsinic acid*, m. p. 204—206° (decomp., eff.) (Found: N, 8·0. $C_{14}H_{21}O_4N_2As$ requires N, 7·9%). The maximum tolerated dose is 0·2 mg.

γ-3-Carbethoxypiperidinopropylarsinic Acid.—The chloro-acid (3·1 g.) was heated with ethyl nipecotinate (15·7 g.) (prepared from nicotine by the method of Adams and McElvain, *J. Amer. Chem. Soc.*, 1923, **45**, 2745) for 15 hours at 90°. The ethyl nipecotinate was then removed by adding sodium hydroxide (8 c.c.; 40%) to a solution of the product in water (30 c.c.) at 0°, followed by extraction

with ether. The aqueous residue was then made acid with hydrochloric acid (methyl-orange) and evaporated to dryness at 50°. Extraction of this solid with boiling methyl alcohol (20 c.c.), followed by the addition of ethyl alcohol, yielded the desired amino-acid in an impure condition. For analysis and physiological testing, it was dissolved in methyl alcohol (15 c.c.) and poured into dry ether (120 c.c.). *γ-3-Carbethoxypiperidinopropylarsinic acid* thus obtained was dried in a vacuum in the presence of sulphuric acid and sodium hydroxide and ground under dry ether; it then formed an amorphous, deliquescent solid (Found: N, 4·3; As, 22·9. $C_{11}H_{22}O_5NAs$ requires N, 4·3; As 23·2%). The maximum tolerated dose is 1·5 mg.

Interaction of Trimethylene Glycol and p-*Toluenesulphonyl Chloride in the Presence of Pyridine.*

p-Toluenesulphonyl chloride (19 g.) was added in small portions to a mixture of trimethylene glycol (4 g.) and pyridine (8 g.) at 0°. Crystals of pyridine hydrochloride filled the liquid after about ½ hour, but became smaller in bulk after 20 hours, whereupon the whole was treated with water (100 c.c.). The oil which separated was removed and washed twice with dilute hydrochloric acid and with water. Since it possessed a pronounced smell of trimethylene dichloride, it was distilled with water under reduced pressure. By this treatment a small amount of volatile oil was obtained which, when extracted with ether and dried, gave trimethylene dichloride, b. p. 120—122°. The semi-solid residue of the steam distillation, after being dried in a vacuum, was extracted with ether, and the insoluble portion crystallised from methyl alcohol (6 c.c.). It separated in hexagonal plates (2·5 g.) which proved to be *trimethylene glycol di-p-toluenesulphonate*, m. p. 93—94° (Found: C, 52·8; H, 5·4. $C_{17}H_{20}O_6S_2$ requires C, 53·1; H, 5·3%). The aqueous extract of the original reaction mixture was freed from pyridine by distillation with sodium hydroxide under reduced pressure, concentrated (to 20 c.c.), and made neutral to litmus with hydrochloric acid; addition of saturated aqueous mercuric chloride solution then yielded a crystalline *mercury* salt, which in turn afforded an amine hydrochloride in the usual way. For examination of the properties of this amine the original reaction was conducted under modified conditions calculated to favour the production of a quaternary compound. Trimethylene glycol (4 g.) and pyridine (8 g.) were mixed with *p*-toluenesulphonyl chloride (19 g.) in a single addition and the reaction was allowed to proceed without cooling. When the reaction had subsided, the mixture was warmed on the water-bath for 2 hours. The crop of large, crystalline plates which separated

on cooling was washed with ether to remove pyridine and crystallised from acetone (30 c.c.). The deposited crystals (3·1 g.) were free from ionised chlorine and proved to be *propane-αγ-dipyridinium di-p-toluenesulphonate*, m. p. 118—120° (Found : N, 5·2. $C_{27}H_{30}O_6N_2S_2$ requires N, 5·2%). When treated with a saturated aqueous solution of mercuric chloride, this substance is converted into the corresponding *mercurichloride*. Crystallisation of the precipitated salt from boiling water gave a product from which the mercuric chloride was found to have partly dissociated (Found : Cl, 26·1; Hg, 57·5. $C_{13}H_{16}N_2Cl_2,4HgCl_2$ requires Cl, 26·1; Hg, 59·1%); but crystallisation in the presence of an excess of mercuric chloride yielded clusters of radiating needles of the pure mercurichloride (Found : Cl, 26·1; Hg, 59·5%). The combination of four molecules of mercuric chloride with one molecule of a diquaternary compound has been observed previously in a few cases (*e.g.*, Curtius and Clemm, *J. pr. Chem.*, 1900, **62**, 194). For the preparation of the diquaternary dichloride the *mercurichloride* was suspended in warm water and decomposed with hydrogen sulphide in the usual way. Evaporation of the aqueous product to dryness yielded an oil which, when dried in a vacuum, formed a mass of needle-like crystals, and recrystallisation from alcohol–ether gave pure *propane-αγ-dipyridinium dichloride* (Found : Cl, 26·3. $C_{13}H_{16}N_2Cl_2$ requires Cl, 26·1%). Treatment of this salt (0·1 g.) in boiling *N*-hydrochloric acid (40 c.c.) with aqueous auric chloride yielded, on cooling, elongated rectangular plates of the *dichloroaurate*, which became dark yellow when heated and were unmelted at 300°; on cooling, the original light yellow colour is restored (Found : Au, 44·7. $C_{13}H_{16}N_2Au_2Cl_8$ requires Au, 44·9%). The corresponding *dipicrate* crystallises from water in long, stout prisms, m. p. 176°.

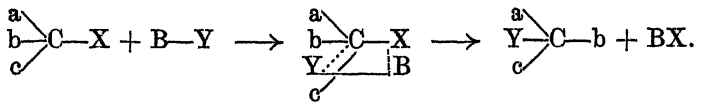
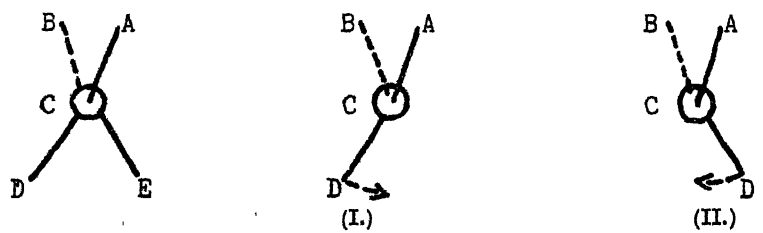
HAMPSTEAD. [*Received, July 5th*, 1928.]



CCCXXIV.—*The Walden Inversion.*

By HANS NICOLAI KELLERMAN RØRDAM.

THE discovery by Walden in 1896 of the stereochemical inversion to which his name is now given raised a problem which still remains unsolved. Since the optical isomerides always possess the same chemical properties, the same energy content, the same solubility, etc., and the corresponding reactions consequently have the same affinities, there is no apparent reason why, for instance, silver oxide and water should transform *l*-chlorosuccinic acid into *l*-malic acid, whilst potassium hydroxide converts it into *d*-malic acid.



Also, although Senter (J., 1915, **107**, 638 *et seq.*) has shown that the nature of the solvent can influence the inversion, and Holmberg (*e.g.*, *J. pr. Chem.*, 1913, **87**, 456; **88**, 553) has demonstrated that it is sensitive to the presence of salts and to changes in concentration of the reagents, yet no mechanism has hitherto been suggested which is capable of explaining all the results or of predicting the occurrence of an inversion.

Holmberg (*Ber.*, 1926, **59**, 125; *Svensk Kem. Tidskr.*, 1927, **39**, 1) has suggested a theory according to which the determining factor for a Walden inversion is to be found in what he has termed "the reaction distance," *i.e.*, the distance between the two reacting parts of the molecule or ion acting upon the optically active compound, *e.g.*, the distance between H and OH in a molecule of water or, in general, between B and Y in the reacting molecule B—Y in the reaction:

If the distance B—Y is greater than the distance C—X, then inversion must take place, but if the latter distance is the greater, no inversion will occur. Since, however, the ratio of these two distances must be the same so long as we are considering the same reaction, this hypothesis (unless additional assumptions are made) is inconsistent with the influence exercised upon the inversion by the various factors mentioned above.

By means of the following conception, it is possible to explain the phenomenon and to calculate the fraction n of the reaction product which has a steric configuration agreeing with that of the initial active substance. Let C represent an asymmetric carbon

atom, and A, B, D, and E the atoms or radicals linked to it. C, D, and E are supposed to lie in the plane of the paper, with A above and B below this plane. If now the atom E is split off, the configuration (I) is formed, and the remaining radicals are assumed to oscillate as the result of this disturbance. For simplicity, I shall consider the oscillation of only one radical, say D, between the

positions occupied in (I) and (II). Whether inversion takes place or not will now depend upon whether the atom, ion, or radical X which enters the molecule instead of E is able to do so while D is still upon its original side of the plane ACB, as in (I), or has passed it, as in (II). (The above representation is purely diagrammatic and makes no assumption as to the actual distribution of the four directed valency sources, but merely postulates a disturbance among them when one is temporarily out of action.)

From these conceptions we can derive a quantitative theory of the Walden inversion based upon the time of oscillation θ of the molecule, the concentrations, and the activity conditions in the solution. Of these factors, at present we know nothing of the time of oscillation and very little about the activity coefficients in such high concentrations as are usually employed in researches on the subject. Moreover, most of the experiments bearing on this inversion were carried out under conditions in which temperature and concentration were varied during the experiment in such a way as to preclude any calculation of the result, but Holmberg's experiments upon the reaction between xanthogenates and active halogenosuccinic acids (*loc. cit.*) are so precise that it is possible to apply to them the equation deduced below.

We assume that the fraction n of the reaction product which retains its original configuration is proportional to the probability that the oscillating molecule reacts with the entering ion X while still in configuration (I); this probability will evidently increase with the length of the time of oscillation and with the speed of the reaction between the single oscillating molecule and X.

Introducing the kinetic activity factor of Brönsted (*Z. physikal. Chem.*, 1922, **102**, 169) in the expression for the reaction velocity, we get the equation $n = kc_{\mathrm{X}}f_1f_2\theta/f_{1,2}$ where c_{X} denotes the mean concentration of X at the beginning and end of the reaction, and f_1, f_2, and $f_{1,2}$ respectively denote the activity coefficients of the oscillating molecule, of X, and of the compound resulting from the union of these two. We can obtain the same equation from Brönsted's formula for the velocity of a bimolecular reaction, *viz.*, $-dc_1/dt = k'c_1c_2f_1f_2/f_{1,2}$; for if we replace dt by $\theta/4$ and let subscripts 1 and X refer to the oscillating molecule and to X respectively, we have

$$n = dc_1/c_1 = k'c_{\mathrm{X}}(f_1f_{\mathrm{X}}/f_{1,\mathrm{X}})(\theta/4) \quad . \quad . \quad . \quad . \quad (a)$$

If, moreover, for lack of knowledge, we assume that θ depends only upon the nature of the oscillating molecule and is independent of the potential in the solution, θ can be included in the constant and the equation takes the form

$$n = kc_{\mathrm{X}}f_1f_{\mathrm{X}}/f_{1,\mathrm{X}} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (b)$$

We shall now test the application of equation (*b*) to Holmberg's experiments, but quantitative agreement with his results cannot be expected, owing to the nature of our approximations and to our lack of precise data relating to activity coefficients.

The first reaction to be considered is that between potassium, sodium, calcium, barium, and strontium salts of *l*-bromosuccinic acid and alkali xanthogenates $\bar{O}\cdot CO\cdot CH_2\cdot CHBr\cdot CO\cdot\bar{O} + CS(OEt)\cdot\bar{S} \longrightarrow \bar{O}\cdot CO\cdot CH_2\cdot CH[S\cdot CS(OEt)]\cdot CO\cdot\bar{O} + \bar{Br}$, which is assumed to take place in two steps, *viz.*, (1) a spontaneous splitting off of the bromine atom: $\bar{O}\cdot CO\cdot CH_2\cdot CHBr\cdot CO\cdot\bar{O} \longrightarrow \bar{O}\cdot CO\cdot CH_2\cdot\overset{+}{C}H\cdot CO\cdot\bar{O} + \bar{Br}$, and (2) an addition of the xanthogenate ion (denoted by X):

$$\bar{O}\cdot CO\cdot CH_2\cdot\overset{+}{C}H\cdot CO\cdot\bar{O} + \bar{X} \longrightarrow \bar{O}\cdot CO\cdot CH_2\cdot CHX\cdot CO\cdot\bar{O}$$

The activity coefficient f_1 for the amphoteric ion $\bar{O}\cdot CO\cdot CH_2\cdot\overset{+}{C}H\cdot CO\cdot\bar{O}$, with an excess of one negative electric charge, is assumed to be approximately equal to that of an ordinary univalent ion; and for both f_1 and f_X we shall use the values of a commoner uni-univalent salt, silver nitrate being chosen for this purpose since its values are known for high ionic strengths (Lewis and Randall, "Thermodynamics," p. 363), and its structure is not so simple as that of the alkali chlorides, which are therefore less comparable with the larger ions involved here.

For the activity coefficient $f_{1,X}$ of the bivalent ion

$$\bar{O}\cdot CO\cdot CH_2\cdot CHX\cdot CO\cdot\bar{O},$$

I have chosen the values for magnesium sulphate in pure solutions of the same ionic strength (see Rørdam, "Studies on Activity," Copenhagen, 1925) up to 0·5*M*-solutions, and values for higher concentrations have been calculated from the freezing-point data of Loomis (Landolt–Börnstein, "Tabellen," 5th edition, 3070) by use of the equation $\log f = -0{\cdot}4343\left[(1-\phi) + \int_0^c \frac{1-\phi}{c}dc\right]$, f being the activity coefficient, c the concentration, and $\phi = i/2$ (i = van 't Hoff's factor). The data thus used are collected in Table I, where the ionic strength μ is added. The assumption that the activity coefficient of a given electrolyte is the same in all

solutions of the same ionic strength (Lewis and Randall, *J. Amer. Chem. Soc.*, 1921, **43**, 1112) is well known to be strictly valid only in dilute solutions, but of necessity we apply it here up to greater concentrations.

In Table II all Holmberg's data relevant to these experiments are collected. For the calculation of n from equation (b), the empirical value $k = 200$ has been employed. (For experiments where the ionic strength exceeds 6, no calculations have been made, the basis for the calculation of the activity coefficients here seeming

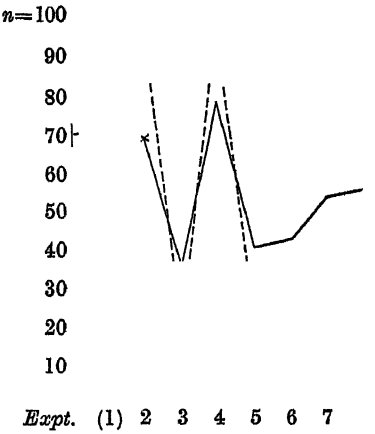
too uncertain.) The third column of the table contains the percentage of dextrorotatory xanthogeno-succinic acid found by Holmberg in the partly active acid resulting from the experiments. If the theory now propounded is valid, it affords a means whereby to decide which of the two possible optical isomerides that may be formed possesses the same steric configuration as the initial active component in a reaction leading to a Walden inversion. Hence we may conclude from the calculations that d-xanthogenosuccinic acid and l-bromosuccinic acid have corresponding configurations.

The results shown in Table II are represented graphically in Fig. 1, the calculated (broken line) and experimental (full line) values of n being given in connexion with the series number of the experiment. These curves show that variation in experimental values is closely related to that in the calculated values. In view of the fact that the individual peculiarities of the activity coefficients

and the deviations in the "rule of ionic strength" are both very marked at the high concentrations used, the agreement seems fairly good.

In spite of the accuracy of Holmberg's experiments, it is possible that the percentages found by him do not agree exactly with the total amount formed in the reaction, for the product was obtained by spontaneous crystallisation from the more or less concentrated salt solutions, and in most cases the solubilities of racemic and corresponding active substances are different in, and perhaps also unequally influenced by, different salt concentrations.

FIG. 1.



In future experimental researches in this field, it would be of interest to avoid uncertainty of this sort by determining the composition optically, without isolation of the reaction product; and in order to test the validity of the present theory it will be necessary to use reaction conditions such that the activity coefficients can be accurately calculated. The theory suggests possibilities for planning experiments which may throw more light upon the Walden inversion. If valid, it will account for the influence of the concentrations of reagents and of salts present in the solution, as well as of the nature of the solvent.

The literature affords only one other series of experiments suitable for testing the present theory, *viz.*, those of Holmberg (*Arkiv. Kemi, Min. Geol.*, 1915, **6**, 1) on the reaction between hydrosulphides and salts of *l*-bromosuccinic acid, which is assumed to occur in two stages exactly like the foregoing reaction. As the SH' ion is considerably less complicated in structure than the

xanthogenate ion, its activity coefficient is more appropriately represented by that of sodium nitrate than that of silver nitrate; the necessary values are only available up to 0·5*M* (Rørdam, *op. cit.*), and values for higher concentrations are therefore obtained by plotting these values by the side of those already used for silver nitrate and extrapolating the curve so that it remains parallel to the curve for silver nitrate.

FIG. 2.

The value used for *k* is 200 as before. The agreement between calculated and observed values is not so good in this case, perhaps owing to the less definite composition of hydrosulphide solutions and to their instability. The data appear in Table III and are represented in Fig. 2 as for the former reaction. The displacement of the curve when foreign salts are present cannot yet be explained.

Finally, it may be remarked that a complete theoretical calculation should perhaps take into consideration the possibility that some of the oscillating molecules can escape reaction both while in configuration (I) and in configuration (II) for the first time, and only react during a subsequent oscillation. It is also possible that very accurate experiments would show that the time of oscillation of the molecule is influenced by the potential in the solution. The conception of the Walden inversion now put forward seems to have the advantage that it is capable of experimental verification.

CCCXXV.—*Derivatives of Tetrahydrocarbazole. Part VII. Reactions of 3-Methyltetrahydrocarbazole, 6-Chlorotetrahydrocarbazole, and their Acyl Derivatives.*

By SYDNEY GLENN PRESTON PLANT and REGINALD JOHN ROSSER.

SOME of the most interesting reactions observed with tetrahydrocarbazole (I; R = R′ = R″ = H) are those of its 9-acyl derivatives with nitric acid (Perkin and Plant, J., 1923, **123**, 676). Besides simple nitro-derivatives in all cases, the 9-benzoyl compound forms a product by the addition of OH and NO_2 to the double linkage, and the 9-acetyl, 9-carbethoxy-, and 9-phenylacetyl derivatives add two hydroxyl radicals to this linkage. The reason for this remarkable difference between 9-benzoyltetrahydrocarbazole and the other 9-acyl derivatives investigated has never been explained, although, of course, it may be quite fortuitous. The present work was therefore undertaken with the view of determining (1) how far these additive reactions can be carried out with other tetrahydrocarbazole compounds, and (2) the effect of the nature and position of substituents upon the reactions. The observations of Manjunath and Plant (J., 1926, 2260) with 9-acetyl-6-methyltetrahydrocarbazole indicated that 3-*methyltetrahydrocarbazole* (I; R = R″ = H; R′ = Me), in which the methyl group is in the reduced part of the molecule, and 6-chlorotetrahydrocarbazole (I; R′ = R″ = H; R = Cl), containing a negative atom, would be suitable for investigation. The former has been obtained by Fischer's indole synthesis from

4-*methyl*cyclo*hexanone phenylhydrazone*, and, on nitration in concentrated sulphuric acid solution, it yielded a single product, which was shown to be 6-*nitro*-3-*methyltetrahydrocarbazole* (I; R = NO_2; R′ = Me; R″ = H). In order to identify some of the derivatives obtained in this work, 6-nitro-3-methyltetrahydrocarbazole and 8-*nitro*-3-*methyltetrahydrocarbazole* have been synthesised by eliminating ammonia from 4-*methyl*cyclo*hexanone* p- and o-*nitrophenylhydrazones*, respectively. The isomeric 5(or 7)-*nitro*- and 7(or 5)-*nitro*-3-*methyltetrahydrocarbazoles* were both obtained from 4-*methyl*cyclo*hexanone* m-*nitrophenylhydrazone*. It is not possible to say which of these is really the 5- and which the 7-nitro-derivative, whilst

it is interesting to note that *cyclo*hexanone *m*-nitrophenylhydrazone yields only one compound, assumed to be 7-nitrotetrahydrocarbazole (Borsche, Witte, and Bothe, *Annalen*, 1908, **359**, 53), under similar conditions. 3-Methyltetrahydrocarbazole has been converted into its 9-*acetyl* derivative with acetic anhydride, but the corresponding 9-*benzoyl* and 9-*carbethoxy*-compounds were made by first obtaining *magnesium* 9-3-*methyltetrahydrocarbazyl iodide* (I; R = H; R′ = Me; R″ = MgI) and subsequently treating this with benzoyl chloride and ethyl chloroformate, respectively. When 9-acetyl-3-methyltetrahydrocarbazole was treated with nitric acid in acetic acid solution, 5(or 7)-*nitro*-9-*acetyl*-3-*methyltetrahydrocarbazole* and 10 : 11-*dihydroxy*-9-*acetyl*-3-*methylhexahydrocarbazole* (II; R = H; R′ = Me; R″ = Ac) were obtained, but the exact nature of the product depended on the conditions used (p. 2458). The position of the nitro-group in the former of these two derivatives was established by hydrolysis to one of the isomeric nitro-compounds obtained synthetically from 4-methyl*cyclo*hexanone *m*-nitrophenylhydrazone. In view of the results obtained with tetrahydrocarbazole itself and the assumptions then made (Perkin and Plant, J., 1921, **119**, 1825), it seems advisable to avoid confusion by regarding this nitro-compound as the 5-nitro-derivative, but to admit the possibility of an alternative structure by adopting the designation " 5(or 7)-nitro." The dihydroxy-compound obtained in this reaction was found to lose water on boiling with acetic anhydride, presumably to give 6-*acetyl*-3-*methyl*-*ψ*-*indoxyl*spirocyclo*pentane*, by a reaction analogous to that observed with the parent substance (Perkin and Plant, *loc. cit.*). 9-Benzoyl-3-methyltetrahydrocarbazole, on treatment with nitric acid in acetic acid solution, yielded a mixture of 11-*nitro*-10-*hydroxy*-9-*benzoyl*-3-*methylhexahydrocarbazole* (III; R = H; R′ = Me; R″ = Bz) and 5(or 7)-*nitro*-9-*benzoyl*-3-*methyltetrahydrocarbazole*, whilst under similar conditions ethyl 3-methyltetrahydrocarbazole-9-carboxylate behaved like the 9-acetyl derivative and gave a mixture of *ethyl* 5(or 7)-*nitro*-3-*methyltetrahydrocarbazole*-9-*carboxylate* and *ethyl* 10 : 11-*dihydroxy*-3-*methylhexahydrocarbazole*-9-*carboxylate* (II; R = H; R′ = Me; R″ = CO_2Et). It is apparent, therefore, that in general the results obtained with 3-methyltetrahydrocarbazole are similar to those in the case of tetrahydrocarbazole itself, but the addition products were not produced quite so readily and were more difficult to isolate.

The three isomeric mononitro-derivatives of 6-chlorotetrahydrocarbazole were obtained synthetically, the 8-*nitro*-compound from cyclo*hexanone* 4-*chloro*-2-*nitrophenylhydrazone*, and a mixture of the 5(or 7)- and 7(or 5)-*nitro*-compounds from cyclo*hexanone* 4-*chloro*-3-*nitrophenylhydrazone*. When 6-chlorotetrahydrocarbazole was

nitrated directly in sulphuric acid, 5(or 7)-nitro-6-chlorotetrahydrocarbazole was produced. 6-*Chloro*-9-*acetyltetrahydrocarbazole* was prepared from its parent substance by direct acetylation, but the 9-*benzoyl* and 9-*carbethoxy*-derivatives were obtained by employing Grignard reactions as in the case of the corresponding products from 3-methyltetrahydrocarbazole. When nitric acid acted on this 9-acetyl compound in acetic acid solution, both 6-*chloro*-5(or 7)-*nitro*-9-*acetyltetrahydrocarbazole* and 6-*chloro*-10 : 11-*dihydroxy*-9-*acetylhexahydrocarbazole* (II; R = Cl; R′ = H; R″ = Ac) were produced, but the relative amounts could be varied by altering the conditions. From 6-chloro-9-benzoyltetrahydrocarbazole both 6-*chloro*-5(or 7)-*nitro*-9-*benzoyltetrahydrocarbazole* and 6-*chloro*-11-*nitro*-10-*hydroxy*-9-*benzoylhexahydrocarbazole* (III; R = Cl; R′ = H; R″ = Bz) were obtained, but in the case of ethyl 6-chlorotetrahydrocarbazole-9-carboxylate unexpected results were observed. *Ethyl* 6-*chloro*-5(or 7)-*nitrotetrahydrocarbazole*-9-*carboxylate* was isolated, but the second product proved to be *ethyl* 6-*chloro*-11-*nitro*-10-*hydroxyhexahydrocarbazole*-9-*carboxylate* (III; R = Cl; R′ = H; R″ = CO_2Et), thus providing an example of the addition of OH and NO_2 to the double linkage in a 9-carbethoxy-derivative. When a solution of this addition compound in alcohol was boiled, a product, which appeared on analysis to be *ethyl* 6-*chloro*-10 : 11-*dihydroxyhexahydrocarbazole*-9-*carboxylate* (II; R = Cl; R′ = H; R″ = CO_2Et), was obtained, apparently by the replacement of NO_2 by OH. The products resulting from the addition of nitric acid decompose, on melting, with the evolution of oxides of nitrogen. The preparation of these compounds from 6-chlorotetrahydrocarbazole required more vigorous conditions than in the case of tetrahydrocarbazole itself.

Since hexahydrocarbazole has been shown to exist in two stereoisomeric modifications (Gurney, Perkin, and Plant, J., 1927, 2676), it follows that theoretically four modifications of 3-methylhexahydrocarbazole might appear during the reduction of 3-methyltetrahydrocarbazole. Two of these would result from the *cis*-addition of hydrogen at the double linkage and would be less strained than the other two, which would result from the *trans*-addition of hydrogen. From the results obtained in the reduction of tetrahydrocarbazole, it might be expected that the former two would be formed in relatively great amounts, but that only very small quantities of the latter two would be present in the reduction product. This point has been investigated, but only one product (presumably one of the *cis*-modifications) resulted on electrolytic reduction. This, which melts at 58·5°, has been called 3-*methylhexahydrocarbazole* (A). When, however, 3-methyltetrahydrocarbazole was reduced with tin

and hydrochloric acid in aqueous alcohol, a small quantity of a second form, 3-*methylhexahydrocarbazole* (B), m. p. 128°, was isolated in addition to the modification (A), which formed the main product. It is hardly possible, on account of the small yield of 3-methylhexahydrocarbazole (B), to say whether this is the second *cis*-modification or one of the two *trans*-forms. It is theoretically possible for all the products formed by addition of OH and NO_2, or OH and OH, at the double linkage in tetrahydrocarbazole to exist in more than one stereoisomeric modification, but so far in no case has more than a single form been isolated.

EXPERIMENTAL.

3-*Methyltetrahydrocarbazole and its Nitro-derivatives.*—The crude, solid 4-*methyl*cyclo*hexanone phenylhydrazone* (7 g.), obtained by mixing equal weights of 4-methyl*cyclo*hexanone and phenylhydrazine, was warmed with aqueous sulphuric acid (120 c.c. of 17%) for 15 minutes on the water-bath, with shaking. 3-*Methyltetrahydrocarbazole* was isolated from alcohol in colourless, rhombic prisms, m. p. 109—110° (Found: N, 7·5. $C_{13}H_{15}N$ requires N, 7·6%).

From a solution of *p*-nitrophenylhydrazine (1·7 g.) and 4-methyl*cyclo*hexanone (1·2 g.) in hot alcohol, 4-*methyl*cyclo*hexanone* p-*nitrophenylhydrazone* separated, on cooling, in yellow needles, m. p. 128·5°, and, after treatment with boiling 25% sulphuric acid for a few minutes, it yielded 6-*nitro*-3-*methyltetrahydrocarbazole*, which crystallised from alcohol (charcoal) in brown prisms, m. p. 165—166° (Found: N, 12·2. $C_{13}H_{14}O_2N_2$ requires N, 12·2%). By a similar process, 4-*methyl*cyclo*hexanone* o-*nitrophenylhydrazone* was obtained in crimson prisms, m. p. 59°, and converted into 8-*nitro*-3-*methyltetrahydrocarbazole*, which separated from alcohol in bright red needles, m. p. 188° (Found: N, 12·1%). 4-*Methyl*cyclo*hexanone* m-*nitrophenylhydrazone*, from alcohol in orange-red prisms, m. p. 80—81°, yielded a mixture with boiling 27% sulphuric acid. The filtered solution of the crude product (6 g.) in hot alcohol deposited, on cooling and leaving for 24 hours, 5(or 7)-*nitro*-3-*methyltetrahydrocarbazole* in yellow needles, m. p. 188° (Found: N, 12·0%), whilst, on concentration of the mother-liquor, a further quantity, contaminated with a little of the isomeride, was obtained. The crude 7(or 5)-*nitro*-3-*methyltetrahydrocarbazole* was then isolated by adding water to the mother-liquor, and purified by crystallisation from chloroform, separating in orange-red plates, m. p. 175° (Found: N, 12·2%). These two nitro-compounds were formed in approximately equal amounts.

A solution of 3-methyltetrahydrocarbazole (10·6 g.) in concentrated sulphuric acid (70 c.c.) was kept at — 10° and treated gradu-

ually with pulverised potassium nitrate (5·9 g.), with continuous stirring. After being poured on ice and collected as quickly as possible, the product, when dried in a desiccator, melted at 159°. It separated from alcohol in brown prisms, m. p. 165—166°, and was shown to be 6-nitro-3-methyltetrahydrocarbazole by a mixed m. p. determination. No other substance could be isolated from the reaction mixture.

Action of Nitric Acid on 9-Acetyl-3-methyltetrahydrocarbazole.—When a solution of 3-methyltetrahydrocarbazole in 2½ times its weight of acetic anhydride was boiled under reflux for 3 hours and cooled, *9-acetyl-3-methyltetrahydrocarbazole* separated, and was obtained from glacial acetic acid in colourless needles, m. p. 108·5° (Found : N, 6·1. $C_{15}H_{17}ON$ requires N, 6·2%). When a solution of the acetyl derivative (3·6 g.) in glacial acetic acid (50 c.c.) was treated with nitric acid (1·8 g., *d* 1·42, dissolved in a little acetic acid) at room temperature, 5(or 7)-*nitro*-9-*acetyl*-3-*methyltetrahydrocarbazole* separated during 24 hours in clusters of yellow needles, m. p. 134° (after recrystallisation from alcohol) (Found : N, 10·3. $C_{15}H_{16}O_3N_2$ requires N, 10·3%). A mixture of this nitro-compound (1·5 g.), sodium hydroxide (9 g.), alcohol (60 c.c.), and water (60 c.c.) was boiled for some time and then diluted with water. When the product was crystallised from alcohol, 5(or 7)-nitro-3-methyltetrahydrocarbazole separated in orange prisms, m. p. 187°. It was shown by a mixed m. p. determination to be identical with one of the products obtained from 4-methyl*cyclo*hexanone *m*-nitrophenylhydrazone. The m. p. of the mixture with 8-nitro-3-methyltetrahydrocarbazole was much lower.

When 9-acetyl-3-methyltetrahydrocarbazole (18 g.) in acetic acid (66 c.c.) was treated at 50° with nitric acid (9·2 g.; *d* 1·42) in acetic acid (10 c.c.), 5(or 7)-nitro-9-acetyl-3-methyltetrahydrocarbazole (3 g.) again separated over-night, but after pouring the mother-liquor into water, adding aqueous sodium hydroxide until nearly neutral, and stirring, a product was obtained which could be easily collected and after being dried in a desiccator yielded 10 : 11-*dihydroxy-9-acetyl-3-methylhexahydrocarbazole* on crystallisation from benzene. After recrystallisation from alcohol, it was obtained in almost colourless plates, m. p. 189—190° (Found : N, 5·4. $C_{15}H_{19}O_3N$ requires N, 5·4%). When a solution of this dihydroxy-compound (2·5 g.) in acetic anhydride (40 c.c.) was boiled under reflux for 2 hours, cooled, and shaken with water, the product, after crystallisation from alcohol, yielded 6-*acetyl*-3-*methyl*-ψ-*indoxyl*-spirocyclo*pentane* in colourless plates, m. p. 93·5° (Found : N, 5·8. $C_{15}H_{17}O_2N$ requires N, 5·8%). 3-*Methyl*-ψ-*indoxyl*spirocyclo*pentane*, obtained from its acetyl derivative by hot aqueous-alcoholic

potassium hydroxide and subsequent addition of water, separated from alcohol in colourless prisms, m. p. 114·5°.

Action of Nitric Acid on 9-Benzoyl-3-methyltetrahydrocarbazole.—3-Methyltetrahydrocarbazole (14·7 g.) was added in portions to a solution of magnesium (1·9 g.) in ethyl iodide (12·8 g.) and dry ether (180 c.c.), and, after the evolution of ethane had ceased, benzoyl chloride (11·4 g.) was gradually introduced with shaking. After some time, ice and dilute hydrochloric acid were added, the ethereal solution was dried with calcium chloride, the ether removed, and the residual red oil distilled under reduced pressure. The distillate, collected at 255—265°/11 mm., was crystallised from alcohol, from which *9-benzoyl-3-methyltetrahydrocarbazole* separated in colourless prisms, m. p. 99° (Found: N, 4·9. $C_{20}H_{19}ON$ requires N, 4·8%).

When a solution of 9-benzoyl-3-methyltetrahydrocarbazole (2·6 g.) in glacial acetic acid (47 c.c.) was treated with nitric acid (0·9 g., *d* 1·42) at 30° and then left for 24 hours, *11-nitro-10-hydroxy-9-benzoyl-3-methylhexahydrocarbazole* separated in pale yellow prisms, m. p. 123° (decomp., with evolution of oxides of nitrogen). It separated from benzene–petroleum in small prisms, m. p. 123—124° (decomp.) (Found: N, 7·6. $C_{20}H_{20}O_4N_2$ requires N, 7·9%). When the solid precipitated by pouring the acetic acid mother-liquor into water was crystallised from methyl alcohol, *5(or 7)-nitro-9-benzoyl-3-methyltetrahydrocarbazole* separated in yellow needles, m. p. 142·5° (Found: N, 8·4. $C_{20}H_{18}O_3N_2$ requires N, 8·4%). This compound, which formed by far the greater part of the product, was hydrolysed by aqueous-alcoholic sodium hydroxide to 5(or 7)-nitro-3-methyltetrahydrocarbazole, m. p. 186°, the identity of which was established by a mixed m. p. determination with the synthetical product.

Action of Nitric Acid on Ethyl 3-Methyltetrahydrocarbazole-9-carboxylate.—*Ethyl 3-methyltetrahydrocarbazole-9-carboxylate* was prepared by the Grignard reaction, similar to that used for the 9-benzoyl derivative, ethyl chloroformate being used. It was unnecessary here to distil the crude product, and the ester separated from alcohol in colourless prisms, m. p. 66—67° (Found: N, 5·7. $C_{16}H_{19}O_2N$ requires N, 5·5%). A solution of the ester (9·2 g.) in glacial acetic acid (16 c.c.) at 25° was treated with nitric acid (3·6 g., *d* 1·42), dissolved in acetic acid (4 c.c.), the temperature not being allowed to rise above 50°. After a short time, the yellow needles, m. p. 101°, which separated, were collected and recrystallised from alcohol, from which *ethyl* 5(or 7)-*nitro-3-methyltetrahydrocarbazole-9-carboxylate* was isolated in yellow prisms, m. p. 104° (Found: N, 9·2. $C_{16}H_{18}O_4N_2$ requires N, 9·3%). When treated with boiling aqueous-alcoholic sodium hydroxide, this product yielded 5(or 7)-nitro-3-methyltetrahydrocarbazole, m. p. 187° (mixed m. p. 187°). The

acetic acid mother-liquor deposited, on being kept for 24 hours, a further quantity, m. p. 100°, of this nitro-derivative. When the filtrate was subsequently concentrated by keeping in a vacuum desiccator over solid sodium hydroxide for several days a second product, m. p. 121—129°, separated, and, after recrystallising this from alcohol, *ethyl* 10 : 11-*dihydroxy*-3-*methylhexahydrocarbazole*-9-*carboxylate* was obtained in clusters of small, colourless prisms, m. p. 135° (Found : N, 4·7. $C_{16}H_{21}O_4N$ requires N, 4·8%).

Reduction of 3-*Methyltetrahydrocarbazole.*—A mixture of 3-methyltetrahydrocarbazole (10 g.), alcohol (20 c.c.), concentrated hydrochloric acid (20 c.c.), and granulated tin (20 g.) was boiled under reflux for 5 hours, filtered, as much alcohol as possible was distilled off, and the residue was made alkaline with sodium hydroxide (20 g. in concentrated aqueous solution). The solid product was collected on asbestos and extracted with ether, the filtrate being also extracted with ether. The solid then remaining was ground with aqueous sodium hydroxide and again extracted with ether. The united ethereal solutions were dried with potassium carbonate, and the oily residue remaining after removal of the solvent was crystallised from alcohol, 3-*methylhexahydrocarbazole* (A) separating in colourless prisms, m. p. 58·5° (Found : C, 83·6; H, 9·1; N, 7·4. $C_{13}H_{17}N$ requires C, 83·4; H, 9·1; N, 7·5%). On concentrating the alcoholic mother-liquor, further quantities of 3-methylhexahydrocarbazole (A) were obtained, but ultimately a product, melting at 50—90°, began to separate. At this point the whole was dissolved in 60% sulphuric acid and then diluted with water to precipitate the very small quantity of non-basic, unreduced 3-methyltetrahydrocarbazole which was present. After filtration and basification by addition of concentrated aqueous ammonia, the resulting solid was recrystallised from alcohol, and 3-*methylhexahydrocarbazole* (B) separated in colourless needles, m. p. 128° (Found : C, 83·8; H, 9·4. $C_{13}H_{17}N$ requires C, 83·4; H, 9·1%).

A solution of 3-methyltetrahydrocarbazole (10 g.) in 60% sulphuric acid (250 c.c.) was submitted to electrolytic reduction in the cathode compartment of an electrolytic cell, lead electrodes and a current of 5·5 amps. (0·03 amp. per sq. cm. of cathode) for 16 hours at room temperature being used, but, on dilution with water, unchanged 3-methyltetrahydrocarbazole was recovered. The reduction was subsequently repeated, the cell being immersed in boiling water ; the solution was then diluted with its own volume of water, filtered, and made alkaline with ammonia. The product was taken up in ether, and, after crystallisation from petroleum, 3-methylhexahydrocarbazole (A) was obtained in colourless plates, m. p. 57—58°, its identity with the substance previously described being established

by a mixed m. p. determination. The presence of a second stereoisomeride in this product was not observed.

When 3-methylhexahydrocarbazole (A) was shaken with an equal weight of benzoyl chloride in the presence of dilute aqueous sodium hydroxide, and the product was crystallised from alcohol, 9-*benzoyl*-3-*methylhexahydrocarbazole* (A) was obtained in colourless needles, m. p. 81·5° (Found: N, 4·8. $C_{20}H_{21}ON$ requires N, 4·8%). 9-*Acetyl*-3-*methylhexahydrocarbazole* (A) was isolated by boiling a solution of the base in acetic anhydride for 20 minutes and subsequently shaking with dilute aqueous sodium carbonate, and was obtained from alcohol in colourless, rhombic prisms, m. p. 101°. The *picrate* of 3-methylhexahydrocarbazole (A) separated from toluene in yellow prisms, m. p. 115—116°.

Nitro-derivatives of 6-Chlorotetrahydrocarbazole.—6-Chlorotetrahydrocarbazole, prepared as described by Borsche, Witte, and Bothe (*loc. cit.*), was obtained from alcohol in colourless prisms, m. p. 144°. A solution of this chloro-compound (2 g.) in concentrated sulphuric acid (13 c.c.) was treated gradually at — 10° with powdered potassium nitrate (1·15 g.), with continuous stirring, and the whole was then poured on ice. When the product was crystallised from alcohol and then ethyl acetate, 6-*chloro*-5(or 7)-*nitrotetrahydrocarbazole* separated in yellow plates, m. p. 183·5° (Found: N, 11·2. $C_{12}H_{11}O_2N_2Cl$ requires N, 11·2%). A mixed m. p. determination showed this product to be identical with the 6-chloro-5(or 7)-nitrotetrahydrocarbazole described below.

4-Chloro-3-nitroaniline (12·5 g.) was dissolved in a warm mixture of concentrated hydrochloric acid (21 c.c.) and water (20 c.c.), the whole was rapidly cooled in a freezing mixture, and diazotised with aqueous sodium nitrite (6 g.). The filtered liquid was then added gradually during 10 minutes to a well-cooled mixture of saturated aqueous ammonium sulphite (40 c.c.) and concentrated ammonia (8 c.c.), and, after ½ hour, concentrated hydrochloric acid (70 c.c.) was added, the mixture warmed to 30°, and left over-night. The solid product was heated at 80° for a short time with concentrated hydrochloric acid (20 c.c.), and, after cooling and standing, the hydrazine hydrochloride was collected, dissolved in boiling water (200 c.c.), and the filtered solution treated with sodium acetate. After crystallisation from methyl alcohol, 4-*chloro*-3-*nitrophenylhydrazine* separated in orange needles, m. p. 109° (Found: N, 22·1. $C_6H_6O_2N_3Cl$ requires N, 22·4%). cyclo*Hexanone* 4-*chloro*-3-*nitrophenylhydrazone* separated from a hot alcoholic solution of 4-chloro-3-nitrophenylhydrazine (2·5 g.) and *cyclo*hexanone, (1·5 g.), on cooling, in red prisms, m. p. 106—107° (Found: N, 15·7. $C_{12}H_{14}O_2N_3Cl$ requires N, 15·7%). When the mixture obtained by

treating this hydrazone (7·5 g.) with boiling aqueous sulphuric acid (170 c.c. of 25%) for 10 minutes was crystallised from methyl alcohol, 6-chloro-5(or 7)-nitrotetrahydrocarbazole separated in brown needles, m. p. 184°, and was found to be identical with the product of the direct nitration of 6-chlorotetrahydrocarbazole. After collecting a further quantity of the same derivative by concentrating the methyl-alcoholic mother-liquor, the remaining filtrate was evaporated to dryness and the residue crystallised from benzene. *6-Chloro-7(or 5)-nitrotetrahydrocarbazole* then separated in orange needles, m. p. 162° (Found: N, 11·1. $C_{12}H_{11}O_2N_2Cl$ requires N, 11·2%). These two isomeric nitro-compounds appeared to be produced in approximately equal amounts.

By a process essentially similar to that described above, 4-chloro-2-nitroaniline was converted into *4-chloro-2-nitrophenylhydrazine*, which was isolated from alcohol in red needles, m. p. 134° (Found: N, 22·0%). cyclo*Hexanone* *4-chloro-2-nitrophenylhydrazone*, which separated from alcohol in red needles, m. p. 101°, was converted into *6-chloro-8-nitrotetrahydrocarbazole* by treating it for 20 minutes with boiling 30% sulphuric acid, the product being obtained from alcohol (charcoal) in orange-red needles, m. p. 213° (Found: N, 11·3%).

Action of Nitric Acid on 6-Chloro-9-acetyltetrahydrocarbazole.—The acetylation of 6-chlorotetrahydrocarbazole proved to be a slow reaction, but when a solution of the substance in four times its weight of acetic anhydride containing 2 drops of concentrated sulphuric acid was boiled for 24 hours, *6-chloro-9-acetyltetrahydrocarbazole* separated, on cooling, in colourless needles, m. p. 136° (unaltered by recrystallisation from acetic acid) (Found: N, 5·4. $C_{14}H_{14}ONCl$ requires N, 5·6%). Nitric acid (*d* 1·42) did not react with this acetyl derivative in acetic acid until the temperature reached about 80°. A solution of the compound (8·8 g.) in glacial acetic acid (48 c.c.) at 90° was treated with nitric acid (3·5 g., *d* 1·42), in a little acetic acid. A vigorous reaction took place and the solution boiled. During 16 hours a yellow product, m. p. 206—207°, separated, and, on recrystallising this from acetic acid, *6-chloro-10 : 11-dihydroxy-9-acetylhexahydrocarbazole* was obtained in colourless prisms, m. p. 222° (Found: N, 4·9. $C_{14}H_{16}O_3NCl$ requires N, 5·0%). If the temperature during this reaction was maintained at 80°, the product, which separated on standing for 24 hours, was clearly a mixture of colourless prisms and yellow needles. After several crystallisations from alcohol, a small quantity of *6-chloro-5(or 7)-nitro-9-acetyltetrahydrocarbazole* was isolated in yellow needles, m. p. 184·5—185·5° (Found: N, 9·6. $C_{14}H_{13}O_3N_2Cl$ requires N, 9·6%). This product was much more readily obtained by treating the 9-acetyl compound (0·8 g.) in acetic acid (15 c.c.) at 55° with

fuming nitric acid (0·25 g., *d* 1·5), whereupon it crystallised on standing. On hydrolysis, by boiling its solution in aqueous-alcoholic sodium hydroxide, it yielded 6-chloro-5(or 7)-nitrotetrahydrocarbazole, m. p. 184°, identical with one of the products from *cyclo*hexanone 4-chloro-3-nitrophenylhydrazone.

Action of Nitric Acid on 6-Chloro-9-benzoyltetrahydrocarbazole.—The benzoylation of 6-chlorotetrahydrocarbazole was accomplished as described for the 3-methyl derivative, but it was unnecessary to distil the crude product. After crystallisation from alcohol, 6-*chloro*-9-*benzoyltetrahydrocarbazole* was obtained in colourless needles, m. p. 122—123° (Found: N, 4·4. $C_{19}H_{16}ONCl$ requires N, 4·5%). When a solution of this benzoyl compound (4·1 g.) in glacial acetic acid (20 c.c.) at 80° was treated with nitric acid (1·5 g., *d* 1·42) in a little acetic acid, yellow needles, m. p. 142°, separated gradually during 12 hours. After recrystallisation from alcohol, 6-*chloro*-5(or 7)-*nitro*-9-*benzoyltetrahydrocarbazole* was obtained in yellow needles, m. p. 148° (Found: N, 7·8. $C_{19}H_{15}O_3N_2Cl$ requires N, 7·9%). When this product was hydrolysed by means of aqueous-alcoholic sodium hydroxide, 6-chloro-5(or 7)-nitrotetrahydrocarbazole, m. p. 184°, identical with the synthetical substance, was obtained. The acetic acid mother-liquor, on keeping, deposited first a further quantity of the nitro-compound and then a pale yellow substance, melting at 142° with evolution of oxides of nitrogen. This was clearly different from the first product, since a mixture of the two melted at 130—133°, and the evolution of oxides of nitrogen on melting is characteristic of the nitric acid addition products. The latter substance was more conveniently prepared by treating a solution of the benzoyl compound (1·8 g.) in acetic acid (10 c.c.) with fuming nitric acid (0·6 g., *d* 1·5, in a little acetic acid) at 40—50°. 6-*Chloro*-11-*nitro*-10-*hydroxy*-9-*benzoylhexahydrocarbazole* immediately separated in colourless prisms, m. p. 147° (decomp., with evolution of oxides of nitrogen) (Found: N, 7·3. $C_{19}H_{17}O_4N_2Cl$ requires N, 7·5%).

Action of Nitric Acid on Ethyl 6-Chlorotetrahydrocarbazole-9-carboxylate.—*Ethyl 6-chlorotetrahydrocarbazole-9-carboxylate*, prepared by a process similar to that described for the 3-methyl derivative, separated from alcohol in colourless needles, m. p. 111—112° (Found: N, 5·1. $C_{15}H_{16}O_2NCl$ requires N, 5·0%). When the ester (2·0 g.) was treated in glacial acetic acid (6 c.c.) at 60° with nitric acid (0·7 g., *d* 1·42), the product gradually separated as a yellow solid, m. p. 120—125°. After two crystallisations from alcohol, *ethyl* 6-*chloro*-5(or 7)-*nitrotetrahydrocarbazole*-9-*carboxylate* was obtained in yellow needles, m. p. 126° (Found: N, 8·7. $C_{15}H_{15}O_4N_2Cl$ requires N, 8·7%), which, on hydrolysis with aqueous-alcoholic

sodium hydroxide, yielded 6-chloro-5(or 7)-nitrotetrahydrocarbazole, m. p. 184°, identical with the synthetical product already described. When ethyl 6-chlorotetrahydrocarbazole-9-carboxylate (2 g.) was treated in acetic acid (12 c.c.) at 40—45° with fuming nitric acid (0·55 g., *d* 1·5), a colourless product immediately separated. This melted at 136—137° with evolution of oxides of nitrogen and was clearly a nitric acid addition product. After crystallisation from ethyl acetate, *ethyl 6-chloro-11-nitro-10-hydroxyhexahydrocarbazole-9-carboxylate* was obtained in colourless prisms, m. p. 136—137° (decomp.) (Found: N, 8·1. $C_{15}H_{17}O_5N_2Cl$ requires N, 8·2%). When its solution in alcohol was boiled for an hour, the product, which separated in colourless prisms, m. p. 132°, appeared to be *ethyl 6-chloro-10 : 11-dihydroxyhexahydrocarbazole-9-carboxylate* (Found: C, 58·1; H, 5·8; N, 4·9. $C_{15}H_{18}O_4NCl$ requires C, 57·8; H, 5·8; N, 4·5%).

CCCXXVI.—*The Decomposition of Bornyl Benzene- and Naphthalene-sulphonates by Heat. The Products of Hydrolysis of Bornyl and Menthyl Benzene- and Naphthalene-sulphonates. The Influence of Solvents on the Temperature of Decomposition of these Bornyl and Menthyl Sulphonates.*

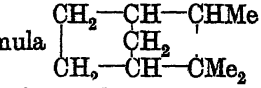
By THOMAS STEWART PATTERSON and IRENE MARY MCALPINE.

IN a recent paper (J., 1927, 349) we showed that the menthyl esters of benzene-, naphthalene-α- and naphthalene-β-sulphonic acids decomposed in two different ways according as they were (*a*) directly distilled under reduced pressure or (*b*) heated for some time before distillation. In the first case the main reaction was decomposition into menthene and the corresponding sulphonic acid, but in the second any menthene originally produced was converted into dimenthene and more complex substances.

These results seemed sufficiently interesting to make it worth while to extend the investigation to the behaviour of the corresponding bornyl esters, and for this purpose we have used mostly the *l*-bornyl derivatives, since *d*-borneol is not easily obtained in pure condition. We examined first, fairly completely, the naphthalene-β-sulphonic ester, as it is rather more easily obtained; the other esters were examined with less completeness, but sufficiently to establish similarity of behaviour in all three.

Decomposition by Distillation under Reduced Pressure.—When bornyl naphthalene-β-sulphonate was distilled from an oil-bath as rapidly as possible under a pressure of 18 mm., a small quantity (15—20% of the theoretical amount) of a clear, optically inactive liquid passed over at about 60°. This on redistillation boiled at 155—158° under ordinary pressure and solidified to a white substance, m. p. 51° (Found: C, 88·2, 88·1; H, 11·85, 11·8; *M*, cryoscopic in benzene, 137. Calc. for $C_{10}H_{16}$: C, 88·2; H, 11·8%; *M*, 136). The substance decolorised bromine and gave, when hydrogen chloride was passed through its solution in ether, a white precipitate which melted at 125—127° after recrystallisation from alcohol containing hydrogen chloride. These data indicate that the decomposition product is camphene.

The residue in the flask after the distillation of the camphene separated into two layers, the lower of which solidified. We found it best to separate these layers by dissolving the whole mass in warm water and extracting the solution with toluene. The extract was dried with calcium chloride and distilled under reduced pressure and after removal of the solvent a viscous, almost inactive liquid distilled at 168°/4 mm. (Found: C, 88·1, 88·2; H, 11·8, 11·8. Calc. for $C_{20}H_{32}$: C, 88·2; H, 11·8%). Since Tschugaev, on distilling bornyl methyl xanthogenate, obtained bornylene and a little camphene, and analogy seems to exist between the reactions of the xanthogenates and sulphonates under similar conditions (*e.g.*, menthyl xanthogenates and sulphonates), the substance we have obtained is presumably dibornylene, for which, however, there is no very satisfactory criterion beyond the analytical data. In addition to this liquid a certain amount of a gelatinous material of indefinite boiling point was obtained, but this we have not been able either to purify or identify.



The aqueous layer after the extraction with toluene was strongly acid: by neutralising it with barium carbonate a salt was obtained (Found: Ba, 24·1, 24·15%), showing that the other product of decomposition was naphthalene-β-sulphonic acid.

Bornyl naphthalene-α-sulphonate and bornyl benzenesulphonate distilled under reduced pressure gave the same volatile products, leaving behind naphthalene-α-sulphonic acid and benzenesulphonic acid respectively.

It thus appears that by distilling these sulphonic esters of borneol, a small quantity of camphene and a considerable quantity of dibornylene and a more complex product are obtained, whereas Tschugaev by decomposing bornyl methyl xanthogenate obtained mainly bornylene and a little camphene.

Bornyl naphthalene-β-sulphonate heated in a sealed tube (no

pressure is developed) at 80—90° for 2—3 hours was completely separated into two layers. On cooling, the lower layer (B) solidified. The upper layer (A) on distillation under reduced pressure gave two fractions, b. p. 60—65°/4 mm. and 140—240°/4 mm. The former on redistillation boiled at 157—160° under ordinary pressure and ultimately solidified; m. p. 85° (Found: C, 86·7, 86·7; H, 13·2, 13·2; *M*, cryoscopic in benzene, 136·8. Calc. for $C_{10}H_{18}$: C, 86·9; H, 13·1%; *M*, 138). The substance did not decolorise bromine and would appear to be dihydrocamphene, since it corresponds closely with the behaviour given for that substance by Vavon (*Compt. rend.*, 1907, **149**, 997) and by Henderson and Pollock (J., 1910, **97**, 1620), and, if Wagner's formula for camphene is accepted, may be presumed to have the formula

but no more satisfactory method of identifying this compound seems to be available.

The higher-boiling portion on distillation under reduced pressure gave two fractions, one boiling at 168°/4 mm., and the other, a gelatinous mass which could not be purified or identified, boiling from 240—270°/4 mm. (Found for the former: C, 88·2, 88·2; H, 11·8, 11·8; *M*, cryoscopic in benzene, 268·7. Calc. for $C_{20}H_{32}$: C, 88·2; H, 11·8%; *M*, 272).

Since on decomposition, in sealed tubes, of the corresponding menthyl sulphonates, dimenthene was formed, the above substance is presumably dibornylene. It has the same physical properties as the substance obtained on decomposition by direct distillation.

The strongly acid, solid layer (B) was dissolved in water and boiled with animal charcoal, and a barium salt was precipitated by means of barium chloride and recrystallised from water [Found: Ba, 24·0, 24·15. Calc. for $Ba(SO_3{\cdot}C_{10}H_7)_2,H_2O$: Ba, 24·1%]. The solid is therefore naphthalene-β-sulphonic acid.

Bornyl naphthalene-α-sulphonate and bornyl benzenesulphonate decomposed in a strictly analogous fashion, yielding also what were probably dihydrocamphene, dibornylene, and a gelatinous mass of high boiling point, along with the corresponding sulphonic acid.

Decomposition in Solution.—When bornyl naphthalene-β-sulphonate was heated to boiling in 10% benzene solution for 6 hours there was no change in the rotation of the solution. If, however, toluene was substituted for benzene and the solution heated to 110°, definite decomposition took place and, on cooling, a solid separated. This was acid and gave the characteristic barium salt of naphthalene-α-sulphonic acid. On distillation of the filtrate a liquid, b. p. 285—

290°, or 168°/4 mm., was obtained identical with the high-boiling liquid presumed to be dibornylene.

The two corresponding esters decomposed in the same way, giving dibornylene and the corresponding sulphonic acid, when heated in solution in toluene. Bornyl benzenesulphonate gave a similar result even in boiling benzene.

Hydrolysis of Bornyl Benzene- and Naphthalene-sulphonates.—*d*-Borneol prepared from camphor by reduction contains a considerable proportion of *l-iso*borneol which renders the preparation of pure *d*-borneol rather difficult. We found that the bornyl naphthalene-β-sulphonate obtained from commercial *d*-borneol, unlike the naphthalene-α-sulphonate or the benzenesulphonate, could be completely purified by recrystallisation, and it seemed a comparatively simple matter to obtain pure *d*-borneol by hydrolysing the ester thus purified. These bornyl esters, however, cannot be hydrolysed in any of the usual ways, the products obtained being somewhat similar to those got by direct decomposition of the esters.

(1) *Action of water and aqueous potassium hydroxide.* When steam was blown through bornyl naphthalene-β-sulphonate suspended in water or in dilute aqueous caustic potash for 20—30 minutes, only water appeared to distil over and the ester seemed to be practically unchanged.

But when the ester was heated on the water-bath for 2—3 hours with either water or caustic alkali, decomposition took place, and steam now removed a colourless liquid. This did not solidify when separated from the water, and was ethereal in odour. Benzene extracted from it a liquid, b. p. 155—159°, which was optically inactive, gave on analysis results corresponding roughly to the formula $C_{10}H_{16}$, and from its odour seemed to be mostly camphene: it decolorised bromine water. It gave no solid hydrochloride when treated in ether with dry hydrogen chloride, but, on evaporation of the ether, the residue separated into a brown oil and a colourless portion. The latter solidified and had the melting point of camphene hydrochloride. Such camphene as was formed, however, was apparently mixed with other substances, it being very probable that even if hydrolysis gave different products from the simple heating of the ester the products of hydrolysis were almost certain, in the circumstances of the experiment, to be mixed with the products due to direct decomposition of the ester by heat. It was not found possible to identify definitely the substances present, but certainly no borneol was obtained.

(2) *Alcoholic potassium hydroxide.* A solution of bornyl naphthalene-β-sulphonate in a slight excess of alcoholic caustic potash, when heated on the water-bath for several hours, deposited

potassium naphthalene-β-sulphonate. The alcoholic solution was dried with potassium carbonate and most of the alcohol distilled off under reduced pressure. On pouring the residue into water a very small quantity of unchanged ester separated. No borneol was obtained, and we found it impossible completely to identify the products of hydrolysis. All that was noticeable was a strong odour of camphene—a substance extremely difficult to separate from its alcoholic solution.

We attempted this separation by distillation with an efficient fractionating column without success, but, by passing dry hydrogen chloride through the alcoholic solution and adding water, camphene hydrochloride was precipitated; it was rapidly filtered off and crystallised from alcohol containing hydrogen chloride, sufficient being obtained for identification. Any other substances present could not be identified.

In another attempt, the alcoholic solution was poured into a large excess of water, and the whole extracted with toluene, although this did not remove all the camphene. The toluene solution was dried with calcium chloride, and the toluene distilled off under reduced pressure. The main portion of the residue distilled at 155° and formed camphene hydrochloride, but some higher-boiling material had also been formed which could not be satisfactorily identified. The amount of terpene isolated in this manner was about 10% of the theoretical. Experiments to hydrolyse the ester with sodium ethoxide in alcohol and with barium hydroxide in aqueous alcohol were equally unsuccessful, the same products being again indicated. It seems very remarkable that, whereas such esters as bornyl acetate, bornyl *p*-nitrobenzoate (Henderson and Heilbron, P., 1913, 381), bornyl hydrogen phthalate (Pickard and Littlebury, J., 1907, **91**, 1973), and bornyl mandelate (McKenzie and Thompson, J., 1905, **87**, 1013) can easily be hydrolysed in a normal manner, bornyl benzene- and naphthalene-sulphonates decompose in an entirely different fashion, presumably similar to that in which they are decomposed by simple heating.

Hydrolysis of Menthyl Benzene- and Naphthalene-sulphonates.—On account of the peculiarities observed with the bornyl esters we examined also the hydrolysis of the corresponding menthyl derivatives.

(i) *Action of aqueous potassium hydroxide.* When menthyl benzenesulphonate was heated for several hours at about 80—85° with aqueous potassium hydroxide solution (10—15%), decomposition (which was not complete even after 5 or 6 hours) took place and a colourless oil separated. This was distilled over in steam and isolated by means of benzene. It boiled at 165°, gave on analysis

figures corresponding almost exactly to the formula $C_{10}H_{18}$, decolorised bromine, formed a nitrosochloride, m. p. 115°, and was therefore menthene. No side reactions seemed to take place in this case.

Menthene was similarly formed when menthyl naphthalene-β-sulphonate was treated with aqueous potassium hydroxide, but even after heating for 6 hours 50% of the ester was recovered unchanged.

(ii) *Hydrolysis with barium hydroxide.* The three menthyl sulphonates were all decomposed by heating with aqueous-alcoholic solutions of barium hydroxide. The barium salt of the acid was formed almost quantitatively in each case. No menthol, however, could be obtained, but menthene was produced and was extracted from the aqueous-alcoholic solution by toluene; little, if any, of the higher-boiling dimenthene was formed. The decomposition, therefore, with aqueous caustic potash and with alcoholic barium hydroxide is practically identical with the decomposition of the esters when distilled rapidly under reduced pressure.

Temperature of Decomposition in Different Solvents.—From the experiments which have been detailed both here and in connexion with the menthyl esters, it appeared that the decomposition of these sulphonates took place more rapidly in certain solvents than in others, and we thought it worth while to examine this phenomenon systematically. We therefore made up 0·8 g. of ester to 10 c.c. with various solvents and heated the solution for one hour in a thermostat kept at a definite temperature. The solution was then cooled rapidly, diluted with 20 c.c. of absolute alcohol (distilled over quicklime), and titrated with alcoholic potash, a blank experiment being carried out in each case. The results are shown in the table on p. 2470.

It will be observed that not only does increase of temperature cause an increase in the velocity of the reaction, but that there is a great diversity of effect between the different solvents, the rate of increase being much greater in some than in others. The effect of the same solvent on the three esters, however, is, in general, fairly similar. Toluene causes little decomposition in 1 hour at any of the temperatures used, and the alcohols cause considerable decomposition at all temperatures, the percentage increasing with decrease in molecular weight of the alcohol. Although decomposition in the non-alcoholic solvents practically ceases below 85°, it continues to be quite appreciable in the alcohols at considerably lower temperatures. In fact, methyl alcohol at 65° causes more decomposition in a given time than the non-alcoholic solvents at 90—95°. Water would probably show the greatest effect, but this could not be proved owing to the insolubility of these esters even in aqueous

alcoholic solutions. Nitrobenzene causes little decomposition below 100°, but at 105° decomposition is practically complete in all cases. Ethylene dibromide causes little decomposition in menthyl benzenesulphonate even at 105°, but almost complete decomposition at this temperature in 1 hour in the two naphthalene-sulphonic esters.

EXPERIMENTAL.

l-Bornyl Benzenesulphonate.—Pure *l*-borneol (18·5 g.) recrystallised from light petroleum [m. p. 203°, $[\alpha]_{5461}^{17°}$ (benzene, $c = 5{\cdot}25$) — 42·81°] was dissolved in pyridine (60 g.) and cooled to 0°. Benzene-sulphonyl chloride (21·1 g.) was then added very slowly with constant stirring, the temperature being kept below 3°. Crystals soon began to separate, and on continued stirring became very abundant. After 3 or 4 hours, a large quantity of water was added and ultimately the oil which first separated solidified; it was then filtered off and dried. In several preparations the oil would not solidify in contact with water. It was then extracted with benzene, the extract dried with calcium chloride, and the benzene removed by evaporation in air and finally over sulphuric acid in a vacuum desiccator; the residue then solidified to a pale yellow, crystalline mass.

l-*Bornyl benzenesulphonate* is very soluble in all common organic solvents; but may be crystallised from light petroleum, giving fine, white, slightly elongated crystals, m. p. 52°; $[\alpha]_{5461}^{17°}$ in benzene ($c = 2{\cdot}5$) — 22·40°, in alcohol ($c = 2{\cdot}5$) — 22·00°. Several crystallisations are necessary to obtain the substance free from borneol; the yield of pure product is about 25% [Found : S (fusion method), 10·7. $C_{16}H_{22}O_3S$ requires S, 10·95%].

d-*Bornyl benzenesulphonate*, m. p. 52°, is prepared and purified in exactly the same way as the *l*-ester. When prepared from crude *d*-borneol, a product is obtained the rotation of which is lower than that of the pure *l*-compound, + 21·30° (similar conditions), and we were unable to raise it by crystallisation.

l-*Bornyl naphthalene-β-sulphonate* was prepared from pure *l*-borneol (18·5 g.) in pure pyridine (90 g.) by means of naphthalene-β-sulphonyl chloride (27·2 g.) in a similar manner to the benzenesulphonate. It is soluble in all the common solvents, but may be recrystallised from methyl or ethyl alcohol, and from light petroleum, from which it separates in stellate masses of glistening, white, needle-shaped crystals. After three crystallisations it has m. p. 76°, and $[\alpha]_{5461}^{17·5°}$ in benzene ($c = 3$) — 16·50° and in alcohol ($c = 2{\cdot}5$) — 16·00°. The yield of pure product is 60% [Found : S (fusion method), 9·2. $C_{20}H_{24}O_3S$ requires S, 9·3%].

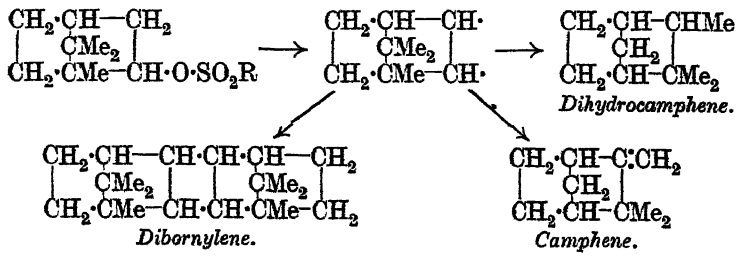
d-*Bornyl naphthalene-β-sulphonate* was prepared, in exactly the same way as the corresponding *l*-ester, from commercial *d*-borneol, which contains *l-iso*borneol. Crystallisation from methyl or ethyl alcohol or light petroleum alone gave a product of m. p. 76°, the rotation of which, however, could not be raised beyond $[\alpha]_{5461}^{17·5°}$ (in benzene, $c = 3$) — 15·8°. But after the ester had been crystallised twice from a *mixture* of methyl alcohol and light petroleum the rotation rose to the value found for the *l*-ester.

l-*Bornyl naphthalene-α-sulphonate* was prepared and isolated in the way described for *l*-bornyl benzenesulphonate, naphthalene-α-sulphonyl chloride (27·2 g.) being used. The substance was difficult to purify owing to its great solubility, but after three to six recrystallisations from light petroleum it was obtained in fine, white crystals, m. p. 90°, $[\alpha]_{5461}^{17·5°}$ in benzene ($c = 2{\cdot}5$) — 23·20° and in alcohol ($c = 2{\cdot}5$) — 26·4° (Found : S, 9·2. $C_{20}H_{24}O_3S$ requires S, 9·3%).

The corresponding *d*-ester was prepared from crude *d*-borneol but could not be completely purified.

Summary.

Menthyl esters of benzene-, naphthalene-α- and naphthalene-β-sulphonic acids, when directly distilled under reduced pressure, yield menthene and the corresponding sulphonic acid; but if they



are heated for some time before distillation, dimenthene and more complex substances are produced, but no menthene.

The corresponding bornyl esters, when directly distilled, yield camphene, dibornylene, a more complex gelatinous material which we have been unable to purify or identify, and sulphonic acid.

The bornyl esters, when heated for 2 or 3 hours and then distilled, yield dihydrocamphene, dibornylene, a gelatinous material, and sulphonic acid.

The bornyl esters, heated to boiling in toluene solution, yield dibornylene and the corresponding sulphonic acid.

These changes may be represented thus :—

if the current formulæ for camphene and dihydrocamphene be accepted.

The menthyl and bornyl esters of benzene- and the naphthalene-sulphonic acids do not hydrolyse to yield menthol and borneol, but, on the contrary, decompose in somewhat the same way as when heated alone.

The rate at which these esters decompose in solution depends quite markedly on the nature of the solvent; and in the alcohols the velocity increases rapidly as the molecular weight diminishes. Tables are given showing this behaviour.

CCCXXVII.—*The Influence of Solvents on the Rotation of Optically Active Compounds. Part XXV. Bornyl Benzene- and Naphthalene-sulphonates in Various Solvents.*

By THOMAS STEWART PATTERSON and IRENE MARY MCALPINE.

WE have examined the rotations of the esters described in the foregoing paper for three colours of light, mercury yellow ($\lambda = 5790$), mercury green ($\lambda = 5461$), and mercury violet ($\lambda = 4358$), in several solvents which, for convenience of reference, are indicated by letters

of the alphabet, namely, (*a*) ethyl alcohol, (*b*) benzene, (*c*) pyridine, (*d*) ethylene dibromide, (*e*) quinoline, (*f*) nitrobenzene. Only one solution was examined in each case at a concentration between 2·5 and 3·5. The data are given in Table I.

TABLE I.

Specific Rotations of Bornyl Sulphonates in Various Solvents.

Violet	43·60	38·80	34·11	49·57	51·43	38·28

The rotations vary considerably in each case with change of solvent. Bornyl naphthalene-β-sulphonate has the lowest rotation values except for the solution in ethylene dibromide, which overlaps some of the values for other esters. The rotations of the other two esters in the different solvents overlap each other completely, the range of variation being greater, however, with the naphthalene-α-sulphonate than with the benzenesulphonic ester. The different solvents do not influence the rotations in the same way, although there are resemblances. Quinoline, which usually has a powerful exalting or depressing influence, produces the highest rotation in bornyl naphthalene-α-sulphonate and in bornyl benzenesulphonate, and the second highest rotation in bornyl naphthalene-β-sulphonate. In ethylene dibromide, which generally has a powerful influence in the opposite direction to quinoline, bornyl naphthalene-β-sulphonate shows the highest rotation and the other two the second highest. Nitrobenzene produces the lowest rotation in bornyl naphthalene-β-sulphonate and in bornyl benzenesulphonate, and the second lowest in bornyl naphthalene-α-sulphonate. The lowest rotation of this ester is produced by pyridine. There is thus some similarity in the action of the same solvent on the three esters.

The values obtained for the rotation of the three esters in the various solvents were plotted on a characteristic diagram, and lay with good agreement along lines intersecting one another very near

the point of origin of the diagram. It therefore follows that the dispersion coefficients for all these compounds, calculated by the ordinary method, ought to be the same throughout. This is seen by Table II to be roughly the case.

TABLE II.

Dispersion Ratios.

Solvent.	Bornyl benzenesulphonate. Hg_v/Hg_g.	Bornyl benzenesulphonate. Hg_y/Hg_g.	Bornyl naphthalene-α-sulphonate. Hg_v/Hg_g.	Bornyl naphthalene-α-sulphonate. Hg_y/Hg_g.	Bornyl naphthalene-β-sulphonate. Hg_v/Hg_g.	Bornyl naphthalene-β-sulphonate. Hg_y/Hg_g.
Alcohol	1·655	0·864	1·625	0·875	1·651	0·863
Benzene	1·654	0·863	1·646	0·863	1·650	0·873
Pyridine	1·655	0·879	1·652	0·868	1·647	0·876
Ethylene dibromide ...	1·665	0·868	1·656	0·866	1·652	0·876
Quinoline ...	1·683	0·878	1·658	0·864	1·667	0·871
Nitrobenzene	1·655	0·867	1·661	0·868	1·675	0·875

This property seems to be characteristic of bornyl and menthyl esters. Indeed the characteristic diagrams for the bornyl sulphonic esters and the menthyl sulphonic esters nearly coincide. Kenyon and Pickard have found (J., 1915, **107**, 35) that most menthyl derivatives lie on the same characteristic diagram with dispersion coefficient mercury violet/mercury green 1·634 to 1·675. The menthyl sulphonic esters have approximately the same coefficient, and lie on the same diagram. The bornyl esters that they plotted had as coefficient V/G = 1·707 to 1·871. The sulphonic esters that we have investigated, however, do not lie on this diagram, but on that which contains the majority of the menthyl compounds.

Our thanks are due to the Department of Scientific and Industrial Research and to the Carnegie Trustees for the Universities of Scotland for assistance in connexion with the work described in this and the preceding paper.

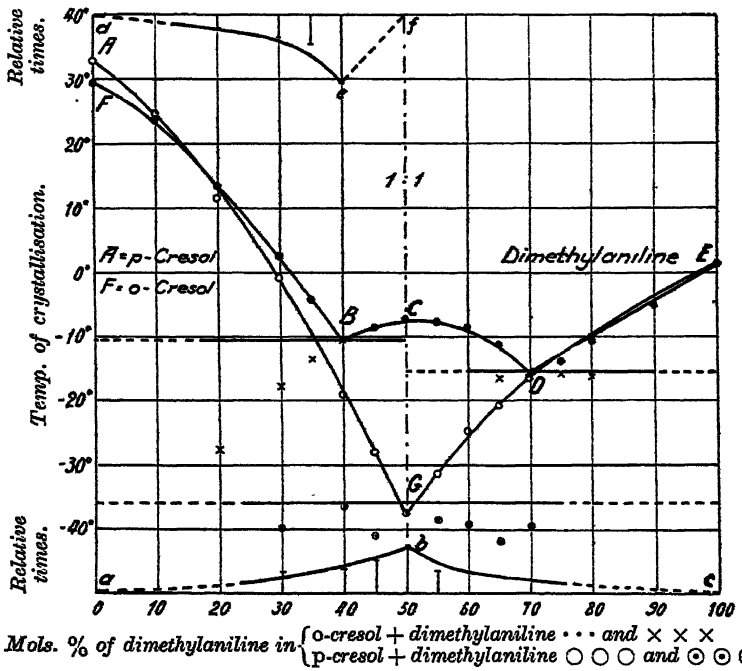
UNIVERSITY OF GLASGOW. [*Received, May 26th*, 1928.]

CCCXXVIII.—*Equilibrium in the Binary Systems Cresols–Amines.*

By NIKOLAI ANTONOVITCH PUSHIN and LJUDEVIT SLADOVIĆ.

IN this paper equilibrium diagrams are described which were obtained from thermal analysis of mixtures of *o*-, *m*-, or *p*-cresol, on the one hand, and dimethylaniline, *p*-toluidine, quinoline, piperidine, 1 : 5-naphthylenediamine, or carbamide, on the other. For every mixture the following data were determined: (1) the temperature of

complete melting of the crystallised mixture; (2) the complete cooling curve; (3) the duration of the eutectic crystallisation.



In the tables the temperature I is that of primary crystallisation, and II that of the eutectic (or final) crystallisation. The temperature III, when given, refers to complete melting of the mixture, and IV (for *o*-cresol and carbamide only) is the transition temperature.

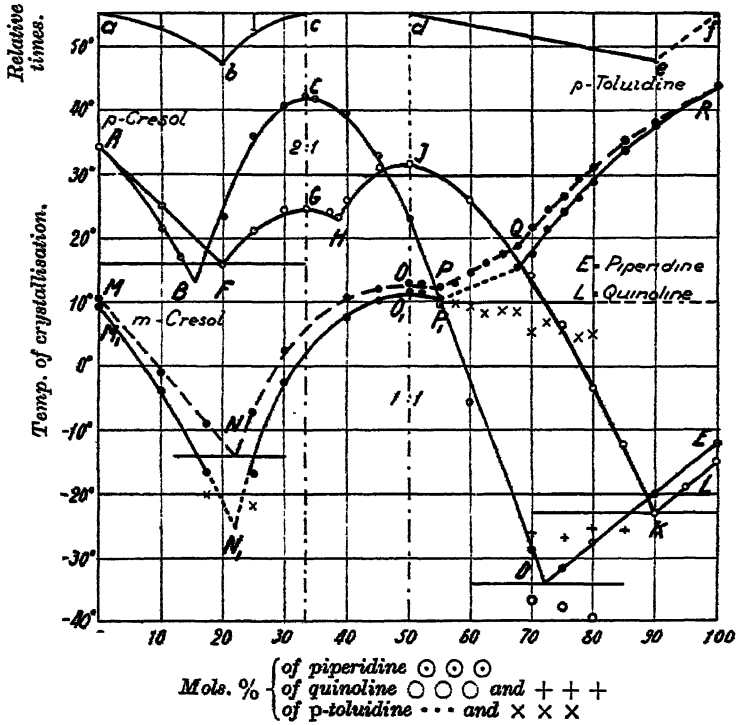
o-*Cresol*–p-*Toluidine* and p-*Cresol*–p-*Toluidine*.—These two systems give very similar diagrams, each consisting of three sections and two eutectic points with one open maximum between them which corresponds to 50 mols.% of each component. Hence each pair forms an equimolecular *compound* of m. p.'s 38° and 20·5°, respectively, melting being without decomposition in each case. In the system *o*-cresol–*p*-toluidine the eutectic points are at 22 and 72 mols.% of *p*-toluidine, and 14° and 25·6°, and in the other system at 32 and 65 mols.% and 12·1° and 16·4°. The duration of eutectic

FIG. 2.

crystallisation of different mixtures (triangles *abc*, *cde*, *fgh*, *hik*) confirms the position of the eutectic points.

Although *o*-cresol melts at a lower temperature (30·3°) than *p*-cresol (34·4°), yet in the equimolecular compounds with *p*-toluidine there is a difference of 18·5° in the reverse direction. If it be assumed that a greater change in physical properties corresponds to a deeper change in the chemical nature and to greater stability of a newly-formed compound, then it follows that the *o*-cresol compound is more stable than its isomeride.



m-*Cresol*–p-*Toluidine*.—In this system the temperature of primary crystallisation is given as well as the temperature of melting of the last crystals. The first curve is shown by a continuous and the

FIG. 4.

and to the proximity to the eutectic point. The positions of the eutectic points N_1 and P_1 can therefore be determined only approximately, but the eutectic point N lies at 22 mols.% of *p*-toluidine and −14°, and P at 56 mols.% and 12°. The maximum at O corresponds to an equimolecular *compound*.

There appears to be a break in the curve at 67 mols.% of *p*-toluidine, and on the cooling curves there is a slight change of

direction, corresponding to a heat effect, at 72·5—80%; no significance can be attached to these, however.

o-Cresol–Quinoline.—For this system the cooling curve, ($A_1B_1C_1D_1E_1F_1G_1$) and the temperatures of complete melting of crystalline mixtures (curve *ABCDEFG*) have been determined (see Fig. 4). These curves are very similar, but in places they are separated by 12°.

The diagram is composed of four sections giving two open maxima at *C* and *E*, corresponding to *compounds* $C_9H_7N,2C_7H_7{\cdot}OH$ (m. p. 34·5°) and $C_9H_7N,C_7H_7{\cdot}OH$ (m. p. 34·2°). Two eutectics are at 15 and 88 mols.% of quinoline and 20° and —24° respectively.

The lines *DH* and D_1H_1 represent a metastable state of the ternary and not of the binary compound, for (1) they are continuations of the curves *CD* and C_1D_1, and (2) every temperature of crystallisation of the mixture along the curve D_1H_1 corresponds to a temperature along the curve *DH*, where the whole mixture is in a liquid state, whereas the crystals of the binary compound melt only at temperature shown by the curve *DEF*.

TABLE VII.

p-Cresol–Quinoline (Fig. 3).

	Temp.			Temp.			Temp.	
	III.	II.	C_9H_7N, mols. %.	III.	II.	C_9H_7N, mols. %.	III.	II.
0	34·4°	—	38·5	23·2°	—	75	6·3°	—27·2°
10	25·0	6·7°	40	26	—	80	— 3·3	—24·8
20	16	—	45	31	—	85	—12·3	—25·4
25	21·2	4	50	31·8	—	90	—23	—26

33·3	24·5	—	70	14	—25·6°	100	—15	—
37	24·2	—						

p-*Cresol–Quinoline.*—The diagram of this system is very similar to that of the system *o*-cresol–quinoline, showing two open maxima corresponding to the *compounds* $C_9H_7N,C_7H_7{\cdot}OH$ and $C_9H_7N,2C_7H_7{\cdot}OH$ of m. p. 31·8° and 24·5° respectively. Two well-defined eutectic points are at 20 and 90 mols.% of quinoline and 16° and —23°, respectively; these have been confirmed by the duration of crystallisation (triangles *abc* and *def*). The minimum at 38·5 mols.% may not be a true eutectic, for it has not yet been ascertained whether a series of solid solutions is formed.

Comparison of the diagrams for the systems *o*-cresol–quinoline and *p*-cresol–quinoline shows that the curves of the first system are higher than those of the second, almost throughout. Both cresols therefore behave towards quinoline just as towards *p*-toluidine except that with quinoline they form not one but two definite compounds.

TABLE VIII.

p-Cresol–Piperidine (Fig. 3).

p-*Cresol–Piperidine.*—The diagram consists of three sections showing two eutectic points and one open maximum, which corresponds to the *compound* $C_5H_{11}N,2C_7H_7{\cdot}OH$, m. p. 42·1°. The eutectics are at 15·5 and 72 mols.% of piperidine (14° and −34°, respectively), the former having been determined by interpolation because within 13—20 mols.% and 60—70 mols.% of piperidine we were unable to make the mixtures crystallise. It is noteworthy that the above compound does not correspond to piperidine as mono-acid base and to *p*-cresol as monobasic phenol.

TABLE IX.

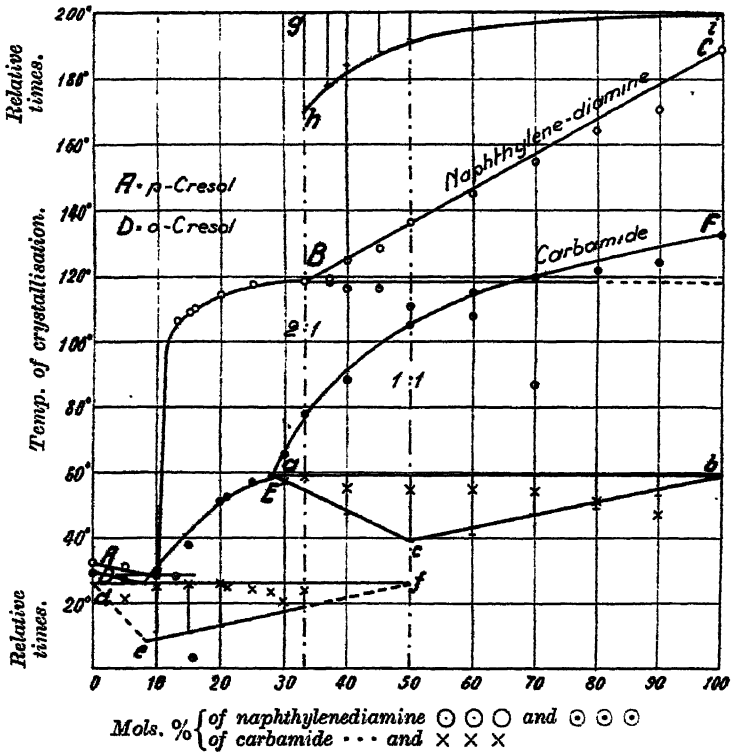
p-*Cresol*–1 : 5-*Naphthylenediamine.*—From naphthylenediamines as diacid bases one might have expected the formation of compounds with *p*-cresol of the type $C_{10}H_6(NH_2)_2,2C_7H_7{\cdot}OH$, and this is actually found.



The diagram is composed of three sections and is characterised by one eutectic point at 10 mols.% of naphthylenediamine and 29° and by one transition point at 33 mols.% of naphthylenediamine and 118°. For the determination of the composition of the compound the duration of crystallisation at the transition temperature was studied (triangle *ghi*), and showed a maximum at 33·3 mols.% of naphthylenediamine.

TABLE X.

FIG. 5.

o-Cresol–Carbamide.—According to Philip (J., 1903, **83**, 814) and Kremann and Rodinois (*Monatsh.*, 1906, **27**, 138), 1 mol. of carbamide forms compounds with 2 mols. of phenol, and with 1 mol. of each cresol (Kremann, *ibid.*, 1907, **28**, 1125), but Kremann studied only

the temperature of first crystallisation and not that of definite crystallisation of the mixtures. He determined the composition of the compounds by analysis. We have now investigated complete cooling curves of all mixtures, and have confirmed Kremann's results.

The diagram of this system consists of three sections and is characterised by a eutectic point at 8 mols.% of carbamide and 26°, and by a transition point at 28 mols.% of carbamide and 59°, corresponding to the dissociation of the compound $C_7H_7\cdot OH,CO(NH_2)_2$ into its components. The composition was determined by the duration of crystallisation at the temperature of formation (triangle *abc*) and at the eutectic temperature (triangle *def*). The maximum duration is shown for the equimolecular mixture.

Summary.

The diagrams of ten binary systems have been constructed for the cresols with certain bases, and the existence of the following compounds has been demonstrated:

$C_5H_5\cdot NMe_2$,*o*-$C_6H_4Me\cdot OH$	C_9H_7N,*o*-$C_6H_4Me\cdot OH$	$C_5H_{11}N$,2*p*-$C_6H_4Me\cdot OH$
p-$C_6H_4Me\cdot NH_2$,*o*-$C_6H_4Me\cdot OH$	C_9H_7N,2*o*-$C_6H_4Me\cdot OH$	1:5-$C_{10}H_6(NH_2)_2$,2*p*-$C_6H_4Me\cdot OH$
p-$C_6H_4Me\cdot NH_2$,*m*-$C_6H_4Me\cdot OH$	C_9H_7N,*p*-$C_6H_4Me\cdot OH$	$CO(NH_2)_2$,*o*-$C_6H_4Me\cdot OH$
p-$C_6H_4Me\cdot NH_2$,*p*-$C_6H_4Me\cdot OH$	C_9H_7N,2*p*-$C_6H_4Me\cdot OH$	

All except the last melt without decomposition.

Dimethylaniline and *p*-cresol form only mechanical mixtures.

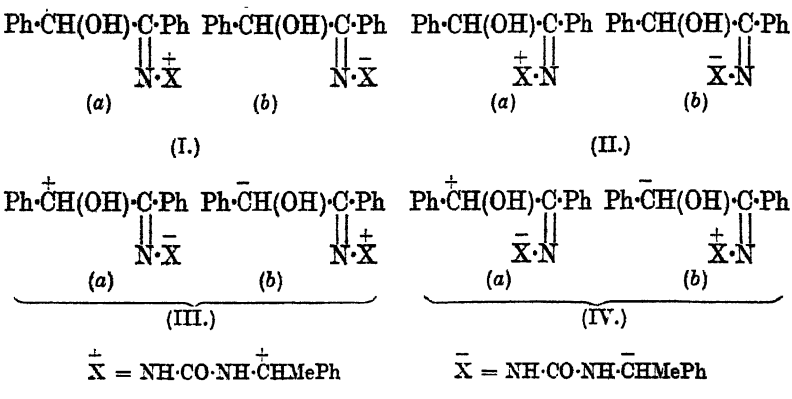
JUGOSLAVIA.

[*Received, May 4th,* 1928.]



CCCXXIX.—*A Resolution of Benzoin.*

By ISAAC VANCE HOPPER and FORSYTH JAMES WILSON.

IN a previous paper (J., 1922, **121**, 866) it was pointed out that *d*-δ-(α-phenylethyl)semicarbazide, $NH_2\cdot NH\cdot CO\cdot NH\cdot CHMePh$, of which we prepared the hydrochloride, should prove of service in resolving racemic aldehydes and ketones. We have now prepared also the *hydrochloride* of the l-*isomeride*, and by means of these reagents have succeeded in isolating the *d*- and *l*-forms of benzoin.

In order to gain experience of the semicarbazones involved, we decided first to experiment with the racemic semicarbazide both in pyridine and alcoholic solution. Since with *r*-benzoin-δ-(α-phenyl-

ethyl)semicarbazone stereoisomerism of the Hantzsch–Werner type is possible, four racemic modifications should exist (+ = *d*, − = *l*):

$\overset{+}{X}$ = NH·CO·NH·$\overset{+}{C}$HMePh $\overset{-}{X}$ = NH·CO·NH·$\overset{-}{C}$HMePh

The reaction between benzoin and *r*-δ-(α-phenylethyl)semicarbazide hydrochloride took place smoothly in pyridine solution and three of the four possible *compounds* were obtained, the α-modification melting at 174°, the β- at 154°, and the γ- (obtained in very small quantity) at 137°: each of these gave benzoin on hydrolysis with acid. The reaction proceeded much less conveniently in alcoholic solution, the α- and β-modifications in addition to some unaltered benzoin being obtained—a result which was somewhat unexpected, since previous experiments (J., 1925, **127**, 1282) had shown that as a rule only one modification of a benzoin-semicarbazone was obtained when working in alcoholic solution. It was decided therefore to employ pyridine as solvent in attempting a resolution of benzoin.

An optically active semicarbazide has not hitherto been successfully employed in a resolution: Forster and Fierz (J., 1905, **87**, 722) prepared camphoryl-ψ-semicarbazide, but do not appear to have used it for this purpose. Other active derivatives of hydrazine have, however, been employed for the resolution of *r*-arabinose (Neuberg, *Ber.*, 1903, **36**, 1192) and of *r*-arabinose and *r*-galactose (Neuberg and Federer, *Ber.*, 1905, **38**, 868). Benzoin itself does not appear to have been previously resolved, although the two enantiomorphs have been synthesised (McKenzie and Wren, J., 1908, **93**, 809; Wren, J., 1909, **95**, 1583).

By combining *r*-benzoin with *d*-δ-(α-phenylethyl)semicarbazide four active modifications of the semicarbazone are possible, *viz.*, I*a*, II*a*, III*b*, and IV*b*. When combination was effected in pyridine solution, however, only one product was obtained in a crystalline condition, the others being oily and very soluble. This lævorotatory

substance, a d-δ-(α-*phenylethyl*)*semicarbazone* of *d*-benzoin, agreed in rotation and m. p. with the product obtained by condensing the *d*-semicarbazide with *d*-benzoin (prepared according to McKenzie and Wren, *loc. cit.*). Hydrolysis of this semicarbazone in aqueous solution with oxalic acid liberated *d*-benzoin. In the same way, from the *l*-semicarbazide hydrochloride and *r*-benzoin, we isolated a dextrorotatory *semicarbazone* which yielded *l*-benzoin on hydrolysis.

EXPERIMENTAL.

Benzoin and r-δ-(α-*Phenylethyl*)*semicarbazide Hydrochloride.*—(a) *In pyridine solution.* Solutions of 8 g. of benzoin (1 mol.) in 80 c.c. of pyridine and 8·1 g. (1 mol.) of the hydrochloride in 100 c.c. of water were mixed in the cold, kept for 6 days, and poured into a large volume of cold water; the sticky product, which would not solidify, was collected, dissolved in ether, the ethereal solution shaken with water to remove pyridine, decolorised with animal charcoal, and filtered hot. In a few hours a product (Crop I) began to separate, and was collected after 2 days. Whilst it was difficult to obtain further solid matter from the filtrate, gradual addition of light petroleum during 2 days precipitated a coloured product, which was filtered and washed with ether until colourless (Crop II). Further gradual addition of light petroleum during a few weeks deposited a small crop (Crop III) which was collected and washed as before. Crop I was recrystallised successively from ether, benzene, and alcohol (the solubility increasing in this order of solvents), from which long, colourless needles (4 g., m. p. 154°) of *benzoin*-δ-(α-*phenylethyl*)*semicarbazone* (β-modification) were deposited (Found: N, 11·19. $C_{23}H_{23}O_2N_3$ requires N, 11·26%). Crop II, which was less soluble in the usual organic solvents, dissolved completely on prolonged boiling with benzene, and a fine, amorphous product separated on cooling. This crystallised from alcohol in prisms (3 g., m. p. 174°) of the α-*modification* of the semicarbazone (Found: N, 11·26%). These two stereoisomerides, a mixture of which melted at 140—145°, both gave benzoin on hydrolysis with either hydrochloric or oxalic acid. Crop III was separated by ether into a less soluble (β-modification) and a more soluble fraction. The latter on recrystallisation from a mixture of ether and light petroleum gave long, woolly needles (0·4 g., m. p. 187°) of the γ-*modification* (Found: N, 11·37%) which gave benzoin on hydrolysis with hydrochloric acid. The colouring matters produced in the reaction had a marked effect on the solubilities of the substances.

(b) *In alcoholic solution.* 4 G. of benzoin in 300 c.c. of alcohol were mixed in the cold with 4 g. of the semicarbazide hydrochloride in a little water. After standing for 6 days, dilution with [illegible]

cold water gave a soft, but filterable, precipitate which was collected and dissolved in the minimum of boiling alcohol. The crystals deposited on cooling were fractionally recrystallised from ether; a little benzoin separated first and was removed, then a mixture of needles and prisms appeared. On reheating the mixture in the mother-liquor, the needles redissolved so much more quickly that it was possible to effect a fairly complete separation of the prisms by filtering the hot solution at the appropriate moment. The prisms on recrystallisation from alcohol proved to be the α-isomeride, m. p. 174°. The ethereal mother-liquor on standing gave needles, mixed with a small quantity of prisms which were separated by reheating and filtering. The warm filtrate diluted with two volumes of light petroleum deposited crystals which, after purification from alcohol, proved to be the β-isomeride, m. p. 154°.

l-δ-(α-*Phenylethyl*)*semicarbazide Hydrochloride.*—26·3 G. of *l*-α-phenylethylamine ($[\alpha]_D^{15°}$ — 41·48°, prepared by a combination of the methods of Lovén and Betti; see Hopper and Ritchie, *J. Roy. Tech. Coll.*, 1926, **3**, 65) and 25 g. of acetonesemicarbazone were heated in a bath at 135—138° for 30 minutes under reflux, and then for a further 30 minutes without the condenser. The product, poured into 200 c.c. of ice-water, solidified on standing for a short time. The acetone-*l*-δ-(α-phenylethyl)semicarbazone was collected and hydrolysed by heating with 5% hydrochloric acid (1 mol., calculated on acetonesemicarbazone used) for 2·5 hours on a boiling water-bath, acetone being thus expelled. On cooling, an amorphous solid—probably a derivative of carbamide—was removed, the filtrate was concentrated under reduced pressure (which increases the yield), and the l-δ-(α-*phenylethyl*)*semicarbazide hydrochloride* allowed to crystallise out in a number of crops so that the heating of very concentrated solutions was avoided. On recrystallisation from boiling absolute alcohol, 36·5 g. (79% yield) of the hydrochloride were obtained; m. p. 188°; $\alpha_D^{12·2°}$ −4·00°, $[\alpha]_D^{12·2°}$ − 66·06° ($c = 3·027$ in water; $l = 2$).

Synthesis of d-*Benzoin*-d-δ-(α-*phenylethyl*)*semicarbazone.*—*d*-Benzoin was synthesised from *d*-mandelic acid by Wren's method (*loc. cit.*) with certain modifications suggested to us by Professor McKenzie and Dr. Roger, to both of whom we are much indebted for advice in this connexion. The *d*-mandelamide was prepared from methyl *d*-mandelate by the method of McKenzie and Smith (J., 1922, **121**, 1358). In this and in subsequent preparations and recrystallisations, quartz vessels were employed and solvents were distilled in quartz before use. It was found more convenient to recrystallise *d*-benzoin from a mixture of alcohol and light petroleum than from alcohol alone. The *d*-benzoin melted at 133—134°; $\alpha_D^{11°}$ + 4·47°,

$[\alpha]_D^{11°} + 118{\cdot}5°$ ($c = 0{\cdot}9433$ in acetone; $l = 4$); a solution in freshly distilled pyridine showed no alteration in specific rotation ($[\alpha]_D^{15°} + 92{\cdot}8°$; $c = 1{\cdot}040$; $l = 1$) on standing for a week in a quartz apparatus. *d*-Benzoin is therefore not racemised by pyridine under these conditions.

A mixture of 1·1 g. of *d*-benzoin, dissolved in 67 c.c. of pyridine, with 1·3 g. of *d*-δ-(α-phenylethyl)semicarbazide hydrochloride, dissolved in 2·5 c.c. of water, deposited crystals of the d-δ-(*α-phenylethyl*)*semicarbazone* of *d*-benzoin when left for 6 days. These were collected, and the filtrate, when worked up as described for the reaction product obtained in the resolution (below) yielded some more; two recrystallisations from absolute alcohol gave needles (0·5 g.), m. p. 181—182°, $\alpha_D^{14°} - 2{\cdot}405°$, $[\alpha]_D^{14°} - 140{\cdot}7°$ ($c = 0{\cdot}4274$ in absolute alcohol; $l = 4$) (Found: N, 11·30. $C_{23}H_{23}O_2N_3$ requires N, 11·26%). Further recrystallisation failed to alter the specific rotation.

Resolution of Benzoin.—(1) *By means of* d-δ-(*α-phenylethyl*)*semicarbazide hydrochloride.* 9 G. of the semicarbazide hydrochloride, dissolved in 18 c.c. of water, were added to a solution of 8 g. of benzoin in 70 c.c. of pyridine at 18°, and the mixture after standing for 7 days was poured into 1000 c.c. of cold water. In about 80 minutes the opalescent liquor was decanted from the thick, sticky oil, and the latter was agitated three times with almost boiling water, with cooling and decanting each time. The hard, glassy solid thus obtained (and the beaker containing it) were exposed for 72 hours in an evacuated desiccator over sulphuric acid to remove the last traces of pyridine and water. A solution of the product in about 50 c.c. of pure dry ether deposited a crop of crystals on standing a few hours or on addition of light petroleum. (The ethereal mother-liquor, after various attempts to recover material from it, gave only a gummy product.) The crystals were collected, washed with ether, and recrystallised twice from boiling absolute alcohol, in which the compound was sparingly soluble when cold. The *d*-δ-(α-phenylethyl)semicarbazone of *d*-benzoin thus obtained was optically pure (repeated recrystallisation from alcohol failing to raise its specific rotation) and consisted of needles, m. p. 181—182°; yield 1·8 g. (Found: N, 11·29%); $\alpha_D^{15°} - 2{\cdot}415°$, $[\alpha]_D^{14°} - 141{\cdot}5°$ ($c = 0{\cdot}4268$ in absolute alcohol; $l = 4$). It showed no lowering of m. p. on admixture with the product (m. p. 181—182°) obtained from synthetic *d*-benzoin; the appearance of both was identical under the microscope, and the specific rotations (— 140·7° and — 141·5°) are identical within the limits of experimental error.

(2) *By means of* l-δ-(*α-phenylethyl*)*semicarbazide hydrochloride.* Using 13·2 g. of the *l*-semicarbazide hydrochloride in 26 c.c. of water, and 12·5 g. of benzoin in 95 c.c. of pyridine, and working up the

product as in the last preparation, we obtained 1·8 g. of pure l-*benzoin*-l-δ-(α-*phenylethyl*)*semicarbazone*, m. p. 181—182° (Found: N, 11·32%). The product was optically pure after two recrystallisations from absolute alcohol, in which $\alpha_D^{14°} = +4·40°$, $[\alpha]_D^{14°} + 140·9°$ ($c = 0·7808$; $l = 4$).

Liberation of d- *and of* l-*Benzoin*—(1) d-*Benzoin*. Boiling solutions of 1·4 g. of *d*-benzoin-*d*-δ-(α-phenylethyl)semicarbazone in 50 c.c. of absolute alcohol and of 15 g. of oxalic acid in 12 c.c. of water were mixed and boiling was continued for 1 minute. (Longer boiling causes oxidation to benzil derivatives; see J., 1925, **127**, 1282.) The solution, cooled immediately and diluted with 250 c.c. of water, gave a precipitate of *d*-benzoin which was collected after a few hours. Boiling for some time with 200 c.c. of light petroleum (b. p. 60—80°) dissolved the active benzoin but left undissolved the traces of unhydrolysed semicarbazone and other impurities. After cooling and standing, the petroleum extract was filtered and concentrated to half its volume; the *d*-benzoin which crystallised was optically pure after one recrystallisation from absolute alcohol; yield 0·7 g.; m. p. 133—134°; mixed m. p. with synthetic *d*-benzoin (with which it is identical in appearance) 133—134°; $\alpha_D^{11°} + 5·954$, $[\alpha]_D^{11°} + 118·3°$ ($c = 1·2581$ in acetone; $l = 4$).

(2) l-*Benzoin*. 1·6 G. of *l*-benzoin-*l*-δ-(α-phenylethyl)semicarbazone were hydrolysed in an exactly similar fashion. The liberated *l*-benzoin was recrystallised once from light petroleum and once from alcohol, and was then optically pure; yield 0·8 g.; m. p. 133—134°; $\alpha_D^{11°} - 5·435°$, $[\alpha]_D^{11°} - 118·5°$ ($c = 1·1467$ in acetone; $l = 4$). Oxidation of both the active benzoins with nitric acid yielded benzil.

The gummy product referred to on p. 2487 was dissolved in boiling alcohol, then mixed with a hot, concentrated, aqueous solution of oxalic acid, and boiled for 5 minutes. The mixture of solid and semi-solid, obtained after dilution with water and standing, was separated by ether into sparingly soluble (m. p. above 200°), soluble (m. p. 129—132°), and very soluble (a gum) fractions. The first fraction on recrystallisation from alcohol proved to be *benzildi*-d-δ-(α-*phenylethyl*)*semicarbazone*, long, fine needles, m. p. 233° (Found: N, 15·86. $C_{32}H_{32}O_2N_6$ requires N, 15·79%); $\alpha_D^{17°} + 3·08°$, $[\alpha]_D^{17°}$ 178·2° ($c = 0·4320$ in glacial acetic acid; $l = 4$). By boiling in alcohol with concentrated hydrochloric acid—but not with oxalic acid—it was hydrolysed to benzil. The second fraction on fractional recrystallisation from ether gave chiefly inactive benzoin, which separated first, followed by a crop of benzoin showing lævorotation, m. p. 132—133°; $\alpha_D^{17°} - 0·46°$, $[\alpha]_D^{17°} - 25·7°$ ($c = 0·8974$ in absolute alcohol; $l = 2$). The corresponding gummy product

obtained in the condensation of benzoin and *l*-δ-(α-phenylethyl)semicarbazide hydrochloride gave, on hydrolysis with oxalic acid, a sparingly soluble product (m. p. 238°), *r*-benzoin (m. p. 134°), and benzoin (m. p. 131—133°) showing dextrorotation.

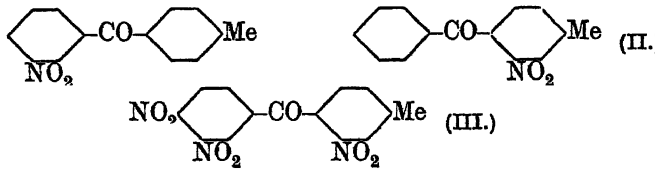
We propose to extend our investigations to the resolution of other racemic ketones and aldehydes by means of active semicarbazides.

We wish to thank the Carnegie Trust for the Universities of Scotland for grants which have partly defrayed the cost of this work.

THE ROYAL TECHNICAL COLLEGE,
GLASGOW.

[*Received, June 11th*, 1928.]

CCCXXX.—*The Nitration and Bromination of 4-Methylbenzophenone.*



By WILLIAM BLAKEY and HAROLD ARCHIBALD SCARBOROUGH.

IT has been shown (J., 1927, 2865) that the influence of a methoxyl group, in the 4-position, in the benzophenone series is to direct the first entering substituent into the 3-position; and that further substitution leads to the 3′- and the 5-positions being occupied successively. The halogens, which are usually classed with the methoxyl group since their ortho-para directive power is also to be ascribed to a conjugative effect, behave in the benzophenone series in a different manner, in that the first entering substituent goes into the unsubstituted nucleus (compare Kunckel, *Ber.*, 1904, **37**, 3485; Montagne, *Ber.*, 1916, **49**, 2262). It thus seemed of interest to investigate the behaviour of the methyl group, the least active of the ortho-para directive series, and compare it with that of the methoxyl group and of a halogen.

In an investigation of the products of nitration of phenyl-*p*-tolylmethane, Zincke and Milne (*Ber.*, 1872, **5**, 685) showed that a nitro-derivative of 4-methylbenzophenone was formed; and in a further communication, Zincke and Plascuda (*Ber.*, 1874, **7**, 983) described the preparation of the mono-, di-, and tri-nitro-derivatives of the ketone, ascribing the structure 3′-nitro-4-methylbenzophenone (I) to the first because it was oxidised by chromic anhydride in glacial acetic acid solution to *m*-nitrobenzoic acid.

A synthesis of 3′-nitro-4-methylbenzophenone, from *m*-nitrobenzoyl chloride and toluene, was carried out by Limpricht and Lenz (*Annalen*, 1895, **286**, 324), but neither this compound nor its derivatives had the properties ascribed to them by Zincke and Plascuda. Basing their opinion upon the product of oxidation,

Limpricht and Lenz reassigned to the alleged substance (I) the structure 2-nitro-4-methylbenzophenone (II); further, they suggested that the continued nitration of 3′-nitro-4-methylbenzophenone yielded 2 : 3′-dinitro-4-methylbenzophenone, and that 3′-nitro-, 4′-nitro-, 2 : 3′-, and 2 : 4′-dinitro-4-methylbenzophenones all gave the same trinitro-compound (III).

The evidence upon which these structures are based seems to be very slender, and, moreover, appears to be contrary to the rules of substitution; the matter was therefore re-investigated.

The nitration of 4-methylbenzophenone, in fuming nitric acid solution, yielded 3-*nitro*-4-*methylbenzophenone*, of which the constitution was established by condensing 3-nitro-*p*-toluoyl chloride with benzene. Under the same conditions, 3′-nitro-4-methylbenzophenone was converted into 3 : 3′-*dinitro*-4-*methylbenzophenone*; the same product was also obtained when 3-nitro-4-methylbenzophenone was nitrated in cold sulphuric acid solution. Further, 4′-nitro-4-methylbenzophenone yielded 3 : 4′-*dinitro*-4-*methylbenzophenone*, since on partial reduction and deamination 3-nitro-4-methylbenzophenone resulted.

The continued nitration of 3 : 3′-dinitro-4-methylbenzophenone in sulphuric acid solution, at 80°, yielded 3 : 3′ : 5-*trinitro*-4-*methylbenzophenone*, which was also obtained when the product of condensation of 3 : 5-dinitro-*p*-toluoyl chloride and benzene was nitrated in sulphuric acid solution, the assigned structure being thus established. Further nitration of 3 : 4′-dinitro-4-methylbenzophenone with a slight excess of nitric acid and in sulphuric acid solution gave 3 : 4′ : 5-*trinitro*-4-*methylbenzophenone*, whereas by use of a large excess of nitric acid at 80°, 3 : 3′ : 4′ : 5-*tetranitro*-4-*methylbenzophenone* was obtained. The proof of the structure of these compounds depends largely upon their reactions with *p*-nitrosodimethylaniline and with piperidine.

The bromination of 4-methylbenzophenone, which was effected by dissolving the compound in a large excess of dry bromine, gave 3-*bromo*-4-*methylbenzophenone*, the structure being established by a synthesis of the compound from 3-bromo-*p*-toluoyl chloride and benzene, and also by reducing 3-nitro-4-methylbenzophenone to the amine and replacing the amino-group by bromine. Under the same conditions 3′- and 4′-nitro- and 3′ : 5′-*dinitro*-4-*methylbenzophenones*

were brominated and in each case the bromine atom entered the 3-position. In the first two cases the products were reduced to the corresponding amino-compounds, and removal of the amino-group yielded 3-bromo-4-methylbenzophenone, thus establishing the constitutions.

The nitration of 4′-chloro-4-methylbenzophenone, in nitric acid solution, gave an almost quantitative yield of *4′-chloro-3-nitro-4-methylbenzophenone*, which was also obtained when 3-nitro-*p*-toluoyl chloride was condensed with chlorobenzene. Further nitration, in sulphuric acid solution, yielded *4′-chloro-3 : 3′-dinitro-4-methylbenzophenone* of which the structure was established by condensing 4-chloro-3-nitrobenzoyl chloride with toluene and nitrating the product by fuming nitric acid. Continued nitration, in sulphuric acid solution at 60°, gave *4′-chloro-3 : 3′ : 5-trinitro-4-methylbenzophenone*; the same compound was obtained on nitration of *4′-chloro-3 : 5-dinitro-4-methylbenzophenone*, which was itself prepared by condensing 3 : 5-dinitro-*p*-toluoyl chloride with chlorobenzene, whereby the structure was established.

On bromination of 4′-chloro-4-methylbenzophenone in excess of dry bromine, *4′-chloro-3-bromo-4-methylbenzophenone* was formed in quantitative yield; its structure was established by reducing 4′-chloro-3-nitro-4-methylbenzophenone to the amine and then replacing the amino-group by bromine.

The results show that the methyl group exerts a marked directive influence, and that the first substituent enters in the ortho-position to this group. The presence of one or two nitro-groups or a chlorine atom in the phenyl nucleus does not appear to affect the position taken up by the entering substituent. The second entering substituent goes to the 3′-position, and the presence of a substituent in the 3-position of the tolyl nucleus would appear to inhibit further substitution in this nucleus. The third entering substituent occupies the 5-position whatever the nature of the substituents previously introduced. The formation of a single product on the further substitution of 4′-chloro-4-methylbenzophenone was to be expected from a consideration of the substitution products of 4-chloro- and of 4-methyl-benzophenone.

A comparison between the behaviour of the methyl and the methoxyl groups shows that they are alike in that the sequence in which substituents enter is the same, with one exception, and the methods by which these substituents are introduced are similar. They differ in that on di- and tri-substitution the methyl group leads to only one isolable isomeride, whereas with the methoxyl group at least two isomerides are obtained.

EXPERIMENTAL.

4-Methylbenzophenone was prepared from benzoyl chloride and toluene according to the method described by Meyer (*Monatsh.*, 1907, **28**, 1223); it separated from light petroleum in plates, m. p. 56°.

3-*Nitro*-4-*methylbenzophenone*.—This was obtained (*a*) from 4-methylbenzophenone by dissolving it in nitric acid (*d* 1·5) and allowing the solution to stand for 1 hour, or (*b*) from 3-nitro-*p*-toluic acid by conversion into the acid chloride, with excess of thionyl chloride, and condensation with benzene in the presence of aluminium chloride; it crystallised from acetic acid or from alcohol in faintly yellow plates, m. p. 129° (Found: N, 5·95. $C_{14}H_{11}O_3N$ requires N, 5·8%).

On reduction of this compound with tin and hydrochloric acid, decomposition of the tin double salt with 30% sodium hydroxide solution, and extraction of the free base with ether, 3-*amino*-4-*methylbenzophenone* was obtained; it separated from methyl alcohol in needles, m. p. 109° (Found: N, 6·7. $C_{14}H_{13}ON$ requires N, 6·65%). The *hydrobromide* separated from its solution in dilute acid in long needles, m. p. 130° (Found: HBr, 27·5. $C_{14}H_{13}ON,HBr$ requires HBr, 27·7%); the *acetyl* derivative, formed by refluxing the base for 6 hours with a mixture of acetic acid and acetic anhydride, crystallised from methyl alcohol in needles, m. p. 108° (Found: C, 76·05; H, 5·95. $C_{16}H_{15}O_2N$ requires C, 75·9; H, 5·95%).

3-*Bromo*-4-*methylbenzophenone*.—This was obtained (*a*) when 3-amino-4-methylbenzophenone was diazotised and treated with cuprous bromide; (*b*) when 4-methylbenzophenone was dissolved in dry bromine and the solution allowed to stand in sunlight for 2 days, the excess of bromine being removed in a current of air and by treatment with sulphurous acid; and (*c*) when 3-bromo-*p*-toluic acid was converted into the acid chloride and condensed with benzene in the presence of aluminium chloride. It separated from methyl alcohol in needles, m. p. 107° (Found: Br, 29·1. $C_{14}H_{11}OBr$ requires Br, 29·1%).

3 : 3′-*Dinitro*-4-*methylbenzophenone*.—5 G. of 3-nitro-4-methylbenzophenone were dissolved in 10 c.c. of sulphuric acid and 5 c.c. of acetic acid, treated with 2 c.c. of nitric acid (*d* 1·5), and the solution allowed to stand for 2 days. A mixture of di- and tri-nitro-derivatives was precipitated on pouring into water, and the more soluble dinitro-compound was isolated by repeated extractions with small quantities of methyl alcohol. The same product, 3 : 3′-*dinitro*-4-*methylbenzophenone*, was obtained when 3′-nitro-4-methylbenzophenone was dissolved in nitric acid (*d* 1·5) and the solution allowed to stand for 2 hours. It crystallised from methyl alcohol in

faintly yellow plates, m. p. 135° (Limpricht and Lenz, *loc. cit.*, give m. p. 125°) (Found : N, 9·8. $C_{14}H_{10}O_5N_2$ requires N, 9·8%).

3 : 5-*Dinitro*-4-*methylbenzophenone*.—5 G. of 3 : 5-dinitro-*p*-toluic acid were refluxed with an excess of thionyl chloride, the excess was removed, and the residue dissolved in 100 c.c. of benzene; 10 g. of aluminium chloride were added gradually, and the reaction completed on the water-bath. 3 : 5-*Dinitro*-4-*methylbenzophenone* crystallised from alcohol in small, yellow plates, m. p. 109° (Found : N, 9·8. $C_{14}H_{10}O_5N_2$ requires N, 9·8%).

5-*Nitro*-3-*amino*-4-*methylbenzophenone*, prepared from this compound by reduction with hydrogen sulphide in alcoholic ammonia solution, crystallised from alcohol in deep orange needles, m. p. 157° (Found : N, 11·0. $C_{14}H_{12}O_3N_2$ requires N, 10·95%).

3 : 3′ : 5-*Trinitro*-4-*methylbenzophenone*.—When 3 : 5-dinitro-4-methylbenzophenone, dissolved in sulphuric acid, was treated with an excess of nitric acid (*d* 1·5) and the solution allowed to stand for some days at room temperature, or when 3-nitro-, 3′-nitro-, or 3 : 3′-dinitro-4-methylbenzophenone was further nitrated under similar conditions, 3 : 3′ : 5-*trinitro*-4-*methylbenzophenone* was obtained; it separated from acetic acid in pale yellow needles, m. p. 173° (Found : N, 12·55. $C_{14}H_9O_7N_3$ requires N, 12·65%).

3 : 4′-*Dinitro*-4-*methylbenzophenone*.—This was prepared by dissolving 4′-nitro-4-methylbenzophenone in an excess of nitric acid (*d* 1·5) and allowing the solution to stand for 2 hours; it separated from alcohol in faintly yellow plates, m. p. 130° (compare Limpricht and Lenz, *loc. cit.*).

3-*Nitro*-4′-*amino*-4-*methylbenzophenone*.—A warm solution of 10 g. of 3 : 4′-dinitro-4-methylbenzophenone in a mixture of 200 c.c. of alcohol and 10 c.c. of ammonia (*d* 0·880) was treated with hydrogen sulphide until saturated; after removal of a part of the alcohol, the residue was poured into dilute hydrochloric acid, heated, and filtered. An unstable hydrochloride separated on cooling. The free *base* was liberated with ammonia; it crystallised from methyl alcohol in yellow plates, m. p. 164° (Found : N, 11·0. $C_{14}H_{12}O_3N_2$ requires N, 10·95%). On removal of the amino-group in the usual manner, 3-nitro-4-methylbenzophenone (m. p. 129°) was obtained.

3 : 4′ : 5-*Trinitro*-4-*methylbenzophenone*.—5 G. of 4′-nitro-4-methylbenzophenone, dissolved in 20 c.c. of sulphuric acid, were treated with 4 c.c. of nitric acid (*d* 1·5), the solution was kept for 24 hours, and the reaction completed on the water-bath. The product crystallised from acetic acid in pale yellow needles, m. p. 160° (Found : N, 12·7. $C_{14}H_9O_7N_3$ requires N, 12·65%). This compound did not react with piperidine, but with *p*-nitrosodimethylaniline in alcoholic solution it yielded a light brown, amorphous powder which could not be

obtained in a sufficiently pure state for analysis. When the trinitro-compound was reduced with hydrogen sulphide in alcoholic ammonia solution, and the product worked up in the manner previously described, *3-nitro-4′ : 5-diamino-4-methylbenzophenone* was obtained; it separated from dilute acetone in orange plates, m. p. 202° (Found: N, 15·2. $C_{14}H_{13}O_3N_3$ requires N, 15·5%). 3-Nitro-4-methylbenzophenone was obtained on the removal of the amino-groups, thus suggesting that one of these groups was present in each nucleus.

3 : 3′ : 4′ : 5-Tetranitro-4-methylbenzophenone.—When either 3 : 4′-dinitro- or 3 : 4′ : 5-trinitro-4-methylbenzophenone was dissolved in a mixture of equal volumes of sulphuric and nitric acids and heated on the water-bath for 6 hours, *3 : 3′ : 4′ : 5-tetranitro-4-methylbenzophenone* was obtained; it separated from acetic acid in small, yellow prisms, m. p. 187° (Found: N, 14·9. $C_{14}H_8O_9N_4$ requires N, 14·9%). This compound reacted with piperidine, with boiling alcoholic ammonia, and with sodium methoxide, but in each case the product was a brown powder which could not be recrystallised from any of the usual solvents.

3-Bromo-3′-nitro-4-methylbenzophenone was obtained when 3′-nitro-4-methylbenzophenone was treated with an excess of dry bromine; it separated from alcohol in faintly yellow plates, m. p. 124° (Found: Br, 24·85. $C_{14}H_{10}O_3NBr$ requires Br, 25·0%). On reduction with stannous chloride in alcoholic hydrogen chloride solution, *3-bromo-3′-amino-4-methylbenzophenone* was obtained, which crystallised from dilute methyl alcohol in yellow needles, m. p. 94° (Found: Br, 27·6. $C_{14}H_{12}ONBr$ requires Br, 27·6%); deamination yielded 3-bromo-4-methylbenzophenone (m. p. 107°).

3′ : 5′-Dinitro-4-methylbenzophenone, prepared by condensation of 3 : 5-dinitrobenzoyl chloride with toluene in the presence of aluminium chloride, crystallised from methyl alcohol in faintly yellow plates, m. p. 134° (Found: N, 9·8. $C_{14}H_{10}O_5N_2$ requires N, 9·8%); on treatment with an excess of dry bromine, this yielded *3-bromo-3′ : 5′-dinitro-4-methylbenzophenone*, which separated from alcohol or acetic acid in faintly yellow needles, m. p. 173° (Found: N, 7·7. $C_{14}H_9O_5N_2Br$ requires N, 7·65%). The structure of the latter compound follows from its analogy with 3-bromo-3′-nitro-4-methylbenzophenone.

3-Bromo-4′-nitro-4-methylbenzophenone, prepared from 4′-nitro-4-methylbenzophenone in the manner previously described, crystallised from alcohol in faintly yellow plates, m. p. 119° (Found: Br, 24·85. $C_{14}H_{10}O_3NBr$ requires Br, 25·0%); on reduction with stannous chloride in alcoholic hydrogen chloride solution, *3-bromo-4′-*

amino-4-methylbenzophenone was formed: faintly yellow needles, m. p. 162°, from methyl alcohol (Found: N, 5·0. $C_{14}H_{12}ONBr$ requires N, 4·9%). Deamination yielded 3-bromo-4-methylbenzophenone (m. p. 107°).

4'-Chloro-3-nitro-4-methylbenzophenone, obtained when *p*-chlorobenzoyl chloride was condensed with toluene in the presence of aluminium chloride, and the product (m. p. 128°) dissolved in excess of nitric acid (*d* 1·5) and allowed to stand for 12 hours, separated from methyl alcohol in long needles, m. p. 98°. It was also obtained when 3-nitro-4'-amino-4-methylbenzophenone was diazotised and treated with cuprous chloride (Found: N, 5·15. $C_{14}H_{10}O_3NCl$ requires N, 5·1%). Reduction of this nitro-compound in the usual manner gave *4'-chloro-3-amino-4-methylbenzophenone*, which crystallised from methyl alcohol in faintly yellow prisms, m. p. 142° (Found: N, 5·6. $C_{14}H_{12}ONCl$ requires N, 5·7%).

4'-Chloro-3'-nitro-4-methylbenzophenone was prepared by dissolving 4-chloro-3-nitrobenzoyl chloride in toluene in the presence of aluminium chloride; it separated from methyl alcohol in heavy yellow prisms, m. p. 121° (Found: N, 5·2; Cl, 12·85. $C_{14}H_{10}O_3NCl$ requires N, 5·1; Cl, 12·9%).

4'-Chloro-3 : 3'-dinitro-4-methylbenzophenone was obtained when the foregoing compound was dissolved in nitric acid (*d* 1·5) and the solution allowed to stand for 24 hours; or when 4'-chloro-3-nitro-4-methylbenzophenone, dissolved in sulphuric acid, was treated with a slight excess of nitric acid. In the latter case, the product was a mixture of di- and tri-nitro-compounds. The substance crystallised from methyl alcohol or dilute acetone in yellow prisms, m. p. 131° (Found: N, 8·75. $C_{14}H_9O_5N_2Cl$ requires N, 8·75%).

4'-Chloro-3 : 5-dinitro-4-methylbenzophenone, resulting from the condensation of 3 : 5-dinitro-4-toluoyl chloride and chlorobenzene in presence of aluminium chloride, crystallised from alcohol or acetic acid in yellow plates, m. p. 118° (Found: N, 8·8. $C_{14}H_9O_5N_2Cl$ requires N, 8·75%).

4'-Chloro-3 : 3' : 5-trinitro-4-methylbenzophenone was obtained when 3'-nitro- or 3 : 3'- or 3 : 5-dinitro-4'-chloro-4-methylbenzophenone was dissolved in a mixture of sulphuric and nitric acids and the solution gently warmed or allowed to stand for some days at the ordinary temperature; it separated from acetic acid in heavy, yellow needles, m. p. 182° (Found: N, 11·45. $C_{14}H_8O_7N_3Cl$ requires N, 11·5%).

4'-Chloro-3-bromo-4-methylbenzophenone was prepared by dissolving 4'-chloro-4-methylbenzophenone in dry bromine, and by treating a diazotised solution of 4'-chloro-3-amino-4-methylbenzo-

phenone with cuprous bromide; it crystallised from alcohol in needles, m. p. 122° (0·1756 G. gave 0·1885 g. of silver halides. $C_{14}H_{10}OClBr$ requires 0·1880 g.).

THE UNIVERSITY CHEMICAL LABORATORIES,
CAMBRIDGE. [*Received, July 4th*, 1928.]

CCCXXXI.—*The Constituents of Some Indian Essential Oils. Part XXV.* 1-*α*- *and* 1-*β*-*Curcumenes.*

By B. SANJIVA RAO and JOHN LIONEL SIMONSEN.

RAO, SHINTRE, and SIMONSEN (*J. Ind. Inst. Sci.*, 1926, **9A**, 140) separated from the essential oil occurring in the rhizomes of *Curcuma aromatica*, Salisb., a sesquiterpene to which they gave the name *l*-curcumene. The hydrocarbon, characterised by the preparation of a number of crystalline derivatives, appeared to be homogeneous and to be monocyclic with three ethylenic linkages. Since it was obtainable comparatively readily in quantity, we decided to attempt to determine its constitution, a problem which it seemed all the more desirable to elucidate, since only a few monocyclic sesquiterpenes have been studied, bisabolene and zingiberene being the more important.

Early in the investigation, evidence was obtained that *l*-curcumene, in spite of its apparent homogeneity, was a mixture of at least two hydrocarbons, the crystalline nitrosate and trihydrochloride previously described being derived from two different sesquiterpenes. It was observed that the yields of these two derivatives varied very considerably with different specimens of the oil, and further, when the sesquiterpene fraction was warmed with dilute sulphuric acid or treated with sodium in amyl-alcoholic solution, the recovered hydrocarbon gave the nitrosate in undiminished yield but the crystalline trihydrochloride could no longer be obtained. Fractional distillation of the oil, from which the trihydrochloride had been separated, showed the presence of a sesquiterpene monohydrochloride, the parent hydrocarbon of which (see p. 2501) gave the crystalline nitrosate in a yield exceeding that obtained with the original terpene, whilst treatment with hydrogen chloride did not give any trihydrochloride. The presence of at least two hydrocarbons in the sesquiterpene "*l*-curcumene" having thus been proved, it became necessary to devise methods for the preparation of each of them in a pure state prior to undertaking experiments on their constitution. In this we have been successful, and as it is no longer possible for us to collaborate, we have decided to place on record the results so far obtained.

We have designated the hydrocarbon yielding the crystalline nitrosate and the liquid monohydrochloride l-*α-curcumene*. This substance can be obtained fairly pure by treatment of the monohydrochloride with sodium acetate in acetic acid solution, but it is obtained in a much higher state of purity by a somewhat indirect method. Treatment of the nitrosate with alcoholic potassium hydroxide solution yields l-*oximino-α-curcumene*, $C_{15}H_{22}$·NOH, a colourless oil which can be distilled in small quantities without decomposition. It was characterised by the preparation of a crystalline *benzoyl* derivative, m. p. 84—85°, and a *monohydrochloride*, m. p. 135—136°. The latter substance is not a salt, but is formed by the addition of hydrogen chloride to one of the ethylenic linkages, since it is not decomposed by alkali. So far as we are aware, this is the first oximino-derivative obtained directly from a sesquiterpene. Semmler and Bode (*Ber.*, 1907, **40**, 1129) and Semmler and Hoffmann (*ibid.*, p. 3527) have described the oximes of *d*-santalal, an aldehyde obtained by the oxidation of a primary alcohol present in sandal-wood oil, and of cedrone, a ketone formed by the oxidation of cedrene. We have not succeeded in converting the above-mentioned oxime into the parent ketone (or aldehyde), but further experiments in this direction are contemplated, for little appears to be known of the properties of the sesquiterpene ketones.

When *l*-oximino-α-curcumene is reduced with sodium in ethylalcoholic solution it is converted into l-*dihydro-α-curcumenylamine*, $C_{15}H_{25}$·NH_2, one of the ethylenic linkages having been reduced as well as the oximino-group. The base, which was most readily purified through its sparingly soluble *hydrogen oxalate*, was a viscid oil possessing a strong ammoniacal smell. The reduction of one of the ethylenic linkages on passing from the oximino-derivative to the base was not anticipated and was somewhat unfortunate, since it had been hoped to introduce a fourth ethylenic linkage by submitting the base to a Hofmann degradation process. It was then expected that, by molecular rearrangement, a substituted derivative of benzene would have resulted which might have proved suitable for oxidation experiments. This reaction would open up a new method of attacking the problem of the constitution of the sesquiterpenes. It is proposed to study the properties of the sesquiterpene amines, only two other members of the series having been previously described (Semmler and Hoffmann, *loc. cit.*; Semmler and Mayer, *Ber.*, 1911, **44**, 3678).

Methylation of *l*-dihydro-α-curcumenylamine with methyl iodide in the presence of alkali yields l-*dihydro-α-curcumenyltrimethylammonium iodide*, $C_{15}H_{25}$·NMe_3I, which crystallises well and gives the corresponding hydroxide on treatment with silver oxide. This

substance, which was also obtained crystalline, could not be purified, since it was extremely hygroscopic, but when distilled under diminished pressure, it decomposed smoothly with formation of a mixture of a hydrocarbon and a base. The base was an oil, distilling without decomposition, and analysis showed it to be *l-dimethyldihydro-α-curcumenylamine*, $C_{15}H_{25}\cdot NMe_2$. It did not yield any crystalline derivatives.

The hydrocarbon was the main product of the degradation and was found to be very pure *l*-α-curcumene. The yield of nitrosate from the terpene prepared in this manner was very much higher than from that regenerated from the monohydrochloride (see p. 2501). On treatment with hydrogen chloride in acetic acid solution, it gives a quantitative yield of a monohydrochloride. *l*-α-Curcumene is very stable. It is not reduced by sodium when dissolved in either ethyl or amyl alcohol, nor is it attacked by dilute sulphuric acid. In alkaline solution it is only slowly oxidised by potassium permanganate, whilst titration with bromine in chloroform solution shows the presence of only one ethylenic linkage. The physical properties of the hydrocarbon indicate, however, that it is monocyclic and it must therefore contain three ethylenic linkages. Two of these are remarkably inert, and this is not without analogy (compare Ruzicka and co-workers, *Helv. Chim. Acta*, 1922, **5**, 331; 1923, **6**, 677; 1924, **7**, 1875; *Rec. trav. chim.*, 1928, **47**, 363). When *l*-α-curcumene is reduced catalytically with hydrogen in the presence of platinum oxide (Adams and Shriner, *J. Amer. Chem. Soc.*, 1923, **45**, 2171), addition of six hydrogen atoms takes place with formation of the saturated hydrocarbon, *hexahydro-α-curcumene*, $C_{15}H_{30}$, which is optically inactive.

Whilst this reaction appears to confirm the presence of three ethylenic linkages, it cannot be regarded as conclusive, since it has been shown (Iyer and Simonsen, J., 1926, 2049) that a *cyclo*propane ring can be reduced catalytically. It was therefore decided to examine the action of benzoylhydroperoxide on the terpene, since it has been shown by Nametkin (*J. pr. Chem.*, 1926, **112**, 169; 1927, **115**, 56) and Meerwein (*ibid.*, 1926, **113**, 56) that this reagent is especially suitable for the estimation of ethylenic linkages. The experiments (see p. 2505) establish definitely the presence of three such linkages in *l*-α-curcumene.

It has not been found possible to dehydrogenate the sesquiterpene with either sulphur or selenium with formation of a naphthalene derivative, as Ruzicka, Meyer, and Mingazzini (*Helv. Chim. Acta*, 1922, **5**, 345) succeeded in doing in the case of the monocyclic sesquiterpene, zingiberene. This would appear to indicate that *l*-α-curcumene does not contain a " potential " naphthalene nucleus.

l-β-Curcumene has been regenerated in a pure state from its trihydrochloride by treatment with anhydrous sodium acetate in acetic acid solution. It is a monocyclic terpene containing three ethylenic linkages, the presence of which can be proved readily by titration with bromine as well as by the formation of the trihydrochloride. On catalytic reduction l-*hexahydro*-β-*curcumene* is formed, the reduction proceeding much more readily than in the case of the isomeride, and the product was optically active. We are not in a position to say whether the two fully reduced hydrocarbons are structurally identical. Oxidation with benzoylhydroperoxide also proceeded smoothly and confirmed the presence of three ethylenic linkages.

Unlike the α-hydrocarbon, *l*-β-curcumene is very unstable and is readily isomerised. After treatment of the hydrocarbon with 10% sulphuric acid or with sodium in amyl-alcoholic solution, the crystalline trihydrochloride can no longer be isolated, although no reduction takes place in the latter reaction. It seems probable from the properties of the recovered hydrocarbon that the action of dilute sulphuric acid results in the formation of a dicyclic terpene, and this will be further investigated. Dehydrogenation with either sulphur or selenium did not lead to any recognisable products.

Reference has been made above to the fact that *l*-dihydro-α-curcumenylamine belongs to a type of base which has been little studied, and it therefore appeared of interest to have its physiological properties examined. Dr. T. A. Henry kindly arranged for the base to be tested by Dr. J. Trevan at the Wellcome Physiological Research Laboratories, and we are very much indebted to him for the following report:

"(1) On the pithed cat (brain destroyed): 0·4 mg. as hydrochloride, no effect; 4·0 mg., a very slight rise in blood pressure; 40 mg. caused a fall in blood pressure from heart failure.

"(2) On isolated rabbit's uterus in Ringer's solution, a concentration of 1/5000 of the hydrochloride killed the muscle.

"(3) In an etherised cat with intact brain, 4 mg. produced a slight fall in blood pressure.

"The base has therefore no characteristic physiological action beyond a general toxic action."

In its toxic properties this base thus resembles the unsaturated amine obtained by the reduction of santonin oxime (Fränkel, "Die Artzneimittel-Synthese," p. 737) and the unsaturated dicyclic amine, camphenamine (*op. cit.*, p. 743).

Experimental.

The sesquiterpene used in these experiments was separated as described in the previous communication (*loc. cit.*, p. 143). It was carefully purified by distillation over sodium and had b. p. 127—129°/6 mm. The constants of the oil obtained in different preparations varied somewhat ($d_{30^\circ}^{30^\circ}$ 0·8760—0·8764; $n_D^{30^\circ}$ 1·4929—1·4940; $[\alpha]_D^{30^\circ}$ − 19·4° to − 25·9°; $[R_L]_D$ 67·67—67·74). This somewhat large variation was due to the different proportions of *l*-α- and *l*-β-curcumenes present in the oil, as indicated by a similar variation in the respective yields of nitrosate and trihydrochloride obtained. Since *l*-β-curcumene is readily isomerised, it appeared possible that distillation over sodium might be injurious, but this was found not to be the case. A specimen of the original sesquiterpene was purified by repeated distillation without the use of sodium, and the constants were very similar (b. p. 129—130°/7 mm.; $d_{30^\circ}^{30^\circ}$ 0·8790; $n_D^{30^\circ}$ 1·4944; $[\alpha]_D^{30^\circ}$ −20·8°). The relative yields of nitrosate and trihydrochloride were not affected by distillation over sodium. An attempt was made to separate *l*-α- and *l*-β-curcumene by fractional distillation through a four-pear Young still-head; ten fractions, b. p. 129—131°/7 mm., were taken, but the difference in physical properties was small [(1) $d_{30^\circ}^{30^\circ}$ 0·882; $n_D^{30^\circ}$ 1·4932; $[\alpha]_D^{30^\circ}$ −22·0°; (5) $d_{30^\circ}^{30^\circ}$ 0·881; $n_D^{30^\circ}$ 1·4940; $[\alpha]_D^{30^\circ}$ −24·8°; (10) $d_{30^\circ}^{30^\circ}$ 0·8740; $n_D^{30^\circ}$ 1·4940; $[\alpha]_D^{30^\circ}$ −24·1°]. No difference was observed in the yields of nitrosate and of trihydrochloride from the ten different fractions of the hydrocarbon.

l-α-*Curcumene.*

Nitrosate.—To a well-cooled mixture of *l*-curcumene (10 c.c.), amyl nitrite (8 c.c.), and acetic acid (20 c.c.), nitric acid (d 1·42; 8 c.c.) was gradually added, efficient stirring being essential during the addition; the mixture was kept for some hours, then alcohol was added, and the voluminous precipitate collected and well washed with alcohol. As previously found (*loc. cit.*, p. 143), the nitrosate after crystallisation from methyl alcohol had m. p. 100—101°, but a sample which was recrystallised after 3 weeks' keeping had m. p. 110° (compare Earl and Kenner, J., 1927, 1275). The nitrosate is readily soluble in most of the ordinary organic solvents with the exception of methyl and ethyl alcohols and light petroleum. In chloroform solution (c = 5·634) $[\alpha]_D^{30^\circ}$ −20·4°. A chloroform solution of the nitrosate did not decolorise bromine and was not acted upon by hydrogen chloride in ethereal solution. The yield of the nitrosate varied considerably (2·3—4·5 g. from 10 g.), depending upon the sample of *l*-curcumene used in its preparation.

l-α-*Curcumenenitrolbenzylamine.*—A mixture of the nitrosate (5 g.), benzylamine (3·6 g.), and alcohol (20 c.c.) was heated on the water-bath for 1 hour. On cooling and addition of water, an oil separated which slowly crystallised. It separated from dilute alcohol in leaflets, m. p. 102—104°. In methyl alcohol ($c = 2·46$) $[\alpha]_D^{30°}$ −19·5° (Found : N, 8·5. $C_{22}H_{32}ON_2$ requires N, 8·2%).

l-α-*Curcumene Monohydrochloride.*—A well-cooled solution of *l*-curcumene (10 g.) in acetic acid (30 c.c.) was saturated with hydrogen chloride, and after standing over-night the mixture was poured on ice. The partly crystalline oil was dissolved in ether, the ether dried and evaporated, and the residue cooled in a freezing mixture. The solid, *l*-β-curcumene trihydrochloride, was removed by filtration through an ice-cooled funnel, and when the liquid hydrochlorides were fractionated under diminished pressure, l-α-*curcumene monohydrochloride* was readily obtained pure, b. p. 150—155°/8 mm. (Found : Cl, 14·7. $C_{15}H_{25}Cl$ requires Cl, 14·8%). The hydrochloride is a colourless oil which has no tendency to crystallise. As was the case with the nitrosate, the relative yields of trihydrochloride and monohydrochloride showed very considerable variation.

In an experiment made with the object of regenerating the parent hydrocarbon, a mixture of the monohydrochloride (40 g.), acetic acid (100 c.c.), and anhydrous sodium acetate (50 g.) was heated in a bath at 140° for 2½ hours. The hydrocarbon separated by distillation in steam and fractionation over sodium had b. p. 118—120°/5 mm.; $d_{30°}^{30°}$ 0·8690, $n_D^{30°}$ 1·4926, $[\alpha]_D^{30°}$ −22·1°; when it was titrated with bromine in chloroform solution, 1 mol. of bromine was absorbed, and treatment with hydrogen chloride did not yield any crystalline trihydrochloride, indicating the absence of *l*-β-curcumene. The hydrocarbon did not, however, consist of pure *l*-α-curcumene, since the yield of nitrosate was low (2 g. from 10 g.).

l-*Oximino*-α-*curcumene.*—When *l*-α-curcumene nitrosate in acetic acid was treated with zinc dust, a vigorous reaction ensued which was difficult to control, and a mixture of hydrocarbons and alcohols was formed. The following method was adopted as the most convenient for the preparation of the oximino-derivative.

The freshly prepared nitrosate was dissolved in the minimum quantity of hot alcohol and heated on the water-bath with an equivalent amount of alcoholic potassium hydroxide for 20 minutes. An excess of water was added, the oil which separated extracted with ether, the ether dried, and evaporated. l-*Oximino*-α-*curcumene* is best purified by distillation under diminished pressure, but it is necessary to distil only small quantities at a time to avoid decomposition. It is thus obtained as a colourless, viscid oil, b. p. 182—

185°/7 mm., $d_{30°}^{30°}$ 0·9817; $n_D^{30°}$ 1·5134; $[\alpha]_D^{30°}$ − 27·2°; $[R_L]_D$ 71·37 (Found: C, 77·5; H, 9·6. $C_{15}H_{23}ON$ requires C, 77·2; H, 9·9%). On titration with bromine in chloroform solution, the presence of only one ethylenic linkage was indicated, although the molecular refraction agrees fairly closely with the value (72·07) required for three such linkages. The oxime is insoluble in aqueous potassium hydroxide and in both aqueous and alcoholic solutions of hydrochloric acid; it is, however, soluble in alcoholic potassium hydroxide. Attempts to prepare a crystalline acetyl derivative or oximino-oxime were unsuccessful.

The *benzoyl* derivative, prepared by the Schotten–Baumann reaction, was only obtained crystalline with difficulty and could not be recrystallised, m. p. 84—85° (Found: N, 4·7. $C_{22}H_{27}ON$ requires N, 4·4%). The *monohydrochloride* was formed when an ethereal solution of the oxime was saturated with hydrogen chloride. It crystallised from alcohol in plates, m. p. 135—136° (Found: Cl, 12·9. $C_{15}H_{24}ONCl$ requires Cl, 13·2%). The hydrochloride was very stable and was not acted upon by cold alkali.

l-*Dihydro-α-curcumenylamine.*—To a boiling solution of *l*-oximino-α-curcumene (10 g.) in ethyl alcohol (120 c.c.), sodium (15 g.) was added as rapidly as possible. When all the sodium had dissolved, the base was distilled in steam, dissolved in ether, and the ethereal extract repeatedly washed with dilute hydrochloric acid (1 : 1). The well-cooled solution of the hydrochloride was basified with sodium hydroxide solution and the resulting oil (5 g.) isolated by extraction with ether. The crude base was mixed with an excess of an aqueous solution of oxalic acid, and the sparingly soluble *hydrogen oxalate* which separated was collected; when crystallised from water it separated in clusters of fine needles, m. p. 143—144°, containing 1 mol. of water of crystallisation, which was lost at 100°. It was readily soluble in methyl alcohol, acetone, and benzene, but very sparingly soluble in cold water, ethyl acetate, and chloroform. A chloroform solution of the oxalate was stable to bromine (Found: C, 62·2; H, 9·3; N, 4·1; H_2O, 5·3. $C_{17}H_{29}O_4N,H_2O$ requires C, 62·0; H, 9·4; N, 4·3; H_2O, 5·5%).

l-*Dihydro-α-curcumenylamine*, obtained by the decomposition of the pure oxalate, is a colourless, viscid oil with a strong basic smell, b. p. 151—152°/17 mm.; $d_{30°}^{30°}$ 0·9026; $n_D^{30°}$ 1·4983; $[\alpha]_D^{30°}$ − 22·2°; $[R_L]_D$ 71·85. The molecular refraction agrees closely with the value (71·76) required for two ethylenic linkages (Found: C, 81·6; H, 11·9; N, 6·5. $C_{15}H_{27}N$ requires C, 81·4; H, 12·2; N, 6·3%). Crystalline derivatives of the base could not be obtained with hydrochloric, perchloric, tartaric, or picric acid; the sulphate was a solid, but was not obtained pure. The base can also be

prepared by the reduction of *l*-α-curcumenylamine nitrosate with sodium and alcohol, and this is probably the most convenient method for its preparation in quantity.

The *acetyl* derivative was formed when a mixture of the base (3 g.) and acetic anhydride (1·4 g.) was allowed to remain in a desiccator over sulphuric acid for 24 hours. The crystalline solid which separated was purified from light petroleum and obtained in needles, m. p. 109—110° (Found: C, 77·9; H, 10·7; N, 5·5. $C_{17}H_{29}ON$ requires C, 77·6; H, 11·0; N, 5·3%).

l-*Dihydro-α-curcumenyltrimethylammonium Iodide and Hydroxide.*—The trimethylammonium iodide is obtained in a poor yield when the base in either methyl-alcoholic or acetone solution is treated with methyl iodide. For its preparation in quantity the following method was adopted: The base (1 mol.) was suspended in aqueous sodium hydroxide solution (1 : 2; 5 mols.), and to the hot solution methyl iodide (4—5 mols.) was added drop by drop, the reaction being complete in 4—5 hours. After the reaction mixture had stood for 2 days, the greater portion of the iodide had separated as a crystalline solid. A further quantity can be obtained by saturating the alkaline solution with carbon dioxide, evaporating it to dryness under diminished pressure, and extracting the inorganic salts with alcohol. The crude iodide was best purified by solution in water, saturation of the solution with carbon dioxide, and evaporation to dryness under diminished pressure. The dry residue was dissolved in alcohol and filtered from inorganic salts, and after removal of the alcohol the residue was finally recrystallised from ether, the *trimethylammonium iodide* being obtained in needles, m. p. 163—164° (Found: C, 55·5; H, 8·9; I, 2·8. $C_{18}H_{34}NI$ requires C, 55·2; H, 8·7; I, 3·2%).

For the preparation of the hydroxide, the iodide was shaken in aqueous solution with an excess of freshly prepared silver oxide for several hours. The filtered, strongly alkaline solution was concentrated under diminished pressure at the ordinary temperature, and finally dried over phosphoric oxide, a crystalline solid being obtained. The hydroxide was extremely hygroscopic and became pasty immediately on exposure to the atmosphere. It was not found possible to purify and analyse it.

l-α-*Curcumene and* l-*Dimethyldihydro-α-curcumenylamine.*—The hydroxide (10 g.) was distilled under diminished pressure (400 mm.), the distillate being collected in dilute sulphuric acid. After separation of the insoluble oil (A) by ether, the acid solution was basified with dilute sodium hydroxide solution, and the organic base extracted with ether. On removal of the solvent, an oil (2 g.) remained, b. p. 130—140°/15 mm.; $d_{30^\circ}^{30^\circ}$ 0·8824; $n_D^{30^\circ}$ 1·4913;

$[\alpha]_D^{30°}$ −23·0° (Found: C, 82·0; H, 12·2; N, 5·6. $C_{17}H_{31}N$ requires C, 81·9; H, 12·4; N, 5·9%). *l-Dimethyldihydro-α-curcumenylamine* was a viscid oil with a strong basic smell; it did not yield any crystalline derivatives.

The oil (A) was distilled over sodium, b. p. 128—130°/7 mm.; $d_{30°}^{30°}$ 0·8633; $n_D^{30°}$ 1·4944; $[\alpha]_D^{30°}$ −22·9°; $[R_L]_D$ 68·23. It was identified as very pure l-α-*curcumene*. It was only very slowly attacked by potassium permanganate in alkaline solution, and when dissolved in chloroform it absorbed one mol. of bromine. Treatment with hydrogen chloride in acetic acid solution gave a quantitative yield of the monohydrochloride (Found: Cl, 14·6. Calc.: Cl, 14·8%) and no trace of a trihydrochloride. The yield of nitrosate was very much higher than that obtained from any other sample of the hydrocarbon examined (0·45 g. from 0·8 g. of the hydrocarbon). *l*-α-Curcumene was not reduced by sodium in ethyl-alcoholic solution, the physical constants of the recovered oil being unchanged, nor was it isomerised by heating at 380° in an inert atmosphere. It did not yield a naphthalene derivative when heated at 270° with sulphur or selenium. A solution in acetic acid gives, with a drop of sulphuric acid, a yellow coloration gradually changing to pink.

Hexahydro-α-curcumene.—A mixture of *l*-α-curcumene (10 c.c.), acetic acid (40 c.c.), and platinum oxide (0·3 g.) (Adams and Shriner, *loc. cit.*) was shaken with hydrogen at a pressure of 2 atm. Reduction was complete after 50 hours and it was necessary to revive the catalyst twice by treatment with oxygen. The *hexahydro-α-curcumene* was a viscid, colourless oil, b. p. about 128°/7 mm.; $d_{30°}^{30°}$ 0·8283; $n_D^{30°}$ 1·4592; $[\alpha]_D^{30°}$ + 0°; $[R_L]_D$ 69·36 (Calc., 69·27) (Found: C, 86·0; H, 14·0. $C_{15}H_{30}$ requires C, 85·7; H, 14·2%). It did not absorb bromine in chloroform solution.

l-β-*Curcumene.*

A mixture of the trihydrochloride (see p. 2501) (80 g.), acetic acid (300 c.c.), and anhydrous sodium acetate (110 g.) was heated at 140° for 8 hours. After addition of water, the sesquiterpene was distilled in steam, dried, and purified by repeated distillation over sodium. l-β-*Curcumene* is a thick, colourless oil, b. p. 128—130°/6 mm.; $d_{30°}^{30°}$ 0·8810; $n_D^{30°}$ 1·4940; $[\alpha]_D^{30°}$ −27·9°. The hydrocarbon did not yield a crystalline nitrosate, and on treatment with hydrogen chloride the trihydrochloride (m. p. 84—85°) was regenerated in a yield of more than 50% of the theoretical. Titration with bromine in chloroform solution gave figures agreeing closely with those required for the presence of three ethylenic linkages, whilst in the presence of alkali a solution of potassium permanganate was im-

mediately decolorised. An acetic acid solution gives with a drop of sulphuric acid a deep brown coloration.

When the hydrocarbon was heated on the water-bath for some hours with a dilute solution of sulphuric acid (10%), it was converted into what would appear to be a dicyclic terpene, b. p. 115—117°/7 mm.; $d_{30^\circ}^{30^\circ}$ 0·8932; $n_D^{30^\circ}$ 1·4936; $[\alpha]_D^{30^\circ}$ − 11·9°: $[R_L]_D$ 66·43. This new hydrocarbon, which awaits investigation, does not yield any crystalline derivatives. *l*-β-Curcumene is not reduced by sodium in amyl-alcoholic solution, but undergoes isomerisation and no longer yields the characteristic trihydrochloride (b. p. 129—130°/7 mm.; $d_{30^\circ}^{30^\circ}$ 0·8780; $n_D^{30^\circ}$ 1·4936). Isomerisation was also observed when the terpene was heated in an inert atmosphere at 380° under pressure. No naphthalene derivatives were formed when the terpene was heated at 270° with either sulphur or selenium.

l-β-*Hexahydrocurcumene.*—*l*-β-Curcumene was catalytically hydrogenated under the same conditions as were used for *l*-α-curcumene. The hydrogenation proceeded with greater ease and was complete in 10 hours. The saturated hydrocarbon had b. p. about 128°/7 mm.; $d_{30^\circ}^{30^\circ}$ 0·8283; $n_D^{30^\circ}$ 1·4552; $[\alpha]_D^{30^\circ}$ + 6·3° (Found: C, 85·9; H, 14·2. $C_{15}H_{30}$ requires C, 85·7; H, 14·2%).

Oxidation of l-α- *and* l-β-*Curcumenes with Benzoylhydroperoxide.*—Weighed quantities of each of the sesquiterpenes were mixed with an excess of a standard solution of benzoylhydroperoxide (von Pechmann and Vanino, *Ber.*, 1894, **27**, 1511; Levy and Legrange, *Bull. Soc. chim.*, 1925, **37**, 1597) in chloroform solution, and maintained at 10—15° until oxidation was complete. A portion of the solution was removed from time to time for titration against sodium thiosulphate in the presence of potassium iodide. Oxidation was found to be complete after about 478 hours, during which period a solution of benzoylhydroperoxide in chloroform kept under similar conditions showed no appreciable alteration in strength. The results confirmed the presence of three ethylenic linkages in each hydrocarbon (*l*-α-Curcumene: peroxide used corresponded to 133·2 c.c. of $Na_2S_2O_3$ solution; calc., 137·3 c.c. *l*-β-Curcumene: peroxide used corresponded to 140·4 c.c. of $Na_2S_2O_3$ solution; calc., 133·6 c.c.).

BANGALORE.

[*Received, July 20th,* 1928.]

CCCXXXII.—*Equilibrium in the Systems* $ZnSO_4$–Na_2SO_4–H_2O *at* 0° *and* 25°; $MnSO_4$–Na_2SO_4–H_2O *at* 0°, 25°, *and* 35°; *and* $CoSO_4$–K_2SO_4–H_2O *at* 25°.

By Robert Martin Caven and William Johnston.

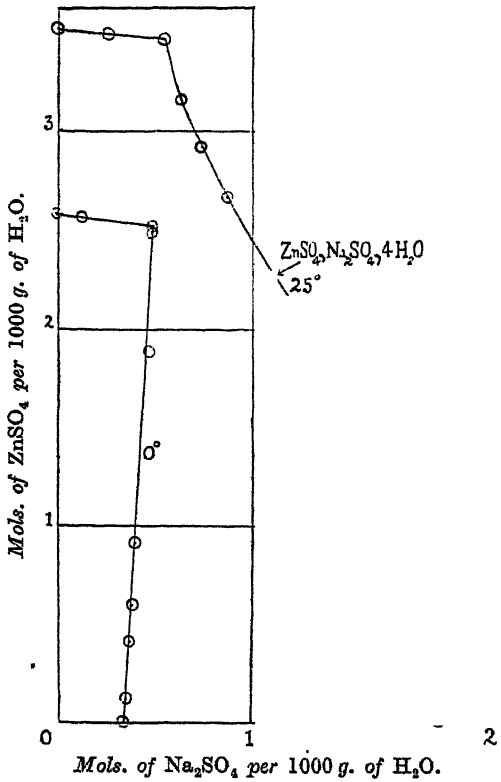
Koppel and Gumperz (*Z. physikal. Chem.*, 1905, **52**, 409) have investigated the double salts formed by sodium sulphate with a series of the sulphates of the bivalent metals. These double sulphates are formed, not at 0°, but at higher temperatures. However, while Koppel and Gumperz were mainly interested in the double salts formed, the present authors are more concerned with the type of isotherms given by the various systems. Thus, whilst Koppel (*Z. physikal. Chem.*, 1903, **42**, 1) showed that the double salt $CuSO_4,Na_2SO_4,2H_2O$ does not crystallise below 16·7° from a solution of its component salts, the authors (J., 1927, 2358) investigated the isotherms of the system $CuSO_4$–Na_2SO_4–H_2O at 0°, 25°, and 37·5°.

Koppel and Gumperz (*loc. cit.*) have shown that the double salt $ZnSO_4,Na_2SO_4,4H_2O$ is formed from a solution of its component salts only above 8·7°. They did not, however, examine the system completely at any given temperature, so it was decided to investigate the isotherms at 0° and 25°.

Geiger (Thesis, Berlin, 1904) alleged that the double salt of manganese sulphate and sodium sulphate existed in two hydrated forms: $MnSO_4,Na_2SO_4,4H_2O$ and $MnSO_4,Na_2SO_4,2H_2O$. According to Marignac (*Ann. Min.*, 1856, **9**, 22), the dihydrate of manganese sodium sulphate crystallises from a solution not below 36·5°, and a tetrahydrate by free evaporation at the ordinary temperature; these results were accepted by Koppel (*loc. cit.*).

Schreinemakers and Provije (*Proc. K. Akad. Wetensch. Amsterdam*, 1913, **15**, 326) investigated the system $MnSO_4$–Na_2SO_4–H_2O at 35°, and noted the formation of two double salts ($9MnSO_4,10Na_2SO_4$ and $MnSO_4,3Na_2SO_4$) according to the composition of the mother-liquor. It was therefore decided to investigate this system at this temperature as well as at 0° and 25°.

The system $CoSO_4$–K_2SO_4–H_2O has been investigated at 25° in order to compare it with the systems $NiSO_4$–K_2SO_4–H_2O (Caven and Johnston, J., 1926, 2628) and $CuSO_4$–K_2SO_4–H_2O (Caven and Mitchell, J., 1924, **125**, 1428) at the same temperature.



Experimental.

The System $ZnSO_4$–Na_2SO_4–H_2O *at* 0° *and* 25°.—For the investigation at 0°, saturated solutions of the two salts were made at

atmospheric temperature, and various proportions of these solutions were placed successively in a flask fitted with a stirrer and kept immersed in ice and water; the mixtures were stirred for 3 days before portions of the solutions were separated and analysed. For the system at 25°, saturated solutions of the two salts were made at 40°, and solutions as above placed in a flask immersed in a thermostat at 25° ± 0·01°. Zinc was determined by means of standard potassium

FIG. 1.

System $ZnSO_4$–Na_2SO_4–H_2O *at* 0° *and* 25°.

ferrocyanide solution, and sodium sulphate was calculated after determination of total sulphate.

The results are expressed as mols. per 1000 g. of water, and are shown by means of rectangular co-ordinates (Fig. 1).

The System $MnSO_4$–Na_2SO_4–H_2O *at* 0°, 25°, *and* 35°.—For this system at 0°, saturated solutions of the two salts were made at room temperature, and the same procedure as above was carried out. A slightly different procedure was necessary at 25°. The solubility

of manganese sulphate decreases above 27°, and there was therefore no advantage in preparing solutions above this temperature. Consequently, solutions of sodium sulphate saturated at 40° and of manganese sulphate saturated at 25° were used. To ensure the presence of a solid phase on the manganese sulphate portion of the isotherm, solid tetrahydrated manganese sulphate (the hydrate stable at 25°) was added to different mixtures of the above solutions. These mixtures were placed in a flask as above, immersed in a thermostat at 25 ± 0·01°, and stirred for 4 days, after which it was found that equilibrium had been reached. At the sodium sulphate end of the isotherm, different proportions of the above solutions were taken, and the mixtures stirred for 3 days. Both solid and liquid phases were analysed. For the experiment at 35°, various proportions of solutions of the two salts saturated at 40° were used, whilst to ensure the presence of the appropriate solid phase, anhydrous sodium sulphate was added at the sodium end of the isotherm and monohydrated manganese sulphate at the manganese end. These mixtures were stirred for 4 days. Both solid and liquid phases were analysed, manganese being estimated volumetrically by the Volhard method, and sodium sulphate calculated after determination of total sulphate.

The results are expressed as mols. per 1000 g. of water (Fig. 2). The results at 25° and 35° are also expressed as g. per 100 g. of solution, and plotted on the triangular diagram in order to show the composition of the double salt (Figs. 3 and 4).

The double salt obtained by us at 25° from an equimolecular solution of its constituent salts was washed with water at the same

temperature, air-dried, and analysed (Found: $MnSO_4$, 45·77; Na_2SO_4, 43·15; H_2O, 11·08. Calc. for $MnSO_4,Na_2SO_4,2H_2O$: $MnSO_4$, 45·88; Na_2SO_4, 43·18; H_2O, 10·94%).

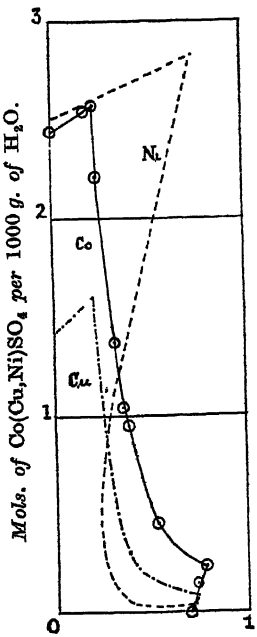
Conclusions.

The Zinc–Sodium System (Fig. 1).—1. No double salt is formed at 0°. This is in agreement with the work of Koppel and Gumperz. The isotherm simply shows the influence of each salt on the solubility of the other.

2. The double salt $ZnSO_4,Na_2SO_4,4H_2O$ is formed over a considerable range at 25°.

3. At both 0° and 25°, the solubility of sodium sulphate is increased by addition of zinc sulphate.

4. At both 0° and 25°, the solubility of zinc sulphate is decreased by addition of sodium sulphate. This is in contrast to the system $CuSO_4$–Na_2SO_4–H_2O (Caven and Johnston, *loc. cit.*) where both at 0° and 25° the solubility of copper sulphate is increased by addition of sodium sulphate.



The Manganese–Sodium System (Fig. 2). -1. No double salt is formed at 0°.

2. The double salt $MnSO_4,Na_2SO_4,2H_2O$ (Fig. 3) is the stable salt at 25°, and is formed over a considerable range.

3. $MnSO_4,Na_2SO_4,2H_2O$ (Fig. 4) is also formed at 35° over a wider range. No evidence was found of the formation of the double salts $MnSO_4,3Na_2SO_4$ and $9MnSO_4,10Na_2SO_4$ (Schreinemakers and Provije, *loc. cit.*), or of $MnSO_4,Na_2SO_4,4H_2O$.

4. A study of the isotherms at 25° and 35° (Fig. 2) shows the interesting fact that the double-salt portion of the 25°-isotherm is nearly coincident along all its length with the double-salt portion of the 35°-isotherm. This indicates that the solubilities of the double salt at these two temperatures are almost identical. A closer inspection of the place where the equimolecular line 0A (Fig. 2) cuts the isotherms shows that the solubility of the double salt $MnSO_4,Na_2SO_4,2H_2O$ is slightly less at 35° than at 25°.

FIG. 5.
System $Co(Cu,Ni)SO_4$–K_2SO_4–H_2O *at* 25°.

5. At all three temperatures the solubility of manganese sulphate is decreased by addition of sodium sulphate. This fact is of much greater interest on more particular examination, for the solid phases are different at the different temperatures. The decrease is least at 25° where the solid phase is $MnSO_4,4H_2O$, and is greatest, being much accentuated, at 35° where the solid phase is $MnSO_4,H_2O$. An intermediate decrease is shown at 0°, where the solid phase is $MnSO_4,7H_2O$. Thus these isotherms show the effect of addition of sodium sulphate on the solubilities of the hepta-, tetra-, and mono-hydrated forms of manganese sulphate.

6. The solubility of $MnSO_4,H_2O$ at 35° is slightly greater than that of $MnSO_4,4H_2O$ at 25°.

7. At 0° and 25° the solubility of sodium sulphate is increased by addition of manganese sulphate. At 35° it is much decreased by increasing quantities of manganese sulphate. Here again there is a change of solid phase from the decahydrated to the anhydrous state.

The Cobalt–Potassium System (Fig. 5).—1. The double salt $CoSO_4,K_2SO_4,6H_2O$ is formed over a wide range at 25°.

2. The solubility of each single salt is increased by addition of the other.

3. The isotherm is of the general type obtainable for double salts of the form $M^{II}SO_4,M^{I}_2SO_4,6H_2O$. It closely resembles the isotherm for the system $CuSO_4$–K_2SO_4–H_2O at 25° (Caven and Mitchell, *loc. cit.*), but differs considerably from the corresponding isotherm for the system $NiSO_4$–K_2SO_4–H_2O (Caven and Johnston, J., 1926, 2628), which deviates appreciably from the typical isotherm (see Fig. 5).

The authors wish to thank the Carnegie Trustees for a Scholarship which has enabled one of them (W. J.) to participate in this research.

ROYAL TECHNICAL COLLEGE, GLASGOW. [*Received, July 28th*, 1928.]

CCCXXXIII.—*The Chemistry of the Three-carbon System. Part XIX. The Homomesitones.*

By AILEEN EDITH ABBOTT, GEORGE ARMAND ROBERT KON, and RALPH DAVID SATCHELL.

IN searching for readily accessible examples of neutral tautomeric substances, we were led to examine the ketones $C_8H_{14}O$, derived from the intermolecular condensation of methyl ethyl ketone, to which the name homomesitones was applied by Porlezza and Gatti (*Gazzetta*, 1925, **25**, 224). Theoretically, there are four possible homomesitones if the very unlikely formation of the substance $CH_2Me{\cdot}CMe{:}CH{\cdot}CH_2{\cdot}COMe$ be left out of consideration.

(I.) $CH_2Me{\cdot}CMe{:}CH{\cdot}COEt$ $CHMe{:}CMe{\cdot}CH_2{\cdot}COEt$ (II.)

(III.) $CH_2Me{\cdot}CMe{:}CMe{\cdot}COMe$ $CHMe{:}CMe{\cdot}CHMe{\cdot}COMe$ (IV.)

These two pairs of compounds are related to one another in the same way as the ketones studied by Kon and Linstead (J., 1925, **127**, 815) and should exhibit tautomerism of the same general character. Homomesitones have been obtained by a variety of methods, but little was known of their chemistry until Bodroux and Taboury (*Bull. Soc. chim.*, 1908, **3**, 831; 1909, **5**, 950), who obtained their product with the aid of calcium carbide, attempted to characterise it by means of the very indefinite semicarbazone melting at 119—120°; subsequently, Becker and Thorpe (J., 1922,

121, 1303) obtained the same ketone and concluded that it had the structure (I) because it condensed with ethyl sodiomalonate to a dihydroresorcinol which gave β-methyl-β-ethylglutaric acid on oxidation; a similar conclusion was reached by Ekeley and Howe (*J. Amer. Chem. Soc.*, 1923, **45**, 1917), who prepared their ketone with the aid of both alkaline and acid condensing agents.

The experience accumulated in the last few years suggested that the ketone (II) would probably be encountered together with (I) in the crude homomesitone prepared in the presence of sodium ethoxide, whilst the mobility of the three-carbon system present in these compounds would doubtless enable (II) to condense with ethyl sodiomalonate just as readily as (I). Closer investigation brought to light considerable divergences in the properties of homomesitones from different sources, and it was therefore necessary to characterise the different compounds met with. The task proved to be one of great difficulty owing to the extremely intractable nature of the mixtures of ketones obtained from methyl ethyl ketone, more especially with the aid of alkaline condensing agents. The semicarbazones prepared from these mixtures are extremely soluble in the crude state, have but little tendency to crystallise, and are probably mixtures of stereoisomerides. For this reason it is only possible to isolate a very small proportion of the constituents of a given mixture in the pure state. We ultimately succeeded in establishing the mutual relationships between the different homomesitones by recourse to synthesis, and the results can be briefly summarised as follows: (*a*) Alkaline condensing agents lead to mixtures of (I) and (II), the former predominating especially in the ketone obtained by Bodroux and Taboury's method; the ketone (I) forms a characteristic *semicarbazone*, m. p. 162°. (*b*) Acid condensing agents lead to ketones with a branched chain (III or IV), sulphuric acid giving a ketone of low density, consisting mainly of the βγ-compound (IV), whereas hydrochloric acid yields a ketone of high density and refractive index, consisting mainly of (III); by far the best method is that of Descudé (*Ann. Chim. Phys.*, 1903, **29**, 486), which generally gives (III) only. The formation of ketones with a branched chain is not altogether unexpected, because it has been shown by Harries and his pupils that aromatic aldehydes condense with methyl ethyl and methyl propyl ketones to give compounds such as CHPh:CR·COMe in presence of hydrochloric acid, whilst straight-chain compounds are formed in alkaline solution. It is surprising that Ekeley and Howe did not suspect differences of structure in the homomesitones prepared by them and subsequently used for synthetic purposes.

The structure of the homomesitones (I), (III), and (IV) was

confirmed by synthesis from the corresponding acids which were prepared by standard methods; all attempts to synthesise the compound (II), however, were unsuccessful, and the only way in which this substance could be obtained consisted in treating the equilibrium mixture of (I) and (II) with aluminium amalgam which converts (I) into a bimolecular reduction product, leaving the $\beta\gamma$-ketone unattacked.

There are definite indications that the homomesitones are capable of *cis-trans* isomerism; thus, the ketone (IV) gives two *semicarbazones*, m. p. 203—204° and 163°, although mixtures melting at about 175° are usually encountered. The *semicarbazone* of (III) has a form of m. p. 166—167° in addition to the usual one, m. p. 186°. The ketone obtained by the action of magnesium ethyl iodide on ethyl ethoxycrotonate (Blaise and Maire, *Ann. Chim. Phys.*, 1908, **15**, 566), which forms a semicarbazone (m. p. 158°) *not* identical with that of (I), must be a stereoisomeride of the latter; stereoisomerism in this case cannot be due to the existence of two forms of the semicarbazone, because the regenerated ketone yields the same semicarbazone on recombining with semicarbazide (compare Locquin and Heilmann, *Compt. rend.*, 1928, **186**, 705). In addition to this, every unsymmetrical ketone can theoretically give rise to two semicarbazones, and it may be that the homomesitones (I) and (II) do actually yield mixtures of *cis-trans* isomeric derivatives, which would in part account for the nature of the semicarbazone usually obtained from them.

Tautomerism of the Homomesitones.—Investigation proves that the homomesitones exhibit tautomerism of the nature to be expected from their structure. In presence of sodium ethoxide or methoxide they form equilibrium mixtures similar to those recently studied by Dickins, Hugh, and Kon (this vol., p. 1630). It is a remarkable fact, however, that both as regards mobility and point of equilibrium the two pairs of homomesitones are very different. Thus, the ketones (I) and (II) form an equilibrium mixture containing 67·5% of the $\alpha\beta$-compound, and this mixture is, as might be expected, indistinguishable from the crude homomesitone obtained by the action of sodium ethoxide on methyl ethyl ketone. The mobility of the system is high, equilibrium being practically established in 24 hours at room temperature. The ketones (III) and (IV) in presence of sodium ethoxide form an equilibrium mixture containing only 17% of the $\alpha\beta$-compound, and the mobility is so low that the equilibration of the $\alpha\beta$-ketone only proceeded half-way in the course of a fortnight at room temperature. The final equilibrium had to be determined at the boiling point of the reagent, and was only reached after 9 hours.
